HARRISON'S Principles of INTERNAL MEDICINE

EDITORS

Anthony S. Fauci, MD
Chief, Laboratory of Immunoregulation; Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda

Eugene Braunwald, MD
Distinguished Hersey Professor of Medicine, Harvard Medical School; Chairman, TIMI Study Group, Brigham and Women's Hospital, Boston

Dennis L. Kasper, MD
William Ellery Channing Professor of Medicine, Professor of Microbiology and Molecular Genetics, Harvard Medical School; Director, Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Boston

Stephen L. Hauser, MD
Robert A. Fishman Distinguished Professor and Chairman, Department of Neurology, University of California, San Francisco, San Francisco

Dan L. Longo, MD
Scientific Director, National Institute on Aging, National Institutes of Health, Bethesda and Baltimore

J. Larry Jameson, MD, PhD
Professor of Medicine; Vice-President for Medical Affairs and Lewis Landsberg Dean, Northwestern University Feinberg School of Medicine, Chicago

Joseph Loscalzo, MD, PhD
Hersey Professor of the Theory and Practice of Medicine, Harvard Medical School; Chairman, Department of Medicine; Physician-in-Chief, Brigham and Women's Hospital, Boston

George W. Thorn
1906–2004

George W. Thorn was an editor of the first seven editions and Editor-in-Chief of the eighth edition. As a founding editor, he had an enormous impact on *Harrison's* and thereby on the education of countless thousands of physicians and medical students. His incisiveness, inventiveness, and originality, coupled with his broad knowledge of clinical medicine and medical science and his unswerving dedication to the application of techniques of contemporary science to the advancement of clinical medicine, played a vital role in the original organization of this textbook.

George Thorn began his remarkable career in endocrinologic research as a medical student at the University of Buffalo School of Medicine. Following a stint in general practice, which subsequently served him well as an educator, clinical investigator, and consultant, he obtained research training and held faculty positions at several institutions. In 1942, at the age of 36, he became Hersey Professor of the Theory and Practice of Physic (Medicine) at Harvard Medical School and Physician-in-Chief at Brigham and Women's. During the three decades in which he filled these positions with distinction, he created one of the first modern academic medical units where the education of physician-scientists, the highest standards of clinical care, and the conduct of exciting clinical research were inextricably intertwined and mutually reinforcing. Thorn's personal investigative interests focused on the adrenal cortex and the kidney. He developed techniques for the diagnosis of adrenal disease that are still in wide use. He characterized salt-losing nephritis and catalyzed the development of renal dialysis and the work that led to the development of renal transplantation.

George Thorn played many leadership roles in medicine and medical science. As a member of the governing board of the Massachusetts Institute of Technology (MIT) he was instrumental in the development of the Harvard-MIT program in Health Science and Technology. He was the founder, Director, and then President of the Howard Hughes Medical Institute, which became a major world force in the conduct of fundamental biomedical research under his leadership.

Thorn has influenced most profoundly a number of institutions: Harvard, the Brigham, MIT, and the Hughes Institute. To these and to *Harrison's*, he brought a unique blend of ebullience, imagination, curiosity, personal leadership, good humor, warmth, and compassion, which inspired generations of Harvard medical students, Brigham residents and research fellows, Hughes investigators, and editorial colleagues. The present Editors are pleased to express their admiration for this medical giant and beloved friend by dedicating this seventeenth edition of *Harrison's* to George W. Thorn, one of the founders of this book.

THE EDITORS

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

COVER ILLUSTRATIONS

(1) **Figure 222-10.** Three-dimensional reconstruction of a CT angiogram demonstrating a normal main left coronary artery arising from the aorta and its two branches, the left anterior descending artery (left) and the left circumflex artery (right).
(2) Computer rendition of chains of *Streptococcus pneumoniae* bacteria. This gram-positive oval-shaped bacterium is one of the causes of pneumonia. Although found living harmlessly in the body, *S. pneumoniae* can cause dangerous opportunistic infections of the lung. *(Credit: Hybrid Medical Animation/Photo Researchers, Inc.)*
(3) Three-dimensional representation of blood cells.
(4) Illustration of a myelinated axon with sodium channels clustered at the nodes of Ranvier where axonal depolarization occurs; this event results in saltatory conduction, with nerve impulse jumping from one node to the next.
(5) **Figure 364-15A.** A CT perfusion mean transit–time map showing delayed perfusion of the left middle cerebral artery distribution.

CONTENTS

Summaries of Chapters e1 to e39 xvii
Contributors xxi
Preface xxxv

PART 1 Introduction to Clinical Medicine

1 **The Practice of Medicine** 1
The Editors

2 **Global Issues in Medicine** 6
Jim Yong Kim / Paul Farmer

3 **Decision-Making in Clinical Medicine** 16
Daniel B. Mark

4 **Screening and Prevention of Disease** 24
Gary J. Martin

5 **Principles of Clinical Pharmacology** 27
Dan M. Roden

6 **Women's Health** 39
Andrea E. Dunaif

7 **Medical Disorders during Pregnancy** 44
Robert L. Barbieri / John T. Repke

8 **Medical Evaluation of the Surgical Patient** 49
Wei C. Lau / Kim A. Eagle

9 **Geriatric Medicine** 53
Lisa B. Caruso / Rebecca A. Silliman

10 **Complementary and Alternative Medicine** 62
Stephen E. Straus

11 **Palliative and End-of-Life Care** 66
Ezekiel J. Emanuel / Joshua Hauser / Linda L. Emanuel

e1 **The Safety and Quality of Health Care** e1
David W. Bates

e2 **Economic Considerations in the Practice of Medicine** e7
David Meltzer

e3 **Racial and Ethnic Disparities in Health Care** e11
Joseph R. Betancourt / David Blumenthal

e4 **Ethical Issues in Clinical Medicine** e19
Bernard Lo

PART 2 Cardinal Manifestations and Presentation of Diseases

SECTION 1 PAIN

12 **Pain: Pathophysiology and Management** 81
Howard L. Fields / Joseph B. Martin

13 **Chest Discomfort** 87
Thomas H. Lee

14 **Abdominal Pain** 91
William Silen

15 **Headache** 95
Peter J. Goadsby / Neil H. Raskin

16 **Back and Neck Pain** 107
John W. Engstrom

SECTION 2 ALTERATIONS IN BODY TEMPERATURE

17 **Fever and Hyperthermia** 117
Charles A. Dinarello / Reuven Porat

18 **Fever and Rash** 121
Elaine T. Kaye / Kenneth M. Kaye

e5 **Atlas of Rashes Associated with Fever** e23
Kenneth M. Kaye / Elaine T. Kaye

19 **Fever of Unknown Origin** 130
Jeffrey A. Gelfand / Michael V. Callahan

20 **Hypothermia and Frostbite** 135
Daniel F. Danzl

SECTION 3 NERVOUS SYSTEM DYSFUNCTION

21 **Syncope** 139
Mark D. Carlson

22 **Dizziness and Vertigo** 144
Robert B. Daroff

23 **Weakness and Paralysis** 147
Michael J. Aminoff

24 **Gait and Balance Disorders** 151
Lewis Sudarsky

25 **Numbness, Tingling, and Sensory Loss** 154
Michael J. Aminoff / Arthur K. Asbury

26 **Confusion and Delirium** 158
S. Andrew Josephson / Bruce L. Miller

e6 **Memory Loss** e33
Thomas D. Bird / Bruce L. Miller

27 **Aphasia, Memory Loss, and Other Focal Cerebral Disorders** 162
M.-Marsel Mesulam

28 **Sleep Disorders** 171
Charles A. Czeisler / John W. Winkelman / Gary S. Richardson

SECTION 4 DISORDERS OF EYES, EARS, NOSE, AND THROAT

29 **Disorders of the Eye** 180
Jonathan C. Horton

30 **Disorders of Smell, Taste, and Hearing** 196
Anil K. Lalwani

31 **Pharyngitis, Sinusitis, Otitis, and Other Upper Respiratory Tract Infections** 205
Michael A. Rubin / Ralph Gonzales / Merle A. Sande

32 **Oral Manifestations of Disease** 214
Samuel C. Durso

e7 **Atlas of Oral Manifestations of Disease** e37
Samuel C. Durso / Janet A. Yellowitz / Jane C. Atkinson

SECTION 5 ALTERATIONS IN CIRCULATORY AND RESPIRATORY FUNCTIONS

33 **Dyspnea and Pulmonary Edema** 221
Richard M. Schwartzstein

34 **Cough and Hemoptysis** 225
Steven E. Weinberger / David A. Lipson

35 **Hypoxia and Cyanosis** 229
Eugene Braunwald

36 **Edema** 231
Eugene Braunwald / Joseph Loscalzo

e8 **Approach to the Patient with a Heart Murmur** e43
Patrick T. O'Gara / Eugene Braunwald

37 **Palpitations** 236
Joseph Loscalzo

SECTION 6 ALTERATIONS IN GASTROINTESTINAL FUNCTION

38 **Dysphagia** 237
Raj K. Goyal

39 **Nausea, Vomiting, and Indigestion** 240
William L. Hasler

40 **Diarrhea and Constipation** 245
Michael Camilleri / Joseph A. Murray

41 **Weight Loss** 255
Carol M. Reife

42 **Gastrointestinal Bleeding** 257
Loren Laine

43 **Jaundice** 261
Daniel S. Pratt / Marshall M. Kaplan

44 **Abdominal Swelling and Ascites** 266
Robert M. Glickman / Roshini Rajapaksa

SECTION 7 ALTERATIONS IN RENAL AND URINARY TRACT FUNCTION

45 **Azotemia and Urinary Abnormalities** 268
Bradley M. Denker / Barry M. Brenner

e9 **Atlas of Urinary Sediments and Renal Biopsies** ... e53
Agnes B. Fogo / Eric G. Neilson

46 **Fluid and Electrolyte Disturbances** 274
Gary G. Singer / Barry M. Brenner

47 **Hypercalcemia and Hypocalcemia** 285
Sundeep Khosla

48 **Acidosis and Alkalosis** 287
Thomas D. DuBose, Jr.

SECTION 8 ALTERATIONS IN SEXUAL FUNCTION AND REPRODUCTION

49 **Sexual Dysfunction** 296
Kevin T. McVary

50 **Hirsutism and Virilization** 301
David A. Ehrmann

51 **Menstrual Disorders and Pelvic Pain** 304
Janet E. Hall

SECTION 9 ALTERATIONS IN THE SKIN

52 **Approach to the Patient with a Skin Disorder** 308
Thomas J. Lawley / Kim B. Yancey

53 **Eczema, Psoriasis, Cutaneous Infections, Acne, and Other Common Skin Disorders** 312
Calvin O. McCall / Thomas J. Lawley

54 **Skin Manifestations of Internal Disease** 321
Jean L. Bolognia / Irwin M. Braverman

55 **Immunologically Mediated Skin Diseases** 336
Kim B. Yancey / Thomas J. Lawley

56 **Cutaneous Drug Reactions** 343
Jean-Claude Roujeau / Robert S. Stern / Bruce U. Wintroub

57 **Photosensitivity and Other Reactions to Light** 350
David R. Bickers

e10 **Atlas of Skin Manifestations of Internal Disease** e61
Thomas J. Lawley / Stephen F. Templeton

SECTION 10 HEMATOLOGIC ALTERATIONS

58 **Anemia and Polycythemia** 355
John W. Adamson / Dan L. Longo

59 **Bleeding and Thrombosis** 363
Barbara A. Konkle

60 **Enlargement of Lymph Nodes and Spleen** 370
Patrick H. Henry / Dan L. Longo

61 **Disorders of Granulocytes and Monocytes** 375
Steven M. Holland / John I. Gallin

e11 **Atlas of Hematology and Analysis of Peripheral Blood Smears** e77
Dan L. Longo

PART 3 Genetics and Disease

62 **Principles of Human Genetics** 385
J. Larry Jameson / Peter Kopp

63 **Chromosome Disorders** 407
Terry J. Hassold / Stuart Schwartz

64 **The Practice of Genetics in Clinical Medicine** 414
Susan Miesfeldt / J. Larry Jameson

65 **Gene Therapy in Clinical Medicine** 420
Katherine A. High

PART 4 Regenerative Medicine

66 **Stem Cell Biology** 425
Minoru S. H. Ko

67 **Applications of Stem Cell Biology in Clinical Medicine** 427
John A. Kessler

68 **Hematopoietic Stem Cells** 430
David T. Scadden / Dan L. Longo

69 **Tissue Engineering** 434
Jennifer Anderson / Joseph P. Vacanti

PART 5 Nutrition

70 **Nutritional Requirements and Dietary Assessment** ... 437
Johanna Dwyer

71 **Vitamin and Trace Mineral Deficiency and Excess** 441
Robert M. Russell / Paolo M. Suter

72 **Malnutrition and Nutritional Assessment** 450
Douglas C. Heimburger

73 **Enteral and Parenteral Nutrition Therapy** 455
Bruce R. Bistrian / David F. Driscoll

74 **Biology of Obesity** 462
Jeffrey S. Flier / Eleftheria Maratos-Flier

75 **Evaluation and Management of Obesity** 468
Robert F. Kushner

76 **Eating Disorders** 473
B. Timothy Walsh

CONTENTS

PART 6 Oncology and Hematology

SECTION 1 NEOPLASTIC DISORDERS

77 **Approach to the Patient with Cancer** 479
Dan L. Longo

78 **Prevention and Early Detection of Cancer** 486
Otis W. Brawley / Barnett S. Kramer

79 **Cancer Genetics** 492
Pat J. Morin / Jeffrey M. Trent / Francis S. Collins / Bert Vogelstein

80 **Cancer Cell Biology and Angiogenesis** 498
Robert G. Fenton / Dan L. Longo

81 **Principles of Cancer Treatment** 514
Edward A. Sausville / Dan L. Longo

82 **Infections in Patients with Cancer** 533
Robert Finberg

83 **Cancer of the Skin** 541
Arthur J. Sober / Hensin Tsao / Carl V. Washington

84 **Head and Neck Cancer** 548
Everett E. Vokes

85 **Neoplasms of the Lung** 551
John D. Minna / Joan H. Schiller

86 **Breast Cancer** 563
Marc E. Lippman

87 **Gastrointestinal Tract Cancer** 570
Robert J. Mayer

88 **Tumors of the Liver and Biliary Tree** 580
Brian I. Carr

89 **Pancreatic Cancer** 586
Yu Jo Chua / David Cunningham

90 **Bladder and Renal Cell Carcinomas** 589
Howard I. Scher / Robert J. Motzer

91 **Benign and Malignant Diseases of the Prostate** 593
Howard I. Scher

92 **Testicular Cancer** 601
Robert J. Motzer / George J. Bosl

93 **Gynecologic Malignancies** 604
Robert C. Young

94 **Soft Tissue and Bone Sarcomas and Bone Metastases** 610
Shreyaskumar R. Patel / Robert S. Benjamin

95 **Carcinoma of Unknown Primary** 614
Gauri R. Varadhachary / James L. Abbruzzese

96 **Paraneoplastic Syndromes: Endocrinologic/Hematologic** 617
J. Larry Jameson / Bruce E. Johnson

97 **Paraneoplastic Neurologic Syndromes** 623
Josep Dalmau / Myrna R. Rosenfeld

e12 **Thymoma** e89
Dan L. Longo

e13 **Late Consequences of Cancer and Its Treatment** e91
Michael C. Perry / Dan L. Longo

SECTION 2 HEMATOPOIETIC DISORDERS

98 **Iron Deficiency and Other Hypoproliferative Anemias** 628
John W. Adamson

99 **Disorders of Hemoglobin** 635
Edward J. Benz, Jr.

100 **Megaloblastic Anemias** 643
A. Victor Hoffbrand

101 **Hemolytic Anemias and Anemia Due to Acute Blood Loss** 652
Lucio Luzzatto

102 **Aplastic Anemia, Myelodysplasia, and Related Bone Marrow Failure Syndromes** 663
Neal S. Young

103 **Polycythemia Vera and Other Myeloproliferative Diseases** 671
Jerry L. Spivak

104 **Acute and Chronic Myeloid Leukemia** 677
Meir Wetzler / John C. Byrd / Clara D. Bloomfield

105 **Malignancies of Lymphoid Cells** 687
Dan L. Longo

106 **Plasma Cell Disorders** 700
Nikhil C. Munshi / Dan L. Longo / Kenneth C. Anderson

107 **Transfusion Biology and Therapy** 707
Jeffery S. Dzieczkowski / Kenneth C. Anderson

108 **Hematopoietic Cell Transplantation** 713
Frederick R. Appelbaum

SECTION 3 DISORDERS OF HEMOSTASIS

109 **Disorders of Platelets and Vessel Wall** 718
Barbara A. Konkle

110 **Coagulation Disorders** 725
Valder Arruda / Katherine A. High

111 **Venous Thrombosis** 731
F.R. Rosendaal / H.R. Büller

112 **Antiplatelet, Anticoagulant, and Fibrinolytic Drugs** 735
Jeffrey I. Weitz

PART 7 Infectious Diseases

SECTION 1 BASIC CONSIDERATIONS IN INFECTIOUS DISEASES

113 **Introduction to Infectious Diseases: Host–Pathogen Interactions** 749
Lawrence C. Madoff / Dennis L. Kasper

114 **Molecular Mechanisms of Microbial Pathogenesis** . . . 753
Gerald B. Pier

115 **Approach to the Acutely Ill Infected Febrile Patient** 761
Tamar F. Barlam / Dennis L. Kasper

116 **Immunization Principles and Vaccine Use** 767
Gerald T. Keusch / Kenneth J. Bart / Mark Miller

117 **Health Advice for International Travel** 782
Jay S. Keystone / Phyllis E. Kozarsky

e14 **Laboratory Diagnosis of Infectious Diseases** e97
Alexander J. McAdam / Andrew B. Onderdonk

SECTION 2 CLINICAL SYNDROMES: COMMUNITY-ACQUIRED INFECTIONS

118 **Infective Endocarditis** 789
Adolf W. Karchmer

119 **Infections of the Skin, Muscle, and Soft Tissues** 798
Dennis L. Stevens

120 **Osteomyelitis** 803
Jeffrey Parsonnet

121 **Intraabdominal Infections and Abscesses** 807
Miriam J. Baron / Dennis L. Kasper

122 **Acute Infectious Diarrheal Diseases and Bacterial Food Poisoning** 813
Joan R. Butterton / Stephen B. Calderwood

123 ***Clostridium difficile*–Associated Disease, Including Pseudomembranous Colitis** 818
Dale N. Gerding / Stuart Johnson

124 **Sexually Transmitted Infections: Overview and Clinical Approach** 821
King K. Holmes

e15 **Infectious Complications of Burns and Bites** ... e107
Lawrence C. Madoff / Florencia Pereyra

SECTION 3 CLINICAL SYNDROMES: HEALTH CARE–ASSOCIATED INFECTIONS

125 **Health Care–Associated Infections** 835
Robert A. Weinstein

126 **Infections in Transplant Recipients** 842
Robert Finberg / Joyce Fingeroth

SECTION 4 APPROACH TO THERAPY FOR BACTERIAL DISEASES

127 **Treatment and Prophylaxis of Bacterial Infections** ... 851
Gordon L. Archer / Ronald E. Polk

SECTION 5 DISEASES CAUSED BY GRAM-POSITIVE BACTERIA

128 **Pneumococcal Infections** 865
Daniel M. Musher

129 **Staphylococcal Infections** 872
Franklin D. Lowy

130 **Streptococcal and Enterococcal Infections** 881
Michael R. Wessels

131 **Diphtheria and Other Infections Caused by Corynebacteria and Related Species** 890
William R. Bishai / John R. Murphy

132 **Infections Caused by *Listeria monocytogenes*** 895
Elizabeth L. Hohmann / Daniel A. Portnoy

133 **Tetanus** 898
Elias Abrutyn

134 **Botulism** 901
Elias Abrutyn

135 **Gas Gangrene and Other Clostridial Infections** 903
Dennis L. Kasper / Lawrence C. Madoff

SECTION 6 DISEASES CAUSED BY GRAM-NEGATIVE BACTERIA

136 **Meningococcal Infections** 908
Lee M. Wetzler

137 **Gonococcal Infections** 914
Sanjay Ram / Peter A. Rice

138 ***Moraxella* Infections** 921
Daniel M. Musher

139 ***Haemophilus* Infections** 923
Timothy F. Murphy

140 **Infections Due to the HACEK Group and Miscellaneous Gram-Negative Bacteria** 926
Tamar F. Barlam / Dennis L. Kasper

141 ***Legionella* Infection** 929
Miguel Sabria / Victor L. Yu

142 **Pertussis and Other *Bordetella* Infections** 933
Scott A. Halperin

143 **Diseases Caused by Gram-Negative Enteric Bacilli** ... 937
Thomas A. Russo / James R. Johnson

144 ***Helicobacter pylori* Infections** 946
John C. Atherton / Martin J. Blaser

145 **Infections Due to *Pseudomonas* Species and Related Organisms** 949
Reuben Ramphal

146 **Salmonellosis** 956
David A. Pegues / Samuel I. Miller

147 **Shigellosis** 962
Philippe Sansonetti / Jean Bergounioux

148 **Infections Due to *Campylobacter* and Related Species** 965
Martin J. Blaser

149 **Cholera and Other Vibrioses** 968
Matthew K. Waldor / Gerald T. Keusch

150 **Brucellosis** 973
Michael J. Corbel / Nicholas J. Beeching

151 **Tularemia** 976
Richard F. Jacobs / Gordon E. Schutze

152 **Plague and Other *Yersinia* Infections** 980
David T. Dennis / Grant L. Campbell

153 ***Bartonella* Infections, Including Cat-Scratch Disease** 987
David H. Spach / Emily Darby

154 **Donovanosis** 991
Gavin Hart

SECTION 7 MISCELLANEOUS BACTERIAL INFECTIONS

155 **Nocardiosis** 992
Gregory A. Filice

156 **Actinomycosis** 996
Thomas A. Russo

157 **Infections Due to Mixed Anaerobic Organisms** 999
Dennis L. Kasper / Ronit Cohen-Poradosu

SECTION 8 MYCOBACTERIAL DISEASES

158 **Tuberculosis** 1006
Mario C. Raviglione / Richard J. O'Brien

159 **Leprosy (Hansen's Disease)** 1021
Robert H. Gelber

160 **Nontuberculous Mycobacteria** 1027
C. Fordham von Reyn

161 **Antimycobacterial Agents** 1032
Richard J. Wallace, Jr. / David E. Griffith

SECTION 9 SPIROCHETAL DISEASES

162 **Syphilis** 1038
Sheila A. Lukehart

163 **Endemic Treponematoses** 1046
Sheila A. Lukehart

164 **Leptospirosis** 1048
Peter Speelman / Rudy Hartskeerl

165 **Relapsing Fever** 1052
David T. Dennis

166 **Lyme Borreliosis** 1055
Allen C. Steere

SECTION 10 DISEASES CAUSED BY RICKETTSIAE, MYCOPLASMAS, AND CHLAMYDIAE

167 **Rickettsial Diseases** 1059
David H. Walker / J. Stephen Dumler / Thomas Marrie

168 **Infections Due to Mycoplasmas** 1068
William M. McCormack

169 **Chlamydial Infections** 1070
Walter E. Stamm

SECTION 11 VIRAL DISEASES: GENERAL CONSIDERATIONS

170 **Medical Virology** 1079
Fred Wang / Elliott Kieff

171 **Antiviral Chemotherapy, Excluding Antiretroviral Drugs** 1087
Lindsey R. Baden / Raphael Dolin

SECTION 12 INFECTIONS DUE TO DNA VIRUSES

172 **Herpes Simplex Viruses** 1095
Lawrence Corey

173 **Varicella-Zoster Virus Infections** 1102
Richard J. Whitley

174 **Epstein-Barr Virus Infections, Including Infectious Mononucleosis** 1106
Jeffrey I. Cohen

175 **Cytomegalovirus and Human Herpesvirus Types 6, 7, and 8** 1109
Martin S. Hirsch

176 **Molluscum Contagiosum, Monkeypox, and Other Poxviruses, Excluding Smallpox Virus** 1113
Fred Wang

177 **Parvovirus Infections** 1114
Kevin E. Brown

178 **Human Papillomavirus Infections** 1117
Richard C. Reichman

SECTION 13 INFECTIONS DUE TO DNA AND RNA RESPIRATORY VIRUSES

179 **Common Viral Respiratory Infections and Severe Acute Respiratory Syndrome (SARS)** 1120
Raphael Dolin

180 **Influenza** 1127
Raphael Dolin

SECTION 14 INFECTIONS DUE TO HUMAN IMMUNODEFICIENCY VIRUS AND OTHER HUMAN RETROVIRUSES

181 **The Human Retroviruses** 1132
Dan L. Longo / Anthony S. Fauci

182 **Human Immunodeficiency Virus Disease: AIDS and Related Disorders** 1137
Anthony S. Fauci / H. Clifford Lane

SECTION 15 INFECTIONS DUE TO RNA VIRUSES

183 **Viral Gastroenteritis** 1204
Umesh D. Parashar / Roger I. Glass

184 **Enteroviruses and Reoviruses** 1208
Jeffrey I. Cohen

185 **Measles (Rubeola)** 1214
Anne Gershon

186 **Rubella (German Measles)** 1217
Anne Gershon

187 **Mumps** 1220
Anne Gershon

188 **Rabies and Other Rhabdovirus Infections** 1222
Alan C. Jackson / Eric C. Johannsen

189 **Infections Caused by Arthropod- and Rodent-Borne Viruses** 1226
Clarence J. Peters

190 **Ebola and Marburg Viruses** 1240
Clarence J. Peters

SECTION 16 FUNGAL AND ALGAL INFECTIONS

191 **Diagnosis and Treatment of Fungal Infections** 1242
John E. Edwards, Jr.

192 **Histoplasmosis** 1244
Chadi A. Hage / L. Joseph Wheat

193 **Coccidioidomycosis** 1247
Neil M. Ampel

194 **Blastomycosis** 1249
Stanley W. Chapman / Donna C. Sullivan

195 **Cryptococcosis** 1251
Arturo Casadevall

196 **Candidiasis** 1254
John E. Edwards, Jr.

197 **Aspergillosis** 1256
David W. Denning

198 **Mucormycosis** 1261
Alan M. Sugar

199 **Miscellaneous Mycoses and Algal Infections** 1263
Stanley W. Chapman / Donna C. Sullivan

200 ***Pneumocystis* Infection** 1267
A. George Smulian / Peter D. Walzer

SECTION 17 PROTOZOAL AND HELMINTHIC INFECTIONS: GENERAL CONSIDERATIONS

e16 **Laboratory Diagnosis of Parasitic Infections** e113
Sharon L. Reed / Charles E. Davis

201 **Agents Used to Treat Parasitic Infections** 1270
Thomas A. Moore

e17 **Pharmacology of Agents Used to Treat Parasitic Infections** e119
Thomas A. Moore

SECTION 18 PROTOZOAL INFECTIONS

202 **Amebiasis and Infection with Free-Living Amebas** 1275
Sharon L. Reed

203 **Malaria** 1280
Nicholas J. White / Joel G. Breman

204 **Babesiosis** 1294
Jeffrey A. Gelfand / Edouard Vannier

e18 **Atlas of Blood Smears of Malaria and Babesiosis** e127
Nicholas J. White / Joel G. Breman

205 **Leishmaniasis** 1296
Barbara L. Herwaldt

206 **Trypanosomiasis** 1300
Louis V. Kirchhoff

207 ***Toxoplasma* Infections** 1305
Lloyd H. Kasper

208 **Protozoal Intestinal Infections and Trichomoniasis** ... 1311
Peter F. Weller

SECTION 19 HELMINTHIC INFECTIONS

209 ***Trichinella* and Other Tissue Nematodes** 1316
Peter F. Weller

210 **Intestinal Nematodes** 1319
Peter F. Weller / Thomas B. Nutman

211 **Filarial and Related Infections** 1324
Thomas B. Nutman / Peter F. Weller

212 **Schistosomiasis and Other Trematode Infections** ... 1330
Adel A. F. Mahmoud

213 **Cestodes** 1336
A. Clinton White, Jr. / Peter F. Weller

PART 8 Bioterrorism and Clinical Medicine

214 **Microbial Bioterrorism** 1343
H. Clifford Lane / Anthony S. Fauci

215 **Chemical Bioterrorism** 1352
Charles G. Hurst / Jonathan Newmark / James A. Romano, Jr.

216 **Radiation Bioterrorism** 1358
Zelig A. Tochner / Eli Glatstein

PART 9 Disorders of the Cardiovascular System

SECTION 1 INTRODUCTION TO CARDIOVASCULAR DISORDERS

217 **Basic Biology of the Cardiovascular System** 1365
Joseph Loscalzo / Peter Libby / Eugene Braunwald

218 **Epidemiology of Cardiovascular Disease** 1375
Thomas A. Gaziano / J. Michael Gaziano

219 **Approach to the Patient with Possible Cardiovascular Disease** 1379
Eugene Braunwald

SECTION 2 DIAGNOSIS OF CARDIOVASCULAR DISORDERS

220 **Physical Examination of the Cardiovascular System** 1382
Robert A. O'Rourke / Eugene Braunwald

221 **Electrocardiography** 1388
Ary L. Goldberger

e19 **Atlas of Electrocardiography** e131
Ary L. Goldberger

222 **Noninvasive Cardiac Imaging: Echocardiography, Nuclear Cardiology, and MRI/CT Imaging** 1397
Rick A. Nishimura / Raymond J. Gibbons / James F. Glockner / A. Jamil Tajik

e20 **Atlas of Noninvasive Cardiac Imaging** e149
Rick A. Nishimura / Raymond J. Gibbons / James F. Glockner / A. Jamil Tajik

223 **Diagnostic Cardiac Catheterization and Angiography** 1405
Donald S. Baim

SECTION 3 DISORDERS OF RHYTHM

224 **Principles of Electrophysiology** 1410
Gordon F. Tomaselli

225 **The Bradyarrhythmias** 1416
Gordon F. Tomaselli

226 **The Tachyarrhythmias** 1425
Francis Marchlinski

e21 **Atlas of Cardiac Arrhythmias** e159
Ary L. Goldberger

SECTION 4 DISORDERS OF THE HEART

227 **Heart Failure and Cor Pulmonale** 1443
Douglas L. Mann

228 **Cardiac Transplantation and Prolonged Assisted Circulation** 1455
Sharon A. Hunt

229 **Congenital Heart Disease in the Adult** 1458
John S. Child

230 **Valvular Heart Disease** 1465
Patrick O'Gara / Eugene Braunwald

231 **Cardiomyopathy and Myocarditis** 1481
Joshua Wynne / Eugene Braunwald

232 **Pericardial Disease** 1488
Eugene Braunwald

233 **Tumors and Trauma of the Heart** 1495
Eric H. Awtry / Wilson S. Colucci

234 **Cardiac Manifestations of Systemic Disease** 1498
Eric H. Awtry / Wilson S. Colucci

SECTION 5 VASCULAR DISEASE

235 **The Pathogenesis, Prevention, and Treatment of Atherosclerosis** 1501
Peter Libby

e22 **Atlas of Atherosclerosis** e171
Peter Libby

236 **The Metabolic Syndrome** 1509
Robert H. Eckel

237 **Ischemic Heart Disease** 1514
Elliott M. Antman / Andrew P. Selwyn / Eugene Braunwald / Joseph Loscalzo

238 **Unstable Angina and Non-ST-Elevation Myocardial Infarction** 1527
Christopher P. Cannon / Eugene Braunwald

239 **ST-Segment Elevation Myocardial Infarction** 1532
Elliott M. Antman / Eugene Braunwald

240 **Percutaneous Coronary Intervention** 1544
Donald S. Baim

e23 **Atlas of Percutaneous Revascularization** e173
Donald S. Baim

241 **Hypertensive Vascular Disease** 1549
Theodore A. Kotchen

242 **Diseases of the Aorta** 1563
Mark A. Creager / Joseph Loscalzo

243 **Vascular Diseases of the Extremities** 1568
Mark A. Creager / Joseph Loscalzo

244 **Pulmonary Hypertension** 1576
Stuart Rich

PART 10 Disorders of the Respiratory System

SECTION 1 DIAGNOSIS OF RESPIRATORY DISORDERS

245 **Approach to the Patient with Disease of the Respiratory System** 1583
David A. Lipson / Steven E. Weinberger

246 **Disturbances of Respiratory Function** 1586
Steven E. Weinberger / Ilene M. Rosen

247 **Diagnostic Procedures in Respiratory Disease** 1593
Scott Manaker / Steven E. Weinberger

e24 **Atlas of Chest Imaging** e179
Patricia A. Kritek / John J. Reilly, Jr.

SECTION 2 DISEASES OF THE RESPIRATORY SYSTEM

248 **Asthma** 1596
Peter J. Barnes

249 **Hypersensitivity Pneumonitis and Pulmonary Infiltrates with Eosinophilia** 1607
Joel N. Kline / Gary W. Hunninghake

250 **Environmental Lung Disease** 1611
Frank E. Speizer / John R. Balmes

251 **Pneumonia** 1619
Lionel A. Mandell / Richard Wunderink

252 **Bronchiectasis and Lung Abscess** 1629
Gregory Tino / Steven E. Weinberger

253 **Cystic Fibrosis** 1632
Richard C. Boucher

254 **Chronic Obstructive Pulmonary Disease** 1635
John J. Reilly, Jr. / Edwin K. Silverman / Steven D. Shapiro

255 **Interstitial Lung Diseases** 1643
Talmadge E. King, Jr.

256 **Deep Venous Thrombosis and Pulmonary Thromboembolism** 1651
Samuel Z. Goldhaber

257 **Disorders of the Pleura and Mediastinum** 1658
Richard W. Light

258 **Disorders of Ventilation** 1661
Eliot A. Phillipson

259 **Sleep Apnea** 1665
Neil J. Douglas

260 **Lung Transplantation** 1668
Elbert P. Trulock

PART 11 Critical Care Medicine

SECTION 1 RESPIRATORY CRITICAL CARE

261 **Principles of Critical Care Medicine** 1673
John P. Kress / Jesse B. Hall

262 **Acute Respiratory Distress Syndrome** 1680
Bruce D. Levy / Steven D. Shapiro

263 **Mechanical Ventilatory Support** 1684
Edward P. Ingenito

SECTION 2 SHOCK AND CARDIAC ARREST

264 **Approach to the Patient with Shock** 1689
Ronald V. Maier

265 **Severe Sepsis and Septic Shock** 1695
Robert S. Munford

266 **Cardiogenic Shock and Pulmonary Edema** 1702
Judith S. Hochman / David H. Ingbar

267 **Cardiovascular Collapse, Cardiac Arrest, and Sudden Cardiac Death** 1707
Robert J. Myerberg / Agustin Castellanos

SECTION 3 NEUROLOGIC CRITICAL CARE

268 **Coma** 1714
Allan H. Ropper

269 **Neurologic Critical Care, Including Hypoxic-Ischemic Encephalopathy and Subarachnoid Hemorrhage** 1720
J. Claude Hemphill III / Wade S. Smith

SECTION 4 ONCOLOGIC EMERGENCIES

270 **Oncologic Emergencies** 1730
Rasim Gucalp / Janice P. Dutcher

PART 12 Disorders of the Kidney and Urinary Tract

271 **Cellular and Molecular Biology of the Kidney** 1741
Alfred L. George, Jr. / Eric G. Neilson

272 **Adaptation of the Kidney to Renal Injury** 1748
Raymond C. Harris / Eric G. Neilson

273 **Acute Renal Failure** 1752
Kathleen D. Liu / Glenn M. Chertow

274 **Chronic Kidney Disease** 1761
Joanne M. Bargman / Karl Skorecki

275 **Dialysis in the Treatment of Renal Failure** 1772
Kathleen D. Liu / Glenn M. Chertow

276 **Transplantation in the Treatment of Renal Failure** 1776
Charles B. Carpenter / Edgar L. Milford / Mohamed H. Sayegh

277 **Glomerular Diseases** 1782
Julia B. Lewis / Eric G. Neilson

278 **Polycystic Kidney Disease and Other Inherited Tubular Disorders** 1797
David J. Salant / Parul S. Patel

279 **Tubulointerstitial Diseases of the Kidney** 1806
Alan S. L. Yu / Barry M. Brenner

280 **Vascular Injury to the Kidney** 1811
Kamal F. Badr / Barry M. Brenner

281 **Nephrolithiasis** 1815
John R. Asplin / Fredric L. Coe / Murray J. Favus

282 **Urinary Tract Infections, Pyelonephritis, and Prostatitis** 1820
Walter E. Stamm

283 **Urinary Tract Obstruction** 1827
Julian L. Seifter / Barry M. Brenner

PART 13 Disorders of the Gastrointestinal System

SECTION 1 DISORDERS OF THE ALIMENTARY TRACT

284 **Approach to the Patient with Gastrointestinal Disease** 1831
William L. Hasler / Chung Owyang

285 **Gastrointestinal Endoscopy** 1836
Louis Michel Wong-Kee-Song / Mark Topazian

e25 **Video Atlas of Gastrointestinal Endoscopy** e195
Louis Michel Wong-Kee-Song / Mark Topazian

286 **Diseases of the Esophagus** 1847
Raj K. Goyal

287 **Peptic Ulcer Disease and Related Disorders** 1855
John Del Valle

288 **Disorders of Absorption** 1872
Henry J. Binder

289 **Inflammatory Bowel Disease** 1886
Sonia Friedman / Richard S. Blumberg

290 **Irritable Bowel Syndrome** 1899
Chung Owyang

291 **Diverticular Disease and Common Anorectal Disorders** 1903
Susan L. Gearhart

292 **Mesenteric Vascular Insufficiency** 1910
Susan L. Gearhart

293 **Acute Intestinal Obstruction** 1912
Susan L. Gearhart / William Silen

294 **Acute Appendicitis and Peritonitis** 1914
Susan L. Gearhart / William Silen

SECTION 2 LIVER AND BILIARY TRACT DISEASE

295 **Approach to the Patient with Liver Disease** 1918
Marc Ghany / Jay H. Hoofnagle

296 **Evaluation of Liver Function** 1923
Daniel S. Pratt / Marshall M. Kaplan

297 **The Hyperbilirubinemias** 1927
Allan W. Wolkoff

298 **Acute Viral Hepatitis** 1932
Jules L. Dienstag

299 **Toxic and Drug-Induced Hepatitis** 1949
Jules L. Dienstag

300 **Chronic Hepatitis** 1955
Jules L. Dienstag

301 **Alcoholic Liver Disease** 1969
Mark E. Mailliard / Michael F. Sorrell

302 **Cirrhosis and Its Complications** 1971
Bruce R. Bacon

e26 **Atlas of Liver Biopsies** e203
Jules L. Dienstag / Atul K. Bhan

303 **Genetic, Metabolic, and Infiltrative Diseases Affecting the Liver** 1980
Bruce R. Bacon

304 **Liver Transplantation** 1983
Jules L. Dienstag / Raymond T. Chung

305 **Diseases of the Gallbladder and Bile Ducts** 1991
Norton J. Greenberger / Gustav Paumgartner

SECTION 3 DISORDERS OF THE PANCREAS

306 **Approach to the Patient with Pancreatic Disease** 2001
Phillip P. Toskes / Norton J. Greenberger

307 **Acute and Chronic Pancreatitis** 2005
Norton J. Greenberger / Phillip P. Toskes

PART 14 Disorders of the Immune System, Connective Tissue, and Joints

SECTION 1 THE IMMUNE SYSTEM IN HEALTH AND DISEASE

308 **Introduction to the Immune System** 2019
Barton F. Haynes / Kelly A. Soderberg / Anthony S. Fauci

309 **The Major Histocompatibility Complex** 2045
Gerald T. Nepom

310 **Primary Immune Deficiency Diseases** 2053
Max D. Cooper / Harry W. Schroeder, Jr.

e27 **Primary Immunodeficiencies Associated with or Secondary to Other Diseases** e207
Max D. Cooper / Harry W. Schroeder, Jr.

SECTION 2 DISORDERS OF IMMUNE-MEDIATED INJURY

311 **Allergies, Anaphylaxis, and Systemic Mastocytosis** 2061
K. Frank Austen

312 **Autoimmunity and Autoimmune Diseases** 2071
Peter E. Lipsky / Betty Diamond

313 **Systemic Lupus Erythematosus** 2075
Bevra Hannahs Hahn

314 **Rheumatoid Arthritis** 2083
Peter E. Lipsky

315 **Acute Rheumatic Fever** 2092
Jonathan R. Carapetis

316 **Systemic Sclerosis (Scleroderma) and Related Disorders** 2096
John Varga

317 **Sjögren's Syndrome** 2107
Haralampos M. Moutsopoulos

318 **The Spondyloarthritides** 2109
Joel D. Taurog

319 **The Vasculitis Syndromes** 2119
Carol A. Langford / Anthony S. Fauci

e28 **Atlas of Clinical Imaging in the Vasculitic Syndromes** e209
Carol A. Langford / Anthony S. Fauci

320 **Behçet's Syndrome** 2132
Haralampos M. Moutsopoulos

321 **Relapsing Polychondritis** 2133
Carol A. Langford / Bruce C. Gilliland

322 **Sarcoidosis** 2135
Robert P. Baughman / Elyse E. Lower

323 **Familial Mediterranean Fever** 2142
Daniel L. Kastner

324 **Amyloidosis** 2145
David C. Seldin / Martha Skinner

SECTION 3 DISORDERS OF THE JOINTS AND ADJACENT TISSUES

325 **Approach to Articular and Musculoskeletal Disorders** 2149
John J. Cush / Peter E. Lipsky

326 **Osteoarthritis** 2158
David T. Felson

327 **Gout and Other Crystal-Associated Arthropathies** 2165
H. Ralph Schumacher / Lan X. Chen

328 **Infectious Arthritis** 2169
Lawrence C. Madoff

329 **Fibromyalgia** 2175
Carol A. Langford / Bruce C. Gilliland

330 **Arthritis Associated with Systemic Disease and Other Arthritides** 2177
Carol A. Langford / Bruce C. Gilliland

331 **Periarticular Disorders of the Extremities** 2184
Carol A. Langford / Bruce C. Gilliland

PART 15 Endocrinology and Metabolism

SECTION 1 ENDOCRINOLOGY

332 **Principles of Endocrinology** 2187
J. Larry Jameson

333 **Disorders of the Anterior Pituitary and Hypothalamus** 2195
Shlomo Melmed / J. Larry Jameson

334 **Disorders of the Neurohypophysis** 2217
Gary L. Robertson

335 **Disorders of the Thyroid Gland** 2224
J. Larry Jameson / Anthony P. Weetman

336 **Disorders of the Adrenal Cortex** 2247
Gordon H. Williams / Robert G. Dluhy

337 **Pheochromocytoma** 2269
Hartmut P. H. Neumann

338 **Diabetes Mellitus** 2275
Alvin C. Powers

339 **Hypoglycemia** 2305
Philip E. Cryer

340 **Disorders of the Testes and Male Reproductive System** 2310
Shalender Bhasin / J. Larry Jameson

341 **The Female Reproductive System: Infertility and Contraception** 2324
Janet E. Hall

342 **The Menopause Transition and Postmenopausal Hormone Therapy** 2334
JoAnn E. Manson / Shari S. Bassuk

343 **Disorders of Sex Development** 2339
John C. Achermann / J. Larry Jameson

344 **Endocrine Tumors of the Gastrointestinal Tract and Pancreas** 2347
Robert T. Jensen

345 **Disorders Affecting Multiple Endocrine Systems** 2358
Camilo Jimenez / Robert F. Gagel

SECTION 2 DISORDERS OF BONE AND MINERAL METABOLISM

346 **Bone and Mineral Metabolism in Health and Disease** 2365
F. Richard Bringhurst / Marie B. Demay / Stephen M. Krane / Henry M. Kronenberg

347 **Diseases of the Parathyroid Gland and Other Hyper- and Hypocalcemic Disorders** 2377
John T. Potts, Jr.

348 **Osteoporosis** 2397
Robert Lindsay / Felicia Cosman

349 **Paget Disease and Other Dysplasias of Bone** 2408
Murray J. Favus / Tamara J. Vokes

SECTION 3 DISORDERS OF INTERMEDIARY METABOLISM

350 **Disorders of Lipoprotein Metabolism** 2416
Daniel J. Rader / Helen H. Hobbs

351 **Hemochromatosis** 2429
Lawrie W. Powell

352 **The Porphyrias** 2434
Robert J. Desnick / Kenneth H. Astrin

353 **Disorders of Purine and Pyrimidine Metabolism** 2444
Robert L. Wortmann

354 **Wilson Disease** 2449
George J. Brewer

355 **Lysosomal Storage Disease** 2452
Robert J. Hopkin / Gregory A. Grabowski

356 **Glycogen Storage Diseases and Other Inherited Disorders of Carbohydrate Metabolism** 2457
Yuan-Tsong Chen

357 **Heritable Disorders of Connective Tissue** 2461
Darwin J. Prockop / Malwina Czarny-Ratajczak

358 **Inherited Disorders of Amino Acid Metabolism in Adults** 2470
Nicola Longo

359 **Inherited Defects of Membrane Transport** 2474
Nicola Longo

Chapter e1 The Safety and Quality of Health Care

A number of interventions that have been demonstrated to improve the safety and quality of care are available today and should be used more widely in clinical practice. Other interventions are undergoing evaluation, and still others are being developed in parallel with new technologies such as electronic health records systems. Many interventions will require changing the structure of care—for example, moving to a more team-oriented approach and ensuring that patients are more involved in their own care. Payers and the general public are now demanding better information about safety and quality as well as better performance in these areas. The clear implication is that these domains will need to be addressed directly by providers. Thus, physicians must learn about these two domains, how they can be improved, and the relative strengths and limitations of our current ability to measure them.

Chapter e2 Economic Considerations in the Practice of Medicine

Physicians need to develop and maintain an understanding of this topic and to reflect that understanding in their professional behavior. Covered in this chapter are the many causes of rising health care costs, with new technology being the main one; the ways in which insurance coverage (including Medicare and Medicaid) can drive demand for health care services; the influence of health professionals, hospitals, and the pharmaceutical and device industries on the supply of health care; and the different strategies available for cost control. With health care spending in the United States at >16% of the gross domestic product (as of 2005), this chapter should be of interest to all physicians.

Chapter e3 Racial and Ethnic Disparities in Health Care

This chapter illustrates how such disparities persist in spite of the great improvements in overall health and life expectancy. Many graphs and bar charts document the nature, extent, and root causes of differences in health care for minorities. These causes include social determinants, lack of access, complexity of the health care system, stereotyping, and patient-level factors such as mistrust. Key recommendations to bring about improvement are given, as is advice to the individual health care provider (e.g., being aware of disparities, practicing culturally competent care, avoiding stereotyping, and working to build trust).

Chapter e4 Ethical Issues in Clinical Medicine

This chapter discusses fundamental ethical guidelines, patients who lack decision-making capacity, decisions about life-sustaining interventions, conflicts of interest, and just allocation of resources. The chapter helps the physician to follow two fundamental but frequently conflicting ethical principles: respecting patient autonomy and acting in the patient's best interest. Also discussed are assessment of a patient's capacity to make medical decisions, choice of a surrogate, and standards for surrogate decision-making; care of dying patients, do-not-resuscitate orders, and decisions about when to withdraw or withhold life-sustaining interventions; and the risks of financial incentives, gifts from pharmaceutical companies, fear of treating HIV-infected patients, and reporting medical errors. The less-experienced physician will gain confidence in dealing with these perplexing and, at times, emotionally draining issues.

Chapter e5 Atlas of Rashes Associated with Fever

This chapter presents high-quality images of a variety of rashes that have an infectious etiology and are commonly associated with fever. Even the most astute and experienced clinician is often diagnostically challenged by a patient with fever and rash, given the broad differential diagnosis. This atlas will help the physician to rapidly narrow the differential, promptly recognize key features, and administer appropriate and sometimes life-saving therapy.

Chapter e6 Memory Loss

This chapter discusses the formation of both long- and short-term memories. Long-term memory is divided into declarative and nondeclarative memory; the former is further subdivided into semantic and episodic memories. Nondeclarative memory is subdivided into skills and habits (procedural memory), priming, conditioning, and nonassociative learning. Also covered are the associated anatomic substrates for each. Lesions in any of these associated areas cause deficits in storing, retaining, and retrieving information. Short-term, or working, memory relies on different regions of the brain, and lesions that disrupt their structure or function can be devastating. Testing of working memory can be effectively performed at the bedside. More detailed testing of memory should probably be done by a neuropsychologist, neuropsychiatrist, or behavioral neurologist.

Chapter e7 Atlas of Oral Manifestations of Disease

This atlas presents numerous outstanding photographs illustrating many oral conditions that indicate clinical disease either in the mouth or elsewhere. There is significant clinical value in examining the oral cavity for signs of disease, as the health status of the oral cavity is connected to cardiovascular disease and diabetes mellitus.

Chapter e8 Approach to the Patient with a Heart Murmur

This chapter provides comprehensive coverage of heart murmurs (systolic, diastolic, and continuous), their major attributes, and their response to bedside maneuvers, detected by auscultation. Together with the history, clinical context, and associated findings, this information allows the clinician to construct a differential diagnosis to guide the need for and urgency of further testing, such as echocardiography, transesophageal echocardiography, or cardiac CT or MRI.

Chapter e9 Atlas of Urinary Sediments and Renal Biopsies

This chapter illustrates key diagnostic features of selected kidney diseases, using light microscopy, immunofluorescence, and electron microscopy. Common urinalysis findings are also documented. The chapter amplifies the physician's knowledge of disorders of the kidney and urinary tract.

Chapter e10 Atlas of Skin Manifestations of Internal Disease

The atlas provides pictures of a selected group of inflammatory skin eruptions and neoplastic conditions, illustrating (1) common skin diseases and lesions, (2) nonmelanoma skin cancer, (3) melanoma and pigmented lesions, (4) infectious diseases and the skin, (5) immunologically mediated skin disease, and (6) skin manifestations of internal disease. Physicians frequently have to decide whether a cutaneous process is confined to the skin—a pure dermatologic event—or whether it is a manifestation of internal disease relating to the patient's overall medical condition, given the marked rise in both melanoma and nonmelanoma skin cancer.

Copyright © 2008, 2005, 2001, 1998, 1994, 1991, 1987, 1983, 1980, 1977, 1974, 1970, 1966, 1962, 1958 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Chapter e11 Atlas of Hematology and Analysis of Peripheral Blood Smears

This atlas gives many examples of both normal and abnormal blood smears and a guide to blood smear interpretation. A normal peripheral blood smear is shown, as are normal granulocytes, monocytes, eosinophils, basophils, plasma cells, and bone marrow. Abnormal smears illustrate the defects found in conditions such as iron-deficiency anemia, sickle cell anemia, aplastic anemia, metastatic cancer, erythroid hyperplasia, acute myeloid and lymphoblastic leukemias, chronic myeloid and lymphoid leukemias, adult T cell leukemia, follicular lymphoma, and Burkitt's lymphoma, among others.

Chapter e12 Thymoma

The chapter begins with a brief overview of the composition and function of the thymus and lists the various abnormalities that can occur. A thymoma develops when epithelial cells in the thymus become neoplastic. A link to myasthenia gravis (MG) is noted; about 30% of patients with a thymoma have MG, and MG patients have a high incidence of thymic abnormalities. Thymomas may be associated with other conditions (e.g., pure red cell aplasia) but to a lesser degree. Staging and histologic classification are presented. Early-stage disease is treated by surgical resection, with or without postoperative radiation. A multimodality approach is taken in late-stage disease: neoadjuvant chemotherapy followed by surgery, radiation therapy, and additional consolidation chemotherapy.

Chapter e13 Late Consequences of Cancer and Its Treatment

This chapter discusses the long-term consequences of successful cancer treatment. Some problems may be related to the cancer itself or to the normal aging process, but many are caused by therapy, whether surgery, radiation, or chemotherapy. There may also be associated psychosocial problems. The consequences are covered in two ways—by organ system and by cancer type. It is now apparent that monitoring of cancer survivors is a critical component of their overall health care and that some aspects of primary treatment should be modified, where possible, to reduce later consequences.

Chapter e14 Laboratory Diagnosis of Infectious Diseases

The chapter documents the evolution of methods used in the clinical microbiology laboratory to detect and identify viral, bacterial, fungal, and parasitic agents and to determine the antibiotic susceptibility of bacterial and fungal pathogens. Detection methods range from microscopic visualization, aided by a variety of stains, to systems that detect and amplify biologic signals. Identification methods include both classic biochemical phenotyping and more sophisticated methods such as gas chromatography and nucleic acid tests. Perhaps most useful to the nonspecialist is the large table giving clear and precise instructions for collection and transport of specimens to the laboratory for culture.

Chapter e15 Infectious Complications of Burns and Bites

This chapter details the consequences of breaches in the skin from animal bites and scratches, which allow the inoculation of microorganisms into deeper, susceptible host tissues, and from burns, which may cause massive destruction of the integument and derangements in humoral and cellular immunity. The patient's own flora and organisms from the hospital environment can cause infections in burn injuries, and the frequency of infection parallels the extent and severity of the injury. Immunosuppression resulting from severe burns also puts patients at risk of infections, as do the necessary manipulations for clinical care. The risks of infection, both local and systemic, that can result from the variety of microorganisms involved in an animal or human bite are detailed. The treatment section covers wound management, antibiotic therapy for established infection and for prophylactic purposes, and rabies and tetanus prophylaxis.

Chapter e16 Laboratory Diagnosis of Parasitic Infections

This chapter emphasizes the importance of the history and epidemiology of a patient's illness. Tables provide clear information on the geographic distribution, transmission, anatomic locations, and methods employed for the diagnosis of flatworm, roundworm, and protozoal infections. These tables should help the physician select the appropriate body fluid or biopsy site for microscopic examination. Other tables give information about the identification of parasites in samples from specific anatomic locations. Also listed are parasites frequently associated with eosinophilia and the serologic and molecular tests currently available for parasitic infections.

Chapter e17 Pharmacology of Agents Used to Treat Parasitic Infections

This chapter deals exclusively with the pharmacologic properties of the agents used to treat infections due to parasites. Information on these agents' major toxicities, spectrum of activity, and safety for use during pregnancy and lactation is presented in Chap. 201.

Chapter e18 Atlas of Blood Smears of Malaria and Babesiosis

This chapter provides both thin and thick blood films for *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. The thick film allows detection of densities as low as 50 parasites per microliter, with great sensitivity; the thin film is better for speciation and provides useful prognostic information in severe falciparum malaria. One thin blood film showing trophozoites of *Babesia* is included.

Chapter e19 Atlas of Electrocardiography

This chapter shows electrocardiograms to supplement those used in Chap. 221. The interpretations emphasize findings of specific teaching value.

Chapter e20 Atlas of Noninvasive Cardiac Imaging

This chapter provides "real-time" image clips, as they are viewed in clinical practice, as well as additional static images. Noninvasive cardiac imaging is essential to the diagnosis and management of patients with known or suspected cardiovascular disease. This atlas supplements Chap. 222, which describes the principles and clinical applications of these important techniques.

Chapter e21 Atlas of Cardiac Arrhythmias

This chapter shows electrocardiograms to supplement those used in Chaps. 225 and 226. The interpretations emphasize findings of specific teaching value.

Chapter e22 Atlas of Atherosclerosis

The atlas consists of six videos that highlight some of the current understanding of atherosclerosis. Topics include pulse pressure, plaque instability, rudiments of the clinically important lipoproteins, formation and complications of atherosclerotic plaques, mechanisms of atherogenesis, and metabolic derangements that underlie the metabolic syndrome.

Chapter e23 Atlas of Percutaneous Revascularization

The atlas presents seven case studies ranging from cardiogenic shock with left main coronary artery obstruction to percutaneous aortic

valve replacement. The cases are illustrated by a selection of electrocardiograms, videos of angiograms, graphs, and CT scans, providing a good teaching tool.

Chapter e24 Atlas of Chest Imaging

The atlas is a collection of chest x-rays and CT scans illustrative of specific major findings, which are categorized by those of volume loss, loss of parenchyma, interstitial processes, alveolar processes, bronchiectasis, pleural abnormalities, nodules and masses, and pulmonary vascular abnormalities.

Chapter e25 Video Atlas of Gastrointestinal Endoscopy

This atlas demonstrates endoscopic findings in a variety of infectious, inflammatory, vascular, and neoplastic conditions. The premalignant conditions of Barrett's esophagus and colonic polyps are also illustrated. At the end of the chapter are several video clips demonstrating endoscopic treatment modalities for gastrointestinal bleeding, polyps, and biliary stones.

Chapter e26 Atlas of Liver Biopsies

The atlas gives examples of common morphologic features of acute and chronic liver disorders—some involving the lobular areas and others the portal tracts. Liver biopsy is thought to represent the "gold standard" for assessing the degree of liver injury and fibrosis. Other important histologic features include those found in hepatic steatosis, injury of bile ducts in the portal tract, plasma cell infiltration, and portal inflammation affecting portal veins.

Chapter e27 Primary Immunodeficiencies Associated with or Secondary to Other Diseases

The tables in this chapter add to the information given in Chap. 310 by listing (1) the primary immunodeficiencies associated with or secondary to other conditions, and (2) the genes or genetic loci associated with primary immunodeficiencies.

Chapter e28 Atlas of Clinical Imaging in the Vasculitic Diseases

The atlas enhances the information given in Chap. 319 by images illustrating features associated with vasculitic syndromes such as Wegener's granulomatosis, Churg-Strauss syndrome, polyarteritis nodosa, and giant cell and Takayasu's arteritis. The images have been made using mainly CT scans and arteriograms.

Chapter e29 Atlas of Clinical Manifestations of Metabolic Diseases

The atlas provides a visual survey of selected metabolic disorders, which can be used to facilitate learning and thereby enhance the recognition and care of patients with these disorders. The study of metabolic diseases has been invaluable for advancing understanding of human genetics, leading to novel approaches to therapy such as screening programs, blood and organ transplantation, gene therapy, and enzyme replacement.

Chapter e30 Atlas of Neuroimaging

This atlas comprises 29 cases to assist the clinician caring for patients with neurologic symptoms. The majority of the images are MRIs; other techniques used are MR and conventional angiography and CT scans. Many neurologic diseases are illustrated, such as tuberculosis of the central nervous system (CNS), neurosyphilis, CNS aspergillosis, neurosarcoid, middle cerebral artery stenosis, CNS vasculitis, Huntington's disease, and acute transverse myelitis.

Chapter e31 Electrodiagnostic Studies of Nervous System Disorders: EEG, Evoked Potentials, EMG

This chapter covers the two main techniques for electrodiagnosis of neurologic symptoms: the electroencephalogram (EEG) and the electromyogram (EMG). Evoked potentials (sensory, cognitive, and motor) are also covered. The EEG is most useful in evaluating patients with suspected epilepsy but is also helpful in assessing coma and as a noninvasive screening tool for focal structural abnormalities of the brain. EMG enables disorders of the motor units to be detected and characterized as neurogenic or myopathic, and the findings may provide a guide to the severity of an acute nerve disorder or, in chronic or degenerative disorders, whether the process is active or progressive—important for prognosis. Nerve conduction studies, which complement the EMG, are also covered.

Chapter e32 Technique of Lumbar Puncture

This chapter covers the procedure of lumbar puncture (LP) in detail (with illustrations), from indications for imaging and laboratory studies prior to LP, analgesia, positioning, and the procedure itself (including dealing with complications that may arise during LP). Also included is a section on the main complication of LP—the post-LP headache—and its causes and therapy and strategies to avoid it.

Chapter e33 Special Issues in Inpatient Neurologic Consultation

This chapter provides coverage of neurologic diseases and syndromes that are common reasons for inpatient consultation but that are not covered elsewhere in the text. Detailed here are central nervous system dysfunction (hyperperfusion states, post–cardiac bypass brain injury, and post–solid organ transplant injury); common neurologic complications of electrolyte disturbances (hyper- and hyponatremia, hyperosmolality, hypo- and hyperkalemia, and disturbances of calcium and magnesium); and peripheral nervous system dysfunction (including entrapment and obstetric neuropathies).

Chapter e34 Heavy Metal Poisoning

This chapter provides specific information about the four main heavy metals that pose a significant threat to health via occupational and environmental exposures: lead, mercury, arsenic, and cadmium. A table clearly details the main sources, metabolism, toxic effects produced, diagnosis, and appropriate therapy for poisoning from these metals. Other metals covered, though not in the table, are copper, selenium, aluminum, chromium, manganese, and thallium.

Chapter e35 Poisoning and Drug Overdosage

This chapter provides comprehensive coverage of the dose-related adverse effects following exposure to chemicals, drugs, or other xenobiotics. The section on diagnosis gives thorough coverage of the physical examination, laboratory assessment, electrocardiographic and radiologic studies, and toxicologic analysis. The treatment section gives detailed coverage of the general principles of care, supportive care, prevention of poison absorption, enhancement of poison elimination, administration of antidotes, and prevention of reexposure. Pathophysiologic features and treatment of specific toxic syndromes and poisonings are presented in tabular form.

Chapter e36 Pulmonary Biomarkers in COPD

There has been increasing interest in using pulmonary biomarkers to understand and monitor the inflammation in the respiratory tracts of patients with COPD. A biomarker refers to any molecule or material (e.g., cells and tissue) that reflects the disease process. This chapter covers topics on bronchial biopsies, bronchoalveolar lavage, and sputum, among others.

Chapter e37 Chagas' Disease: Advances in Diagnosis and Management

Chagasic cardiomyopathy is the major complication resulting from infection by *Trypanosoma cruzi*. This infection is related to the close proximity between humans and triatomines carrying *T. cruzi*. This chapter discusses laboratory diagnosis and both etiologic and complementary treatments for the disease.

Chapter e38 The Polypill

Several risk factors contribute to causing atherosclerotic coronary artery disease, and some of these can be reduced by a variety of drugs. This chapter discusses the advantages and disadvantages of combining these drugs into one pill, the so-called polypill. The advantages include convenience of delivery, inclusion of all drugs thought to be essential for prevention, low cost, and possible enhanced compliance; disadvantages include possible overtreatment of low-risk patients, undertreatment of high-risk patients, and side effects from one or more components.

The authors emphasize that the role of a polypill in secondary and high-risk prevention is still speculative, and more trials need to be carried out. The polypill's greatest risk appears to be that both patients and physicians may give up on eliminating smoking and modifying sedentary lifestyles and unhealthy diets—tried and true risk-modification techniques.

Chapter e39 Mitochondrial DNA and Heritable Traits and Diseases

The structure and function of mitochondrial DNA (mtDNA) are discussed in depth in this chapter, which includes the proposition that the total cumulative burden of somatic mtDNA mutations acquired with age may contribute to aging and common age-related disturbances. Also included are an overview of the clinical and pathologic features of human mtDNA diseases and their presentations (enhanced by useful tables) and a discussion of the role of mtDNA mutations in the metabolic syndrome, type 2 diabetes mellitus, and neurodegenerative diseases in particular. Genetic counseling and treatment for mtDNA diseases round out the discussion.

Professor of Medicine, Thomas Jefferson University; Director of the Liver Tumor Program, Kimmel Cancer Center, Philadelphia [88]

Lisa B. Caruso, MD, MPH
Assistant Professor of Medicine, Boston Medical Center, Boston [9]

Arturo Casadevall, MD, PhD
Professor of Microbiology and Immunology and of Medicine; Chair, Department of Microbiology and Immunology, Albert Einstein College of Medicine, New York [195]

Agustin Castellanos, MD
Professor of Medicine; Director, Clinical Electrophysiology, University of Miami Miller School of Medicine, Miami [267]

Stanley W. Chapman, MD
Professor of Medicine and Microbiology; Director, Division of Infectious Diseases; Vice-Chair for Academic Affairs, Department of Medicine, University of Mississippi School of Medicine, Jackson [194, 199]

Vinay Chaudhry, MD
Professor and Vice Chair, The Johns Hopkins University School of Medicine; Co-Director, EMG Laboratory, Johns Hopkins Hospital, Baltimore [379]

Lan X. Chen, MD
Clinical Assistant Professor of Medicine, University of Pennsylvania, Penn Presbyterian Medical Center & Philadelphia Veteran Affairs Medical Center, Philadelphia [327]

Yuan-Tsong Chen, MD
Distinguished Research Fellow and Director, Institute of Biomedical Sciences, Academia Sinica, Taiwan [356]

Glenn M. Chertow, MD
Professor of Medicine, Epidemiology and Biostatistics, University of California, San Francisco School of Medicine; Director, Clinical Services, Division of Nephrology, University of California, San Francisco Medical Center, San Francisco [273, 275]

John S. Child, MD
Director, Ahmanson-UCLA Adult Congenital Heart Disease Center; Streisand Professor of Medicine and Cardiology, David Geffen School of Medicine at UCLA, Los Angeles [229]

Yu Jo Chua, MBBS
Research Fellow (Medical Oncology), Royal Marsden Hospital, London [89]

Raymond T. Chung, MD
Associate Professor of Medicine, Harvard Medical School; Director of Hepatology, Massachusetts General Hospital; Medical Director, Liver Transplant Program, Massachusetts General Hospital, Boston [304]

Fredric L. Coe, MD
Professor of Medicine, University of Chicago, Chicago [281]

Jeffrey I. Cohen, MD
Chief, Medical Virology Section, Laboratory of Clinical Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda [174, 184]

Ronit Cohen-Poradosu, MD
Channing Laboratory, Brigham and Women's Hospital, Boston [157]

Francis Collins, MD, PhD
Director, National Human Genome Research Institute, National Institutes of Health, Bethesda [79]

Wilson S. Colucci, MD
Thomas J. Ryan Professor of Medicine, Boston University School of Medicine; Chief, Cardiovascular Medicine, Boston University Medical Center, Boston [233, 234]

Max D. Cooper, MD
Professor of Medicine, Pediatrics, Microbiology, and Pathology, The University of Alabama at Birmingham, Birmingham [310, e27]

Michael J. Corbel, PhD, DSc(Med), FIBiol
Head, Division of Bacteriology, National Institute for Biological Standards and Control, Potters Bar, United Kingdom [150]

Lawrence Corey, MD
Professor of Medicine and Laboratory Medicine; Chair of Medical Virology, University of Washington; Head, Program in Infectious Diseases, Fred Hutchinson Cancer Research Center, Seattle [172]

Felicia Cosman, MD
Associate Professor of Clinical Medicine, Columbia University College of Physicians and Surgeons; Medical Director, Clinical Research Center, Helen Hayes Hospital, West Haverstraw, New York [348]

Mark A. Creager, MD
Professor of Medicine, Harvard Medical School; Simon C. Fireman Scholar in Cardiovascular Medicine; Director, Vascular Center, Brigham and Women's Hospital, Boston [242, 243]

Philip E. Cryer, MD
Irene E. and Michael M. Karl Professor of Endocrinology and Metabolism in Medicine, Washington University, St. Louis [339]

David Cunningham, MD
Professor of Cancer Medicine, Institute of Cancer Research; Consultant Medical Oncologist, Head of Gastrointestinal Unit, Royal Marsden Hospital, London [89]

John J. Cush, MD
Director of Clinical Rheumatology, Baylor Research Institute; Professor of Medicine and Rheumatology, Baylor University Medical Center, Dallas [325]

Malwina Czarny-Ratajczak, PhD
Research Assistant Professor, Center for Gene Therapy, Tulane University Health Sciences Center, Tulane University, New Orleans [357]

Charles A. Czeisler, MD, PhD
Baldino Professor of Sleep Medicine, and Director, Division of Sleep Medicine, Harvard Medical School; Chief, Division of Sleep Medicine, Department of Medicine, Brigham and Women's Hospital, Boston [28]

Marinos C. Dalakas, MD
Professor of Neurology; Chief, Neuromuscular Diseases Section, NINDS, National Institute of Health, Bethesda [383]

Josep Dalmau, MD, PhD
Professor of Neurology, Division Neuro-Oncology, Department of Neurology, Philadelphia [97]

Daniel F. Danzl, MD
Professor and Chair, Department of Emergency Medicine, University of Louisville School of Medicine, Louisville [20]

Emily Darby, MD
Senior Fellow, Division of Infectious Diseases, University of Washington, Seattle [153]

Robert B. Daroff, MD
Gilbert W. Humphrey Professor of Neurology and Interim Chair, Department of Neurology, Case Western Reserve University School of Medicine and University Hospitals Case Medical Center, Cleveland [22]

Charles E. Davis, MD
Professor of Pathology and Medicine Emeritus, University of California San Diego School of Medicine; Director Emeritus, Microbiology Laboratory, University of California San Diego Medical Center, San Diego [e16]

Mahlon R. DeLong, MD
Timmie Professor of Neurology, Emory University School of Medicine, Atlanta [366]

John Del Valle, MD
Professor and Senior Associate Chair of Graduate Medical Education, Department of Internal Medicine, Division of Gastroenterology, University of Michigan Health System, Ann Arbor [287]

Marie B. Demay, MD
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Massachusetts General Hospital, Boston [346]

Bradley M. Denker,
Associate Professor of Medicine, Harvard Medical School; Physician, Brigham and Women's Hospital; Chief of Nephrology, Harvard Vanguard Medical Associates, Boston [45]

David W. Denning, MBBS
Professor of Medicine and Medical Mycology, University of Manchester; Director, Regional Mycology Laboratory, Manchester Education and Research Centre, Wythenshawe Hospital, Manchester, United Kingdom [197]

David T. Dennis, MD, MPH
Faculty Affiliate, Department of Microbiology, Immunology and Pathology, Colorado State University; Medical Epidemiologist, Division of Influenza, Centers for Disease Control and Prevention, Atlanta [152, 165]

Robert J. Desnick, MD, PhD
Professor and Chair, Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine of New York University, New York [352]

Betty Diamond, MD
Chief, Autoimmune Disease Center, The Feinstein Institute for Medical Research, New York [312]

Jules L. Dienstag, MD
Carl W. Walter Professor of Medicine and Dean for Medical Education, Harvard Medical School; Physician, Gastrointestinal Unit, Massachusetts General Hospital, Boston [298–300, 304, e26]

William P. Dillon, MD
Professor of Radiology, Neurology, and Neurosurgery; Vice-Chair, Department of Radiology; Chief, Neuroradiology, University of California, San Francisco [362, e30]

Charles A. Dinarello, MD
Professor of Medicine, University of Colorado Health Science Center, Denver [17]

Robert G. Dluhy, MD
Program Director, Fellowship in Endocrinology; Professor of Medicine, Brigham and Women's Hospital, Harvard Medical School; Associate Editor, New England Journal of Medicine, Boston [336]

Raphael Dolin, MD
Maxwell Finland Professor of Medicine (Microbiology and Molecular Genetics); Dean for Academic and Clinical Programs, Harvard Medical School, Boston [171, 179, 180]

Neil J. Douglas, MD
Professor of Respiratory and Sleep Medicine, University of Edinburgh; Honorary Consultant Physician, Royal Infirmary of Edinburgh, United Kingdom [259]

Daniel B. Drachman, MD
Professor of Neurology & Neuroscience; WW Smith Charitable Trust Professor of Neuroimmunology, The Johns Hopkins University School of Medicine, Baltimore [381]

David F. Driscoll, PhD
Assistant Professor of Medicine, Harvard Medical School, Boston [73]

Thomas D. DuBose, Jr., MD
Tinsley R. Harrison Professor and Chair of Internal Medicine; Professor of Physiology and Pharmacology, Wake Forest University School of Medicine, Winston-Salem [48]

J. Stephen Dumler, MD
Professor, Division of Medical Microbiology, Department of Pathology, The Johns Hopkins University School of Medicine and Immunology, The Johns Hopkins University Bloomberg School of Public Health, Baltimore [167]

Andrea E. Dunaif, MD
Charles F. Kettering Professor of Medicine and Chief, Division of Endocrinology, Metabolism, and Molecular Medicine, Northwestern University Feinberg School Medicine, Chicago [6]

Samuel C. Durso, MD, MBA
Associate Professor of Medicine, Clinical Director, Division of Geriatric Medicine and Gerontology, The Johns Hopkins University School of Medicine, Baltimore [32, e7]

Janice P. Dutcher, MD
Professor, New York Medical College; Associate Director, Our Lady of Mercy Cancer Center, Bronx [270]

Johanna Dwyer, DSc, RD
Professor of Medicine and Community Health, Tufts University School of Medicine and Friedman School of Nutrition Science and Policy; Senior Scientist Jean Mayer Human Nutrition Research Center on Aging at Tufts; Director of the Frances Stern Nutrition Center, Tufts-New England Medical Center Hospital, Boston [70]

Jeffery S. Dzieczkowski, MD
Physician, St. Alphonsus Regional Medical Center; Medical Director, Coagulation Clinic, Saint Alphonsus Medical Group/Internal Medicine, Boise [107]

Kim A. Eagle, MD
Albion Walter Hewlett Professor of Internal Medicine, Chief of Clinical Cardiology and Director, University of Michigan Cardiovascular Center, University of Michigan, Ann Arbor [8]

Robert H. Eckel, MD
Professor of Medicine, Division of Endocrinology, Metabolism and Diabetes, Division of Cardiology; Professor of Physiology and Biophysics; Charles A. Boettcher II Chair in Atherosclerosis; Program Director, Adult General Clinical Research Center, University of Colorado at Denver and Health Sciences Center; Director Lipid Clinic, University Hospital, Aurora [236]

John E. Edwards, Jr., MD
Chief, Division of Infectious Diseases, Harbor/University of California, Los Angeles Medical Center; Professor of Medicine, David Geffen School of Medicine at the University of California, Los Angeles, Torrance [191, 196]

David A. Ehrmann, MD
Professor of Medicine; Associate Director, University of Chicago General Clinical Research Center, Chicago [50]

Ezekiel J. Emanuel, MD, PhD
Chair, Department of Bioethics, The Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda [11]

Linda L. Emanuel, MD, PhD
Buehler Professor of Medicine; Director, Buehler Center on Aging, Health & Society, Northwestern University Feinberg School of Medicine, Chicago [11]

Joey English, MD, PhD
Assistant Professor of Neurology, University of California, San Francisco, San Francisco [364]

John W. Engstrom, MD
Professor of Neurology; Clinical Chief of Service; Neurology Residency Program Director, University of California, San Francisco, San Francisco [16, 370]

Paul Farmer, MD, PhD
Maude and Lillian Presley Professor of Medical Anthropology, Department of Social Medicine, Harvard Medical School; Associate Chief, Division of Social Medicine and Health Inequalities, Brigham and Women's Hospital; Co-Founder, Partners In Health, Boston [2]

Anthony S. Fauci, MD, DSc (Hon), DM&S (Hon), DHL (Hon), DPS (Hon), DLM (Hon), DMS (Hon)
Chief, Laboratory of Immunoregulation; Director, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda [1, 181, 182, 214, 308, 319, e28]

Murray J. Favus, MD
Professor of Medicine, Interim Head, Endocrine Section; Director, Bone Section, University of Chicago Pritzker School of Medicine, Chicago [281, 349]

David T. Felson, MD, MPH
Professor of Medicine and Epidemiology; Chief, Clinical Epidemiology Unit, Boston University, Boston [326]

Robert G. Fenton, MD, PhD
Staff Clinician, National Institute on Aging, National Institutes of Health, Baltimore [80]

Howard L. Fields, MD, PhD
Professor of Neurology; Director, Wheeler Center for Neurobiology of Addiction, University of California, San Francisco, San Francisco [12]

Gregory A. Filice, MD
Professor of Medicine, University of Minnesota; Chief, Infectious Disease Section, Minneapolis Veterans Affairs Medical Center, Minneapolis [155]

Robert Finberg, MD
Professor and Chair, Department of Medicine, University of Massachusetts Medical School, Worcester [82, 126]

Joyce Fingeroth, MD
Associate Professor of Medicine, Harvard Medical School, Boston [126]

Daniel J. Fink, MD, MPH
Associate Professor of Clinical Pathology, College of Physicians and Surgeons, Columbia University, New York [Appendix]

Jeffrey S. Flier, MD
Caroline Shields Walker Professor of Medicine, Harvard Medical School; Dean of the Faculty of Medicine, Harvard School of Medicine, Boston [74]

Agnes B. Fogo, MD
Professor of Pathology, Medicine and Pediatrics; Director, Renal/EM Division, Department of Pathology, Vanderbilt University Medical Center, Nashville [e9]

Sonia Friedman, MD
Assistant Professor of Medicine, Harvard Medical School; Associate Physician, Brigham and Women's Hospital, Boston [289]

Andre D. Furtado, MD
Associate Specialist at the Department of Radiology, Neuroradiology Section, University of California, San Francisco, San Francisco [e30]

Robert F. Gagel, MD
Professor of Medicine and Head, Division of Internal Medicine, University of Texas MD Anderson Cancer Center, Houston [345]

John I. Gallin, MD
Director, The Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda [61]

J. Michael Gaziano, MD, MPH
Chief, Division of Aging, Brigham and Women's Hospital; Director, Massachusetts Veterans Epidemiology, Research and Information Center (MAVERIC) and Geriatric Research, Education and Clinical Center (GRECC), Boston VA Healthcare System; Associate Professor of Medicine, Harvard Medical School, Boston [218]

Thomas A. Gaziano, MD, MSc
Instructor in Medicine, Harvard Medical School; Associate Physician of Cardiovascular Medicine, Brigham and Women's Hospital, Boston [218]

Susan L. Gearhart, MD
Assistant Professor of Colorectal Surgery and Oncology, The Johns Hopkins University School of Medicine, Baltimore [291, 292, 293, 294]

Robert H. Gelber, MD
Scientific Director, Leonard Wood Memorial Leprosy Research Center, Cebu, Philippines; Clinical Professor of Medicine and Dermatology, University of California, San Francisco, San Francisco [159]

Jeffrey A. Gelfand, MD
Professor of Medicine, Harvard Medical School; Physician, Department of Medicine, Massachusetts General Hospital, Boston [19, 204]

Alfred L. George, MD
Grant W. Liddle Professor of Medicine and Pharmacology; Chief, Division of Genetic Medicine, Department of Medicine, Vanderbilt University, Nashville [271]

Dale N. Gerding, MD
Assistant Chief of Staff for Research, Hines VA Hospital, Hines; Professor, Stritch School of Medicine, Loyola University, Maywood [123]

Anne Gershon, MD
Professor of Pediatrics, Columbia University College of Physicians and Surgeons, New York [185–187]

Marc Ghany, MD
Staff Physician, Liver Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda [295]

Raymond J. Gibbons, MD
Arthur M. and Gladys D. Gray Professor of Medicine, Mayo Clinic College of Medicine; Consultant, Cardiovascular Diseases, Mayo Clinic, Rochester [222, e20]

Bruce C. Gilliland,† MD
Professor of Medicine and Laboratory Medicine, University of Washington School of Medicine, Seattle [321, 329–331]

Roger I. Glass, MD, PhD
Director, Fogarty International Center; Associate Director for International Research, National Institutes of Health, Bethesda [183]

Eli Glatstein, MD
Morton M. Kligerman Professor and Vice Chairman, Clinical Director, Department of Radiation Oncology, University of Pennsylvania Medical Center, Philadelphia [216]

Robert M. Glickman, MD
Professor of Medicine, New York University School of Medicine, New York [44]

James F. Glockner, MD
Assistant Professor of Radiology, Mayo Clinic College of Medicine, Rochester [222]

Peter J. Goadsby, MD, PhD, DSc
Professor of Clinical Neurology, Institute of Neurology, Queen Square London; Professor of Neurology, Department of Neurology, University of California, San Francisco, San Francisco [15]

Ary L. Goldberger, MD
Professor of Medicine, Harvard Medical School; Associate Director, Division of Interdisciplinary Medicine and Biotechnology, Beth Israel Deaconess Medical Center, Boston [221, e19, e21]

Samuel Z. Goldhaber, MD
Professor of Medicine, Harvard Medical School; Director, Venous Thromboembolism Research Group, Director, Anticoagulation Service, and Senior Staff Cardiologist, Department of Medicine, Brigham and Women's Hospital, Boston [256]

†Deceased.

Ralph Gonzales, MD, MSPH
Professor of Medicine, Epidemiology and Biostatistics, University of California, San Francisco, San Francisco [31]

Douglas S. Goodin, MD
Professor of Neurology, University of California, San Francisco, San Francisco [375]

Raj K. Goyal, MD
Mallinckrodt Professor of Medicine, Harvard Medical School, Boston; Physician, VA Boston Healthcare and Beth Israel Deaconess Medical Center, West Roxbury [38, 286]

Gregory A. Grabowski, MD
The A. Graeme Mitchell Chair of Human Genetics; Professor, University of Cincinnati College of Medicine, Department of Pediatrics; Director, Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati [355]

Norton J. Greenberger, MD
Clinical Professor of Medicine, Harvard Medical School; Senior Physician, Brigham and Women's Hospital, Boston [305–307]

David E. Griffith, MD
Professor of Medicine; William A. and Elizabeth B. Moncrief Distinguished Professor, University of Texas Health Center, Tyler [161]

Rasim Gucalp, MD
Professor of Clinical Medicine, Albert Einstein College of Medicine, Montefiore Medical Center, Bronx [270]

Chadi A. Hage, MD
Assistant Professor of Medicine, Indiana University School of Medicine, Roudebush VA Medical Center, Pulmonary-Critical Care and Infectious Diseases, Indianapolis [192]

Bevra Hannahs Hahn, MD
Professor of Medicine; Chief of Rheumatology; Vice Chair, Department of Medicine, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles [313]

Janet E. Hall, MD
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Massachusetts General Hospital, Boston [51, 341]

Jesse B. Hall, MD
Professor of Medicine, Anesthesia & Critical Care; Section Chief, Pulmonary and Critical Care Medicine, University of Chicago, Chicago [261]

Scott A. Halperin, MD
Professor of Pediatrics and of Microbiology and Immunology, Dalhousie University, Halifax, Nova Scotia [142]

Raymond C. Harris, Jr., MD
Ann and Roscoe R. Robinson Professor of Medicine; Chief, Division of Nephrology & Hypertension, Department of Medicine, Vanderbilt University, Nashville [272]

Gavin Hart, MD, MPH
Director, STD Services, Royal Adelaide Hospital; Clinical Associate Professor, School of Medicine, Flinders University, Adelaide, South Australia, Australia [154]

Rudy Hartskeerl, PhD
Head, FAO/OIE, World Health Organization and National Leptospirosis Reference Centre, KIT Biomedical Research, Royal Tropical Institute, Amsterdam, The Netherlands [164]

William L. Hasler, MD
Professor of Medicine, Division of Gastroenterology, University of Michigan Health System, Ann Arbor [39, 284]

Terry J. Hassold, PhD
Eastlick Distinguished Professor, Washington State University, Pullman [63]

Joshua Hauser, MD
Assistant Professor of Medicine and Palliative Care; Assistant Director of the Beuler Center on Aging, Northwestern University, Chicago [11]

Stephen L. Hauser, MD
Robert A. Fishman Distinguished Professor and Chairman, Department of Neurology, University of California, San Francisco, San Francisco [1, 360, 361, 371, 372, 375, 380, e32]

Barton F. Haynes, MD
Frederic M. Hanes Professor of Medicine and Immunology, Departments of Medicine and Immunology; Director, Duke Human Vaccine Institute, Duke University School of Medicine, Durham [308]

Douglas C. Heimburger, MD, MS
Professor of Nutrition Sciences; Professor of Medicine; Director, Clinical Nutrition Fellowship Program, University of Alabama at Birmingham, Birmingham [72]

J. Claude Hemphill III, MD, MAS
Associate Professor of Clinical Neurology and Neurological Surgery, University of California, San Francisco; Director, Neurocritical Care Program, San Francisco General Hospital, San Francisco [269]

Patrick H. Henry, MD
Adjunct Clinical Professor of Medicine, University of Iowa, Iowa City [60]

Barbara L. Herwaldt, MD, MPH
Medical Epidemiologist, Division of Parasitic Diseases, Centers for Disease Control and Prevention, Atlanta [205]

Katherine A. High, MD
William H. Bennett Professor of Pediatrics, University of Pennsylvania School of Medicine; Investigator, Howard Hughes Medical Institute, The Children's Hospital of Philadelphia, Philadelphia [65, 110]

Martin S. Hirsch, MD
Professor of Medicine, Harvard Medical School; Professor of Immunology and Infectious Diseases, Harvard School of Public Health; Physician, Massachusetts General Hospital, Boston [175]

Helen H. Hobbs, MD
Investigator, Howard Hughes Medical Institute; Professor of Internal Medicine and Molecular Genetics, University of Texas Southwestern Medical Center, Dallas [350]

Judith S. Hochman, MD
Harold Synder Family Professor of Cardiology; Clinical Chief, the Leon H. Charney Division of Cardiology; New York University School of Medicine; Director, Cardiovascular Clinical Research, New York [226]

Elizabeth L. Hohmann, MD
Associate Professor of Medicine and Infectious Diseases, Harvard Medical School, Massachusetts General Hospital, Boston [132]

A. Victor Hoffbrand, DM
Emeritus Professor of Haematology, Royal Free and University College, London [100]

Steven M. Holland, MD
Senior Investigator and Head, Immunopathogenesis Unit, Clinical Pathophysiology Section, Laboratory of Host Defenses, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda [61]

King K. Holmes, MD, PhD
William H. Foege Chair, Department of Global Health; Director, Center for AIDS and STD; Professor of Medicine and Global Health, University of Washington; Head, Infectious Diseases, Harborview Medical Center, Seattle [124]

Jay H. Hoofnagle, MD
Director, Liver Diseases Research Branch, Division of Digestive Diseases and Nutrition, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda [295]

Robert J. Hopkin, MD
Assistant Professor of Clinical Pediatrics, The University of Cincinnati College of Medicine; Division and Program in Human Genetics, Cincinnati Children's Hospital Research Foundation, Cincinnati [355]

Jonathan C. Horton, MD, PhD
William F. Hoyt Professor of Neuro-Ophthalmology; Professor of Ophthalmology, Neurology, and Physiology, University of California, San Francisco, San Francisco [29]

Howard Hu, MD, MPH, ScD
NSF International Chair, Department of Environmental Health Sciences; Professor of Environmental Health, Epidemiology and Medicine, University of Michigan Schools of Public Health and Medicine, Ann Arbor [e34]

Gary W. Hunninghake, MD
Sterba Professor of Medicine; Director, Division of Pulmonary, Critical Care and Occupational Medicine; Director, Institute for Clinical and Translational Science; Director, Graduate Program in Translational Biomedicine; Senior Associate Dean for Clinical and Translational Science, Iowa City [249]

Sharon A. Hunt, MD
Professor, Cardiovascular Medicine, Stanford University, Palo Alto [228]

Charles G. Hurst, MD
Chief, Chemical Casualty Care Division, United States Medical Research Institute of Chemical Defense, Maryland [215]

Steven E. Hyman, MD
Provost, Harvard University; Professor of Neurobiology, Harvard Medical School, Boston [385]

David H. Ingbar, MD
Professor of Medicine, Physiology & Pediatrics; Director, Pulmonary, Allergy, Critical Care & Sleep Division; Executive Director, Center for Lung Science & Health, University of Minnesota School of Medicine; Co-Director, Medical ICU & Respiratory Care, University of Minnesota Medical Center, Fairview [266]

Edward P. Ingenito, MD, PhD
Assistant Professor, Harvard Medical School, Boston [263]

Mark A. Israel, MD
Professor of Pediatrics and Genetics, Dartmouth Medical School; Director, Norris Cotton Cancer Center, Dartmouth-Hitchcock Medical Center, Lebanon [374]

Alan C. Jackson, MD, FRCPC
Professor of Medicine (Neurology) and of Medical Microbiology, University of Manitoba; Section Head of Neurology, Winnipeg Regional Health Authority, Winnipeg, Manitoba, Canada [188]

Richard F. Jacobs, MD, FAAP
President, Arkansas Children's Hospital Research Institute; Horace C. Cabe Professor of Pediatrics, University of Arkansas for Medical Sciences, College of Medicine, Little Rock [151]

J. Larry Jameson, MD, PhD
Professor of Medicine; Vice President for Medical Affairs and Lewis Landsberg Dean, Northwestern University Feinberg School of Medicine, Chicago [1, 62, 64, 96, 332, 333, 335, 340, 343, e29]

Robert T. Jensen, MD
Chief, Digestive Diseases Branch, National Institute of Diabetes, Digestive and Kidney Diseases, National Institutes of Health, Bethesda [344]

Camilo Jimenez, MD
Assistant Professor, Department of Endocrine Neoplasia & Hormonal Disorders, The University of Texas, MD Cancer Center, Houston [345]

Eric C. Johannsen, MD
Assistant Professor, Department of Medicine, Harvard Medical School; Associate Physician, Division of Infectious Diseases, Brigham and Women's Hospital, Boston [188]

Bruce E. Johnson, MD
Director, Lowe Center for Thoracic Oncology, Department of Medical Oncology; Dana-Farber Cancer Institute, Department of Medicine, Brigham and Women's Hospital; Professor of Medicine, Harvard Medical School, Boston [96]

James R. Johnson, MD
Professor of Medicine, University of Minnesota, Minneapolis [143]

Stuart Johnson, MD
Associate Professor, Stritch School of Medicine, Loyola University, Maywood; Staff Physician, Hines VA Hospital, Hines [123]

S. Claiborne Johnston, MD, PhD
Professor, Neurology; Professor, Epidemiology and Biostatistics; Director, University of California, San Francisco Stroke Service, San Francisco [364]

S. Andrew Josephson, MD
Assistant Clinical Professor of Neurology, University of California, San Francisco, San Francisco [26, e33]

Jorge L. Juncos, MD
Associate Professor of Neurology, Emory University School of Medicine; Director of Neurology, Wesley Woods Hospital, Atlanta [366]

Eric Kandel, MD
University Professor; Fred Kavli Professor and Director, Kavli Institute for Brain Sciences; Senior Investigator, Howard Hughes Medical Institute, Columbia University, New York [385]

Marshall M. Kaplan, MD
Professor of Medicine, Tufts University School of Medicine; Chief Emeritus, Division of Gastroenterology, Tufts-New England Medical Center, Boston [43, 296]

Adolf W. Karchmer, MD
Professor of Medicine, Harvard Medical School, Boston [118]

Dennis L. Kasper, MD, MA (Hon)
William Ellery Channing Professor of Medicine, Professor of Microbiology and Molecular Genetics, Harvard Medical School; Director, Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Boston [1, 113, 115, 121, 135, 140, 157]

Lloyd H. Kasper, MD
Professor of Medicine and Microbiology/Immunology; Co-Director, Program in Immunotherapeutics, Dartmouth Medical Schoool, Lebanon [207]

Daniel Kastner, MD, PhD
Chief, Genetics and Genomic Section, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda [323]

Elaine T. Kaye, MD
Clinical Assistant Professor of Dermatology, Harvard Medical School; Assistant in Medicine, Department of Medicine, Children's Hospital Medical Center, Boston [18, e5]

Kenneth M. Kaye, MD
Associate Professor of Medicine, Harvard Medical School; Associate Physician, Division of Infectious Diseases, Brigham and Women's Hospital, Boston [18, e5]

Jack A. Kessler, MD
Davis Professor of Stem Cell Biology; Chairman, Davis Department of Neurology, Northwestern University Feinberg School of Medicine, Chicago [67]

Gerald T. Keusch, MD
Associate Provost and Associate Dean for Global Health, Boston University School of Medicine, Boston [116, 149]

Jay S. Keystone, MD, FRCPC
Professor of Medicine, University of Toronto; Staff Physician, Centre for Travel and Tropical Medicine, Toronto General Hospital, Toronto [117]

Sundeep Khosla, MD
Professor of Medicine and Physiology, Mayo Clinic College of Medicine, Rochester [47]

Elliott Kieff, MD, PhD
Harriet Ryan Albee Professor of Medicine and Microbiology and Molecular Genetics, Harvard Medical School; Senior Physician, Brigham and Women's Hospital, Boston [170]

Jim Yong Kim, MD, PhD
Chief, Division of Social Medicine and Health Inequalities, Brigham and Women's Hospital; Director and Professor, François Xavier-Bagnoud Center for Health and Human Rights, Harvard School of Public Health; Professor of Social Medicine and Chair, Department of Social Medicine, Harvard Medical School, Boston [2]

Talmadge E. King, Jr., MD
Constance B. Wofsy Distinguished Professor and Interim Chair, Department of Medicine, University of California, San Francisco, San Francisco [255]

Louis V. Kirchhoff, MD, MPH
Professor, Departments of Internal Mediciene and Epidemiology, University of Iowa; Staff Physician, Department of Veterans Affairs Medical Center, Iowa City [206]

Joel N. Kline, MD, MSc
Professor, Internal Medicine and Occupational & Environmental Health; Director, University of Iowa Asthma Center, Iowa City [249]

Minoru S. H. Ko, MD, PhD
Senior Investigator & Chief, Developmental Genomics & Aging Section, Laboratory of Genetics, National Institute on Aging, NIH, Baltimore [66]

Barbara A. Konkle, MD
Professor of Medicine and Hematology/Oncology, University of Pennsylvania; Director, Penn Comprehensive Hemophilia and Thrombosis Program, Philadelphia [59, 109]

Peter Kopp, MD
Associate Professor, Division of Endocrinology, Metabolism and Molecular Science, Northwestern University Feinberg School of Medicine, Chicago [62]

Walter J. Koroshetz, MD
Deputy Director, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda [377]

Theodore A. Kotchen, MD
Associate Dean for Clinical Research; Director, General Clinical Research Center, Medical College of Wisconsin, Wisconsin [241]

Phyllis E. Kozarsky, MD
Professor of Medicine, Infectious Diseases; Co-Director, Travel and Tropical Medicine, Emory University School of Medicine, Atlanta [117]

Barnett S. Kramer, MD, MPH
Associate Director for Disease Prevention, Office of the Director, National Institutes of Health, Bethesda [78]

Stephen M. Krane, MD
Persis, Cyrus and Marlow B. Harrison Distinguished Professor of Medicine, Harvard Medical School, Massachusetts General Hospital, Boston [346]

Alexander Kratz, MD, PhD, MPH
Assistant Professor of Clinical Pathology, Columbia University College of Physicians and Surgeons; Associate Director, Core Laboratory, Columbia University Medical Center, New York-Presbyterian Hospital; Director, Allen Pavilion Laboratory, New York [Appendix]

John P. Kress, MD
Associate Professor of Medicine, Section of Pulmanary and Critical Care, University of Chicago, Chicago [261]

Patricia A. Kritek, MD, EdM
Instructor in Medicine, Harvard Medical School; Co-Director, Harvard Pulmonary and Critical Care Medicine Fellowship, Brigham and Women's Hospital, Boston [e24]

Henry M. Kronenberg, MD
Chief, Endocrine Unit, Massachusetts General Hospital; Professor of Medicine, Harvard Medical School, Boston [346]

Robert F. Kushner, MD
Professor of Medicine, Northwestern University Feinberg School of Medicine, Chicago [75]

Loren Laine, MD
Professor of Medicine, Keck School of Medicine, University of Southern California, Los Angeles [42]

Anil K. Lalwani, MD
Mendik Foundation Professor and Chairman, Department of Otolaryngology; Professor, Department of Pediatrics; Professor, Department of Physiology and Neuroscience, New York University School of Medicine, New York [30]

H. Clifford Lane, MD
Clinical Director; Director, Division of Clinical Research; Deputy Director, Clinical Research and Special Projects; Chief, Clinical and Molecular Retrovirology Section, Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda [182, 214]

Carol A. Langford, MD, MHS
Associate Professor of Medicine; Director, Center for Vasculitis Care and Research, Department of Rheumatic and Immunologic Diseases, Cleveland Clinic, Cleveland [319, 321, 329–331, e28]

Wei C. Lau, MD
Associate Professor; Medical Director, Cardiovascular Center Operating Rooms; Director, Adult Cardiovascular Anesthesiology, Ann Arbor [8]

Thomas J. Lawley, MD
William P. Timmie Professor of Dermatology; Dean, Emory University School of Medicine, Atlanta [52, 23, 55, e10]

Thomas H. Lee, MD
Professor of Medicine, Harvard Medical School; Chief Executive Officer, Partners Community Health Care, Inc; Network President, Partners Health Care, Boston [13]

Bruce D. Levy, MD
Associate Professor of Medicine, Harvard Medical School; Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston [262]

Julia B. Lewis, MD
Professor of Medicine, Division of Nephrology and Hypertension, Department of Medicine, Vanderbilt University School of Medicine, Nashville [277]

Peter Libby, MD
Mallinckrodt Professor of Medicine, Harvard Medical School; Chief, Cardiovascular Medicine, Brigham and Women's Hospital, Boston [217, 235, e22]

Richard W. Light, MD
Professor of Medicine, Vanderbilt University, Nashville [257]

Christopher H. Linden, MD
Professor, Department of Emergency Medicine, Division of Medical Toxicology, University of Massachusetts Medical School, Worcester [e35]

Robert Lindsay, MD, PhD
Professor of Clinical Medicine, Columbia University College of Physicians and Surgeons; Chief, Internal Medicine, Helen Hayes Hospital, West Haverstraw, New York [348]

Marc E. Lippman, MD
Professor and Chair, Department of Medicine, University of Miami Leonard M. Miller School of Medicine, Miami [86]

Peter E. Lipsky, MD
Chief, Autoimmunity Branch, National Institute of Arthritis, Musculoskeletal, and Skin Diseases, National Institutes of Health, Department of Health and Human Services, Bethesda [312, 314, 325]

David A. Lipson, MD
Assistant Professor of Medicine, Pulmonary, Allergy & Critical Care Division, University of Pennsylvania Medical Center, King of Prussia [34, 345]

Kathleen D. Liu, MD, PhD, MCR
Assistant Professor, Division of Nephrology, San Francisco [273, 275]

Bernard Lo, MD
Professor of Medicine; Director, Program in Medical Ethics, University of California, San Francisco, San Francisco [e4]

Dan L. Longo, MD
Scientific Director, National Institute on Aging, National Institutes of Health, Bethesda and Baltimore [1, 58, 60, 68, 77, 80, 81, 105, 106, 181, e11–e13]

Nicola Longo, MD, PhD
Professor of Pediatrics; Chief, Division of Medical Genetics, Department of Pediatrics, University of Utah, Salt Lake City [358, 359]

Joseph Loscalzo, MD, PhD, MA (Hon)
Hersey Professor of the Theory and Practice of Medicine, Harvard Medical School; Chairman, Department of Medicine, Physician-in-Chief, Brigham and Women's Hospital, Boston [1, 36, 37, 217, 237, 242, 243]

Phillip A. Low, MD
Robert D and Patricia E Kern Professor of Neurology, Mayo Clinic College of Medicine, Rochester [370]

Daniel H. Lowenstein, MD
Professor of Neurology; Director, University of California, San Francisco Epilepsy Center; Associate Dean for Clinical/Translational Research, San Francisco [361, 363]

Elyse E. Lower, MD
Professor of Medicine, University of Cincinnati, Cincinnati [322]

Franklin D. Lowy, MD, PhD
Professor of Medicine and Pathology, Columbia University, College of Physicians & Surgeons, New York [129]

Sheila A. Lukehart, PhD
Professor of Medicine, University of Washington, Seattle [162, 163]

Lucio Luzzatto, MD, PhD
Professor of Hematology, University of Florence; Scientific Director, Instituto Toscano Tumori (ITT), Firenze, Italy [101]

Lawrence C. Madoff, MD
Associate Professor of Medicine, Harvard Medical School, Boston [113, 135, 328, e15]

James H. Maguire, MD, MPH
Professor and Director, International Health Division, Department of Epidemiology and Preventive Medicine, University of Maryland School of Medicine, Baltimore [392]

Adel A. F. Mahmoud, MD, PhD
Professor, Molecular Biology, Princeton University, Princeton [212]

Ronald V. Maier, MD
Jane and Donald D. Trunkey Professor and Vice Chair, Surgery, University of Washington; Surgeon-in-Chief, Harborview Medical Center, Seattle [264]

Mark E. Malliard, MD
Associate Professor and Chief, Division of Gastroenterology and Hepatology, Omaha [301]

Scott Manaker, MD, PhD
Associate Professor of Medicine and Pharmacology, Pulmonary and Critical Care Division, Department of Medicine, University of Pennsylvania, Philadelphia [247]

Hanna Mandel, MD
Director, Metabolic Disease Unit, Rambam Medical Health Care Campus, Haifa, Israel [e39]

Lionel A. Mandell, MD
Professor of Medicine, McMaster University, Hamilton, Ontario [251]

Douglas L. Mann, MD
Professor of Medicine, Molecular Physiology and Biophysics; Chief, Section of Cardiology, Baylor College of Medicine, St. Luke's Episcopal Hospital and Texas Heart Institute, Houston [227]

JoAnn E. Manson, MD, DrPH
Professor of Medicine and the Elizabeth Fay Brigham Professor of Women's Health, Harvard Medical School; Chief, Division of Preventive Medicine, Brigham and Women's Hospital, Boston [342]

Eleftheria Maratos-Flier, MD
Associate Professor of Medicine, Harvard Medical School; Chief, Obesity Section, Joslin Diabetes Center, Boston [74]

Francis Marchlinski, MD
Professor of Medicine; Director of Cardiac Electrophysiology, University of Pennsylvania Health System, University of Pennsylvania School of Medicine, Philadelphia [226]

Daniel B. Mark, MD, MPH
Professor of Medicine, Duke University Medical Center; Director, Outcomes Research, Duke Clinical Research Institute, Durham [3]

Thomas Marrie, MD
Professor, Department of Medicine; Dean, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, Alberta [167]

Gary J. Martin, MD
Raymond J. Langenbach MD Professor of Medicine; Vice Chairman for Faculty Affairs and Education, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago [4]

Joseph B. Martin, MD, PhD, MA (Hon)
Dean Emeritus of the Faculty of Medicine, Edward R. and Anne G. Lefler Professor of Neurobiology, Harvard Medical School, Boston [12, 361]

Robert J. Mayer, MD
Stephen B. Kay Family Professor of Medicine, Harvard Medical School, Dana-Farber Cancer Institute, Boston [87]

Alexander J. McAdam, MD, PhD
Medical Director, Infectious Diseases Diagnostic Division, Children's Hospital, Boston; Assistant Professor, Department of Pathology, Harvard Medical School, Boston [e14]

Calvin O. McCall, MD
Associate Professor of Dermatology, Virginia Commonwealth University Medical Center, Richmond [53]

William M. McCormack, MD
Distinguished Teaching Professor of Medicine; Chief, Infectious Disease Division, SUNY Downstate Medical Center, Brooklyn [168]

Kevin T. McVary, MD
Associate Professor of Urology, Northwestern University Feinberg School of Medicine, Chicago [49]

Nancy K. Mello, PhD
Professor of Psychology (Neuroscience), Harvard Medical School, Boston [389]

Shlomo Melmed, MD
Senior Vice President, Academic Affairs; Associate Dean, Cedars Sinai Medical Center, David Geffen School of Medicine at UCLA, Los Angeles [333]

David Meltzer, MD, PhD
Associate Professor, Departments of Medicine and Economics, Harris School of Public Policy; Director of the Center for Health and the Social Sciences, The University of Chicago, Chicago [e2]

Jerry R. Mendell, MD
Professor of Pediatrics, Neurology and Pathology, The Ohio State University; Director, Center for Gene Therapy, The Research Institute at Nationwide Children's Hospital, Columbus [382]

Jack H. Mendelson, MD
Professor of Psychiatry (Neuroscience), Harvard Medical School, Belmont [389]

M.-Marsel Mesulam, MD
Director, Cognitive Neurology and Alzheimer's Disease Center; Dunbar Professor of Neurology and Psychiatry, Northwestern University Feinberg School of Medicine, Chicago [27]

Susan Miesfeldt, MD
Medical Oncology Medical Director, Cancer Risk and Prevention Clinic, Maine Medical Cancer and Maine Center for Cancer Medicine & Blood Disorders, Portland [64]

Edgar L. Milford, MD
Associate Professor of Medicine, Harvard Medical School; Director, Tissue Typing Laboratory, Brigham and Women's Hospital, Boston [276]

Bruce L. Miller, MD
AW and Mary Margaret Clausen Distinguished Professor of Neurology, University of California, San Francisco School of Medicine, San Francisco [26, 365, 378, e6]

Mark Miller, MD
Associate Director for Research, National Institutes of Health, Bethesda [116]

Samuel I. Miller, MD
Professor of Genome Sciences, Medicine, and Microbiology, University of Washington, Seattle [146]

John D. Minna, MD
Professor, Internal Medicine and Pharmacology; Director, Hamon Center for Therapeutic Oncology Research, University of Texas Southwestern Medical Center, Dallas [85]

Thomas A. Moore, MD
Clinical Professor and Associate Program Director, Department of Medicine, University of Kansas School of Medicine, Wichita [201, e17]

Pat J. Morin, PhD
Senior Investigator, Laboratory of Cellular and Molecular Biology, National Institute on Aging, National Institutes of Health, Bethesda [79]

Robert J. Motzer, MD
Attending Physician, Department of Medicine, Memorial Sloan-Kettering Cancer Center; Professor of Medicine, Weill Medical College of Cornell University, New York [90, 92]

Haralampos M. Moutsopoulos, MD
Professor and Chair, Department of Pathophysiology, School of Medicine, National University of Athens, Greece [317, 320]

Robert S. Munford, MD
Jan and Henri Bromberg Chair in Internal Medicine, University of Texas Southwestern Medical Center, Dallas [265]

Nikhil C. Munshi, MD
Associate Director, Jerome Lipper Multiple Myeloma Center, Dana-Farber Cancer Institute; Associate Professor, Harvard Medical School, Boston [106]

John R. Murphy, PhD
Professor of Medicine and Microbiology; Chief, Section of Molecular Medicine, Boston University School of Medicine, Boston [131]

Timothy F. Murphy, MD
UB Distinguished Professor, Department of Medicine and Microbiology; Chief, Infectious Diseases, State Univerity of New York, Buffalo [139]

Joseph A. Murray, MD
Professor of Medicine, Division of Gastroenterology and Hepatology, The Mayo Clinic, Rochester [40]

Daniel M. Musher, MD
Chief, Infectious Disease Section, Michael E. DeBakey Veterans Affairs Medical Center; Professor of Medicine and Professor of Molecular Virology and Microbiology, Baylor College of Medicine, Houston [128, 138]

Mark B. Mycyk, MD
Assistant Professor of Emergency Medicine; Director of Clinical Toxicology and Toxicological Research, Northwestern University Feinberg School of Medicine, Chicago [e35]

Robert J. Myerberg, MD
Professor of Medicine and Physiology; AHA Chair in Cardiovascular Research, University of Miami Miller School of Medicine, Miami [267]

Nitish Naik, MD, DS
Department of Cardiology, All India Institute of Medical Sciences, Ansari Nagar, New Delhi, India [e38]

Eric G. Neilson, MD
Hugh J. Morgan Professor of Medicine and Cell Biology, Physician-in-Chief, Vanderbilt University Hospital; Chairman, Department of Medicine, Vanderbilt University School of Medicine, Nashville [271, 272, 277, e9]

Gerald T. Nepom, MD, PhD
Director, Benaroya Research Institute at Virginia Mason; Professor, University of Washington School of Medicine, Seattle [309]

Hartmut P. H. Neumann, MD
Head, Section Preventative Medicine, Department of Nephrology and General Medicine, Albert-Ludwigs-University of Freiburg, Germany [337]

Jonathan Newmark, MD, Colonel, Medical Corps, US Army
Deputy Joint Program Executive Officer, Medical Systems, Joint Program Executive Office for Chemical/Biological Defense, US Department of Defense Chemical Casualty Care; Consultant to the US Army Surgeon General; Adjunct Professor, Neurology, F. Edward Hébert School of Medicine, Uniformed Services University of the Health Sciences, Falls Church [215]

Rick A. Nishimura, MD
Judd and Mary Morris Leighton Professor of Cardiovascular Diseases; Professor of Medicine, Mayo Clinic College of Medicine, Rochester [222, e20]

Robert L. Norris, MD
Associate Professor, Department of Surgery, Division of Emergency Medicine, Stanford University School of Medicine, Stanford [391]

Thomas B. Nutman, MD
Head, Helminth Immunology Section; Head, Clinical Parasitology Unit; Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Insitutes of Health, Bethesda [210, 211]

Richard J. O'Brien, MD
Head of Scientific Evaluation, Foundation for Innovative New Diagnostics, Geneva, Switzerland [158]

Patrick O'Gara, MD
Associate Professor of Medicine, Harvard Medical School; Director, Clinical Cardiology, Brigham and Women's Hospital, Boston [230, e8]

Robert A. O'Rourke, MD
Distinguished Professor of Medicine Emeritus, University of Texas Health Science Center, San Antonio [220]

C. Warren Olanow, MD
Henry P. and Georgette Goldschmidt Professor and Chairman of the Department of Neurology, Professor of Neuroscience, The Mount Sinai School of Medicine, New York [367]

Andrew B. Onderdonk, PhD
Professor of Pathology, Harvard Medical School and Brigham and Women's Hospital, Boston [e14]

Chung Owyang, MD
Professor of Internal Medicine, H. Marvin Pollard Collegiate Professor; Chief, Division of Gastroenterology, University of Michigan Health System, Ann Arbor [284, 290]

Umesh D. Parashar, MBBS, MPH
Lead, Enteric and Respiratory Viruses Team, Epidemiology Branch, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta [183]

Jeffrey Parsonnet, MD
Associate Professor of Medicine and Microbiology, Dartmouth Medical School, Lebanon [120]

Parul S. Patel, MD
Transplant Neurologist, California Pacific Medical Center, San Francisco [278]

Shreyaskumar R. Patel, MD
Professor of Medicine, Deputy Chairman, Department of Sarcoma Medical Oncology, University of Texas, Houston [94]

Gustav Paumgartner, MD
Professor of Medicine, University of Munich, Munich, Germany [305]

David A. Pegues, MD
Professor of Medicine, Division of Infectious Diseases, David Geffen School of Medicine at UCLA, Los Angeles [146]

Florencia Pereyra, MD
Instructor in Medicine, Harvard Medical School; Division of Infectious Disease, Brigham and Women's Hospital, Boston [e15]

Michael C. Perry, MD, MS
Professor and Director, Division of Hematology/Medical Oncology, Department of Internal Medicine, Nellie B. Smith Chair of Oncology, Columbia [e13]

Michael A. Pesce, PhD
Clinical Professor of Pathology, Columbia University College of Physicians and Surgeons; Director of Specialty Laboratory, New York Presbyterian Hospital, Columbia University Medical Center, New York [Appendix]

Clarence J. Peters, MD
John Sealy Distinguished University Chair in Tropical and Emerging Virology, Director for Biodefense, Center for Biodefense and Emerging Infectious Diseases, University of Texas Medical Branch in Galveston, Galveston [189, 190]

Eliot A. Phillipson, MD
Professor, Department of Medicine, University of Toronto, Toronto [258]

Gerald B. Pier, PhD
Professor of Medicine (Microbiology and Molecular Genetics), Harvard Medical School; Microbiologist, Brigham and Women's Hospital, Boston [114]

Ronald E. Polk, PharmD
Chair, Department of Pharmacy, Professor of Pharmacy and Medicine, School of Pharmacy, Virginia Commonwealth University, Richmond [127]

Richard J. Pollack, MD
Research Associate in Immunology and Infectious Diseases, Harvard School of Public Health, Boston [392]

Reuven Porat, MD
Professor of Medicine; Director, Internal Medicine, Tel Aviv Sourasky Medical Center, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv [17]

Daniel A. Portnoy, PhD
Professor of Biochemistry and Molecular Biology, Department of Molecular and Cell Biology, University of California, Berkeley [132]

John T. Potts, Jr., MD
Jackson Distinguished Professor of Clinical Medicine, Harvard Medical School; Director of Research and Physician-in-Chief Emeritus, Massachusetts General Hospital, Charlestown [347]

Lawrie W. Powell, MD, PhD
Professor of Medicine, The University of Queensland and The Royal Brisbane and Women's Hospital, Brisbane, Queensland, Australia [351]

Alvin C. Powers, MD
Joe C. Davis Chair in Biomedical Science; Professor of Medicine, Molecular Physiology and Biophysics; Director, Vanderbilt Diabetes Research and Training Center; Director, Vanderbilt Diabetes Center, Nashville [338]

Daniel S. Pratt, MD
Assistant Professor of Medicine, Harvard Medical School; Director, Liver-Billary-Pancreas Center, Massachusetts General Hospital, Boston [43, 296]

Darwin J. Prockop, MD, PhD
Director of Center for Gene Therapy and Professor of Biochemistry, Tulane Health Sciences Center, New Orleans [357]

Stanley B. Prusiner, MD
Director, Institute for Neurodegenerative Diseases; Professor, Department of Neurology; Professor, Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco [378]

Daniel J. Rader, MD
Cooper-McClure Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia [350]

Roshini Rajapaksa, MD, BA
Assistant Professor, Department of Medicine, Gastroenterology, New York University Medical Center School of Medicine and Hospitals Center, New York [44]

Sanjay Ram, MD
Assistant Professor of Medicine, Division of Infectious Diseases and Immunology, University of Massachusetts Medical School, Worcester [137]

Jose A. F. Ramires
Head Professor of Cardiology; University of São Paulo Medical School and Heart Institute-INCOR, São Paulo, Brazil [e37]

Reuben Ramphal, MD
Professor, Division of Infectious Diseases, Department of Medicine, University of Florida College of Medicine, Gainesville [145]

Neil H. Raskin, MD
Professor of Neurology, University of California, San Francisco, San Francisco [15]

Mario C. Raviglione, MD
Director, StopTB Department, World Health Organization, Geneva [158]

K. Srinath Reddy, MD, DM, MSC
Department of Cardiology, All India Institute of Medical Sciences, Ansari Nagar, New Delhi, India [e38]

Sharon L. Reed, MD
Professor of Pathology and Medicine; Director, Microbiology and Virology Laboratories, University of California, San Diego Medical Center, San Diego [202, e16]

Richard C. Reichman, MD
Professor of Medicine and of Microbiology and Immunology; Director, Infectious Diseases Division, University of Rochester School of Medicine, Rochester [178]

Carol M. Reife, MD
Clinical Associate Professor of Medicine, Jefferson Medical College, Philadelphia [41]

John J. Reilly, Jr., MD
Associate Professor of Medicine, Harvard Medical School; Vice Chairman, Integrative Services, Department of Medicine, Brigham and Women's Hospital, Boston [254, e24]

John T. Repke, MD
University Professor and Chairman, Department of Obstetrics and Gynecology, Penn State University College of Medicine; Obstetrician-Gynecologist-In-Chief, The Milton S. Hershey Medical Center, Hershey [7]

Victor I. Reus, MD
Professor, Department of Psychiatry, University of California, San Francisco School of Medicine; Attending Physician, Langley Porter Hospital and Clinics, San Francisco [386]

Peter A. Rice, MD
Professor of Medicine, Division of Infectious Diseases and Immunology, University of Massachusetts Medical School, Worcester [137]

Stuart Rich, MD
Professor of Medicine, Section of Cardiology, University of Chicago, Chicago [244]

Gary S. Richardson, MD
Assistant Professor of Psychiatry, Case Western Reserve University, Cleveland; Senior Research Scientist, Sleep Disorders and Research Center, Henry Ford Hospital, Detroit [28]

Elizabeth Robbins, MD
Associate Clinical Professor, University of California, San Francisco, San Francisco [e32]

Gary L. Robertson, MD
Emeritus Professor of Medicine, Northwestern University Feinberg School of Medicine, Chicago [334]

Daniel M. Roden, MD
Professor of Medicine and Pharmacology, Assistant Vice-Chancellor for Personalized Medicine, Vanderbilt University, Nashville [5]

James A. Romano, Jr., PhD, DABT
Senior Principal Life Specialist, Science Applications International Corporation, Frederick [215]

Karen L. Roos, MD
John and Nancy Nelson Professor of Neurology, Indiana University School of Medicine, Indianapolis [376]

Allan H. Ropper, MD
Executive Vice-Chair, Department of Neurology, Brigham and Women's Hospital, Harvard Medical School, Boston [268, 372, 373]

Ilene M. Rosen, MD, MSc
Associate Director, Internal Medical Residency Program; Assistant Professor of Clinical Medicine, University of Pennsylvania School of Medicine, Philadelphia [246]

Roger N. Rosenberg, MD
Zale Distinguished Chair and Professor of Neurology, Department of Neurology, University of Texas Southwestern Medical Center, Dallas [368]

F. R. Rosendaal, MD
Professor of Clinical Epidemiology; Chairman, Department of Clinical Epidemiology, and Department of Thrombosis and Hemostasis, Leiden University Medical Center, The Netherlands [111]

Myrna R. Rosenfeld, MD, PhD
Associate Professor of Neurology, Division Neuro-Oncology, Department of Neurology, University of Pennsylvania, Philadelphia [97]

Jean-Claude Roujeau, MD
Professor of Dermatology, Hôpital Henri Mondor, Université Paris XII, Créteil, France [56]

Ambuj Roy, MD, DM
Department of Cardiology, All India Institute of Medical Sciences, Ansari Nagar, New Delhi, India [e38]

Michael A. Rubin, MD, PhD
Assistant Professor of Medicine, Division of Epidemiology and Infectious Diseases, Department of Internal Medicine, University of Utah School of Medicine, Salt Lake City [31]

Robert M. Russell, MD
Director, Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University; Professor of Medicine and Nutrition, Tufts University, Boston [71]

Thomas A. Russo, MD, CM
Professor of Medicine and Microbiology, State University of New York, Buffalo [143, 156]

Miguel Sabria, MD, PhD
Professor of Medicine, Autonomous University of Barcelona; Chief, Infectious Diseases Section, Germans Trias i Pujol Hospital, Barcelona, Spain [141]

Stephen M. Sagar, MD
Professor of Neurology, Case Western Reserve School of Medicine; Director of Neuro-Oncology, Ireland Cancer Center, University Hospitals of Cleveland, Cleveland [374]

David J. Salant, MD
Professor of Medicine, Pathology, and Laboratory Medicine, Boston University School of Medicine; Chief, Section of Nephrology, Boston Medical Center, Boston [278]

Martin A. Samuels, MD, DSc (Hon)
Chairman, Department of Neurology, Brigham and Women's Hospital; Professor of Neurology, Harvard Medical Center, Boston [e33]

Merle A. Sande,† MD
Professor of Medicine, University of Washington School of Medicine; President, Academic Alliance Foundation, Seattle [31]

Philippe Sansonetti
Professeur à l'Institut Pasteur, Paris, France [147]

Edward A. Sausville, MD, PhD
Professor of Medicine; Associate Director for Clinical Research, Marlene & Stewart Greenebaum Cancer Center, University of Maryland, Baltimore [81]

†Deceased.

Mohamed H. Sayegh, MD
Director, Warren E. Grupe and John P. Morill Chair in Transplantation Medicine; Professor of Medicine and Pediatrics, Harvard Medical School, Boston [276]

David T. Scadden, MD
Gerald and Darlene Jordan Professor of Medicine, Harvard University; Co-Chair, Department of Stem Cell and Regenerative Biology, Harvard University, Boston [68]

Howard I. Scher, MD
Professor of Medicine, Weill Medical College of Cornell University; D. Wayne Calloway Chair in Urologic Oncology; Chief, Genitourinary Oncology Service, Memorial Sloan-Kettering Cancer Center, New York [90, 91]

Joan H. Schiller, MD
Professor of Medicine and Hematology/Oncology, University of Texas Southwestern Medical School; Simmons Comprehensive Cancer Center, Dallas [85]

Harry W. Schroeder, Jr., MD, PhD
Professor of Medicine, Microbiology, and Genetics, The University of Alabama, Birmingham [310, e27]

Marc A. Schuckit, MD
Distinguished Professor of Psychiatry, School of Medicine, University of California, San Diego; Director, Alcohol Research Center, VA San Diego Healthcare System, San Diego [387, 388]

H. Ralph Schumacher, MD
Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia [327]

Gordon E. Schutze, MD
Professor of Pediatrics and Pathology, University of Arkansas for Medical Sciences, College of Medicine; Chief, Pediatric Infectious Diseases, Arkansas Children's Hospital, Little Rock [151]

Stuart Schwartz, PhD
Professor of Human Genetics, Medicine and Pathology, University of Chicago, Chicago [63]

Richard M. Schwartzstein, MD
Professor of Medicine, Harvard Medical School; Associate Chair, Pulmonary and Critical Care Medicine; Vice-President for Education, Beth Israel Deaconess Medical Center, Boston [33]

Julian L. Seifter, MD
Physician, Brigham and Women's Hospital; Associate Professor of Medicine, Harvard Medical School, Boston [283]

David C. Seldin, MD, PhD
Professor of Medicine and Microbiology; Director, Amyloid Treatment and Research Program Section of Hematology-Oncology, Department of Medicine, Boston University School of Medicine and Boston Medical Center, Boston [324]

Andrew P. Selwyn, MA, MD
Professor of Medicine, Harvard Medical School, Boston [237]

Steven D. Shapiro, MD
Jack D. Myers Professor and Chair, University of Pittsburgh, Pittsburgh [254, 262]

William Silen, MD
Johnson and Johnson Distinguished Professor of Surgery, Emeritus, Harvard Medical School, Boston [14, 293, 294]

Rebecca A. Silliman, MD, PhD
Professor of Medicine and Epidemiology, Boston University Schools of Medicine and Public Health; Chief, Section of Geriatrics, Boston University Medical Center, Boston [9]

Edwin K. Silverman, MD, PhD
Associate Professor of Medicine, Harvard Medical School, Brigham and Women's Hospital, Boston [254]

Gary G. Singer, MD
Assistant Professor of Clinical Medicine, Washington University School of Medicine, St. Louis [46]

Martha Skinner, MD
Professor of Medicine, Boston University School of Medicine; Director, Special Projects, Amyloid Treatment and Research Program, Boston [324]

Karl Skorecki, MD
Annie Chutick Professor in Medicine (Nephrology); Director, Rappaport Research Institute, Director of Medical and Research Development, Rambam Medical Health Care Campus, Haifa, Israel [274, e39]

Wade S. Smith, MD, PhD
Professor of Neurology, Daryl R. Gress Endowed Chair of Neurocritical Care and Stroke; Director, University of California, San Francisco Neurovascular Service, San Francisco [269, 364]

A. George Smulian, MB, BCh
Associate Professor, University of Cincinnati College of Medicine; Chief, Infectious Disease Section, Cincinnati VA Medical Center, Cincinnati [200]

Arthur J. Sober, MD
Professor, Department of Dermatology, Harvard Medical School; Associate Chief, Department of Dermatology, Massachusetts General Hospital, Boston [83]

Kelly A. Soderberg, PhD, MPH
Director, Program Management, Duke Human Vaccine Institute, Duke University School of Medicine, Durham [308]

Michael F. Sorrell, MD
Robert L. Grissom Professor of Medicine, University of Nebraska Medical Center, Omaha [301]

David H. Spach, MD
Professor of Medicine, Division of Infectious Diseases, University of Washington, Seattle [153]

Peter Speelman, MD, PhD
Professor of Medicine and Infectious Diseases; Head, Division of Infectious Diseases, Tropical Medicine and AIDS; Department of Internal Medicine, Academic Medical Center, University of Amsterdam, The Netherlands [164]

Frank E. Speizer, MD
Edward H. Kass Professor of Medicine, Harvard Medical School, Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, Boston [250]

Jerry L. Spivak, MD
Professor of Medicine, The Johns Hopkins University School of Medicine; Attending Physician, Johns Hopkins Hospital, Baltimore [103]

Andrei C. Sposito
Professor of Medicine, University of Basilia Medical School, Basilia, Brazil [e37]

Walter E. Stamm, MD
Professor of Medicine; Head, Division of Allergy and Infectious Diseases, University of Washington School of Medicine, Seattle [169, 282]

Allen C. Steere, MD
Professor of Medicine, Harvard Medical School, Boston [166]

Robert S. Stern, MD
Dermatologist-in-Chief; Carl J. Herzog Professor of Medicine, Harvard Medical School, Boston [56]

Dennis L. Stevens, MD, PhD
Chief, Infectious Diseases Section, Veteran Affairs Medical Center, Boise; Professor of Medicine, University of Washington School of Medicine, Seattle [119]

Stephen E. Straus,† MD
Senior Investigator, Laboratory of Clinical Investigation, National Institute of Allergy and Infectious Diseases; Director, National Center for Complementary and Alternative Medicine, National Institutes of Health, Bethesda [10, 384]

Lewis Sudarsky, MD
Associate Professor of Neurology, Harvard Medical School; Director of Movement Disorders, Brigham and Women's Hospital, Boston [24]

Alan M. Sugar, MD
Professor of Medicine, Boston University School of Medicine; Medical Director, Infectious Diseases Clinical Services, HIV/AIDS Program, and Infection Control, Cape Cod Healthcare, Hyannis [198]

Donna C. Sullivan, PhD
Associate Professor of Medicine and Microbiology, Division of Infectious Diseases, Department of Medicine, University of Mississippi School of Medicine, Jackson [194, 199]

†Deceased.

Paolo M. Suter, MD, MS
Professor of Medicine, Medical Policlinic, Zurich, Switzerland [71]

Morton N. Swartz, MD
Professor of Medicine, Harvard Medical School; Chief, Jackson Firm Medical Service and Infectious Disease Unit, Massachusetts General Hospital, Boston [377]

A. Jamil Tajik, MD
Thomas J. Watson, Jr., Professor; Professor of Medicine and Pediatrics; Chairman (Emeritus), Zayed Cardiovascular Center, Mayo Clinic, Rochester, Minnesota; Consultant, Cardiovascular Division, Mayo Clinic, Scottsdale [222, e20]

Joel D. Taurog, MD
Professor of Internal Medicine, William M. and Gatha Burnett Professor for Arthritis Research, University of Texas Southwestern Medical Center, Dallas [318]

Stephen F. Templeton, MD
Clinical Assistant Professor of Dermatology, Emory University School of Medicine, Atlanta [e10]

Gregory Tino, MD
Associate Professor of Medicine, University of Pennsylvania School of Medicine; Chief, Pulmonary Clinical Service Hospital of the University of Pennsylvania, Philadelphia [252]

Zelig A. Tochner, MD
Associate Professor of Radiation Oncology; Clinical Director, Proton Therapy Project, University of Pennsylvania, Philadelphia [216]

Gordon F. Tomaselli, MD
David J. Carver Professor of Medicine, Vice Chairman, Department of Medicine for Research, The Johns Hopkins University, Baltimore [224, 225]

Mark Topazian, MD
Associate Professor of Medicine, Mayo College of Medicine, Rochester [285, e25]

Phillip P. Toskes, MD
Professor of Medicine, Division of Gastroenterology, Hepatology and Nutrition, University of Florida College of Medicine, Gainesville [306, 307]

Jeffrey M. Trent, PhD
President and Scientific Director, Translational Genomics Research Institute, Phoenix [79]

Elbert P. Trulock, MD
Professor of Medicine, Rosemary and I. Jerome Flance Professor of Pulmonary Medicine, Washington University School of Medicine, St. Louis [260]

Hensin Tsao, MD
Assistant Professor of Dermatology, Harvard Medical School; Clinical Director, Melanoma Genetics Program, Massachusetts General Hospital, Boston [83]

Kenneth L. Tyler, MD
Reuler-Lewin Family Professor of Neurology and Professor of Medicine and Microbiology, University of Colorado Health Sciences Center; Chief, Neurology Service, Denver Veterans Affairs Medical Center, Denver [376]

Joseph P. Vacanti, MD
John Homan Professor of Surgery, Harvard Medical School; Surgeon-in-Chief, Massachusetts General Hospital for Children, Boston [69]

Edouard Vannier, PhD
Assistant Professor, Department of Medicine, Division of Infectious Diseases, Tufts–New England Medical Center and Tufts University School of Medicine, Boston [204]

Gauri R. Varadhachary, MD
Associate Professor, Department of Gastrointestinal Medical Oncology, University of Texas MD Anderson Cancer Center, Houston [95]

John Varga, MD
Hughes Professor of Medicine, Northwestern University Feinberg School of Medicine, Chicago [316]

Bert Vogelstein, MD
Director, Ludwig Center for Cancer Genetics & Therapeutics; Investigator, Howard Hughes Medical Institute; Clayton Professor for Oncology & Pathology, Baltimore [79]

Everett E. Vokes, MD
Director, Section of Hematology/Oncology; Vice Chairman for Clinical Research, Department of Medicine; Deputy Director, Cancer Research Center; John E. Ultmann Professor of Medicine and Radiation and Cellular Oncology, Chicago [84]

Tamara J. Vokes, MD
Associate Professor, Section of Endocrinology, University of Chicago, Chicago [349]

C. Fordham von Reyn, MD
Professor of Medicine (Infectious Disease) and International Health; Director, DARDAR International Programs, Dartmouth Medical School, Lebanon [160]

Matthew K. Waldor, MD, PhD
Professor of Medicine (Microbiology and Molecular Genetics), Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston [149]

David H. Walker, MD
The Carnage and Martha Walls Distinguished University Chair in Tropical Diseases; Professor and Chairman, Department of Pathology; Executive Director, Center for Biodefense and Emerging Infectious Disease, University of Texas Medical Branch, Galveston [167]

Richard J. Wallace, Jr., MD
Chairman, Department of Microbiology, University of Texas Health Center at Tyler, Tyler [161]

B. Timothy Walsh, MD
Professor of Psychiatry, College of Physicians & Surgeons, Columbia University; Director, Eating Disorders Research Unit, New York Psychiatric Institute, New York [76]

Peter D. Walzer, MD, MSc
Associate Chief of Staff for Research, Cincinnati VA Medical Center; Professor of Medicine, University of Cincinnati College of Medicine, Cincinnati [200]

Fred Wang, MD
Professor of Medicine, Harvard Medical School, Boston [170, 176]

Carl V. Washington, Jr., MD
Associate Professor of Dermatology, Emory University School of Medicine; Co-Director, Dermatologic Surgery Unit, The Emory Clinic, Atlanta [83]

Anthony P. Weetman, MD, DSc
Professor of Medicine and Dean of the School of Medicine and Biomedical Sciences, University of Sheffield, Sheffield, United Kingdom [335]

Steven E. Weinberger, MD
Senior Vice President for Medical Education Division, American College of Physicians; Senior Lecturer on Medicine, Harvard Medical School; Adjunct Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia [34, 245–247, 252]

Robert A. Weinstein, MD
Professor of Medicine, Rush University Medical Center; Chairman, Infectious Diseases, Cook County Hospital; Chief Operating Officer, CORE Center, Chicago [125]

Jeffrey I. Weitz, MD
Professor of Medicine and Biochemistry, McMaster University; Director, Henderson Research Centre, Heart and Stroke Foundation/J. Fraser Mustard Chair in Cardiovascular Research; Canada Research Chair (Tier1) in Thrombosis; Career Investigator, Heart and Stroke Foundation of Canada [112]

Peter F. Weller, MD
Professor of Medicine, Harvard Medical School; Co-Chief, Infectious Diseases Division; Chief, Allergy and Inflammation Division; Vice-Chair for Research, Department of Medicine, Beth Israel Deaconess Medical Center, Boston [208–211, 213]

Michael R. Wessels, MD
Professor of Pediatrics and Medicine (Microbiology and Molecular Genetics), Harvard Medical School; Chief, Division of Infectious Diseases, Children's Hospital, Boston [130]

Lee M. Wetzler, MD
Professor of Medicine, Associate Professor of Microbiology, Boston University School of Medicine, Boston [136]

Meir Wetzler, MD
Professor of Medicine, Roswell Park Cancer Institute, Buffalo [104]

L. Joseph Wheat, MD
President and Director, MiraVista Diagnostics and MiraBella Technology, Indianapolis [192]

A. Clinton White, Jr., MD
The Paul R. Stalnaker, MD, Distinguished Professor of Internal Medicine; Director, Infectious Disease Division, Department of Internal Medicine, University of Texas Medical Branch, Galveston [213]

Nicholas J. White, DSc
Professor of Tropical Medicine, Oxford University, United Kingdom; Mahidol University, Bangkok, Thailand [203, e18]

Richard J. Whitley, MD
Loeb Scholar in Pediatrics, Professor of Pediatrics, Microbiology, Medicine, and Neurosurgery, University of Alabama, Birmingham [173]

Gordon H. Williams, MD
Professor of Medicine, Harvard Medical School; Chief, Cardiovascular Endocrinology Section, Brigham and Women's Hospital, Boston [336]

John W. Winkleman, MD, PhD
Assistant Professor of Psychiatry, Harvard Medical School; Medical Director, Sleep Health Center, Brigham and Women's Hospital, Boston [28]

Bruce U. Wintroub, MD
Professor and Chair of Dermatology, Department of Dermatology; Vice Dean, School of Medicine Dean's Office, University of California, San Francisco, San Francisco [56]

Allan W. Wolkoff, MD
Professor of Medicine and Anatomy and Structural Biology; Director, Belfer Institute for Advanced Biomedical Studies; Associate Chair of Medicine for Research; Chief, Division of Hepatology, Albert Einstein College of Medicine, Bronx [297]

Louis Michel Wong-Kee-Song, MD
Assistant Professor of Medicine, Division of Gastroenterology and Hepatology, Mayo College of Medicine, Rochester [285, e25]

Robert L. Wortmann, MD
Dartmouth-Hitchcock Medical Center, Lebanon [353]

Richard Wunderink, MD
Professor, Division of Pulmonary and Critical Care, Department of Medicine, Northwestern University Feinberg School of Medicine; Director, Medical Intensive Care Unit, Northwestern Memorial Hospital, Chicago [251]

Joshua Wynne, MD, MBA, MPH
Executive Associate Dean, Professor of Medicine, University of North Dakota School of Medicine and Health Sciences, Grand Forks [231]

Kim B. Yancey, MD
Professor and Chair, Department of Dermatology, University of Texas, Southwestern, Dallas [52, 55]

Janet A. Yellowitz, DMD, MPH
Associate Professor; Director, Geriatric Dentistry, Baltimore [e7]

Neal S. Young, MD
Chief, Hematology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda [102]

Robert C. Young, MD
Chancellor, Fox Chase Cancer Center, Philadelphia [93]

Alan S. L. Yu, MB, BChir
Associate Professor of Medicine, Physiology and Biophysics, University of Southern California Keck School of Medicine, Los Angeles [279]

Victor L. Yu, MD
Professor of Medicine, University of Pittsburgh, Pittsburgh [141]

The first edition of *Harrison's Principles of Internal Medicine* was published almost 60 years ago. Over the decades, the field of internal medicine has evolved greatly and has incorporated the spectacular advances that have occurred in the science of medicine into its armamentarium of diagnosis, prevention, and treatment. This textbook has evolved simultaneously to keep step with these advances while at the same time maintaining an appreciation of the art of medicine and the principles underlying the optimal care of the patient. In shaping and revising this latest edition, the Editors have committed themselves to making the textbook an invaluable resource for students and practitioners coping with the demands of modern medicine.

From the standpoint of physical appearance, one of the most striking elements of the textbook is the number of new and updated figures. The seventeenth edition features 300 additional illustrations (20% more than the previous edition); with the new illustrations included on the enclosed DVD, this edition has approximately 800 more images, a 60% increase in the course of just one edition. Many images have been redrawn by graphic artists working closely with the authors and editors to illustrate complex concepts, pathways, and algorithms in a clear and compelling manner. The seventeenth edition also features many additional plain film, CT, MRI, and ultrasound images, in recognition of the increased use of radiologic diagnosis in general medical practice. The notably increased use of pathologic and clinical photographs completes our concerted approach to a more robustly illustrated edition of *Harrison's*.

The seventeenth edition of *Harrison's* has a full-color format that draws from and extends the excellent appearance of the sixteenth edition to make the content more accessible and pleasant to read. The placement of color illustrations within the chapters rather than in the separate atlas was very favorably received by our sixteenth edition readers and has been continued in the current edition. Many changes to the design of this edition have been made in order to speed the reader's navigation through the textual and visual materials. For example, tables have been shaded for ease of reading, citations in tables and illustrations are now more instantly notable and in color, and our Treatment sections in each chapter have been redesigned to allow even faster access. The new global icons call greater attention to key epidemiologic and clinical differences in the practice of medicine throughout the world.

Evolving information technology enables us to broaden and deepen the nature, format, and medium of content included under the *Harrison's* name. Purchase of this textbook now includes a DVD, which has allowed the editors to expand the content in *Harrison's* by the use of "e-chapters," 39 in number. In addition to new chapters in traditional narrative format, the DVD includes a number of diagnostic and procedural atlases, which readers should find enormously helpful. The DVD also includes dozens of motion video clips of endoscopic and cardiac imaging. These diagnostic approaches have become central to the practice of medicine, and the video clips show crystal-clear depictions of abnormal anatomy, function, and results.

Globalization of economies and trade has had an enormous impact on nations throughout the world, both developing and developed. This phenomenon has underscored the reality of the globalization of medicine. In this regard, as this textbook is widely used by students and practitioners throughout the world and as we in the United States are more frequently confronted with issues related to global health, a special emphasis has been placed in this edition on global health in individual chapters together with an over-arching view presented by Dr. Kim and Dr. Farmer in a new chapter entitled "Global Issues in Medicine." We have highlighted, where appropriate, regional differences in the prevalence, approach, and treatment of diseases that need to be considered for delivery of the highest-quality medical care possible in various geographic settings. These are only highlights of the changes that the Editors hope will make the new *Harrison's* a helpful tool, not only for the student who needs an expert source of basic knowledge in internal medicine, but also for the pressured practitioner who needs a clear, concise, and balanced distillation of the best information on which to base daily clinical decisions.

The seventeenth edition has been enriched by the addition of a new editor, Joseph Loscalzo, MD, PhD, who joined with our most senior editor Eugene Braunwald, MD, in contributing to and/or editing of chapters in the Parts on Disorders of the Cardiovascular System, Disorders of the Respiratory System, and Disorders of the Kidney and Urinary Tract. The addition of Dr. Loscalzo provides a smooth editorial transition in preparation for the upcoming retirement from *Harrison's* of Dr. Braunwald who has served as an esteemed editor for 12 editions.

Part 1, "Introduction to Clinical Medicine," contains a new chapter that lays the framework for appreciating the global issues in medicine and the variations in disease incidence and patterns throughout the world. It sets the stage for the discussion in individual chapters of global issues related to specific diseases, a novel feature in this edition. In addition, there are e-chapters on quality and safety issues in patient care, economics of health care delivery, ethics in clinical medicine, and health care disparities. The last chapter addresses the evidence for racial and ethnic disparities in health care in the United States and globally and offers a variety of approaches for minimizing them.

Part 2, "Cardinal Manifestations and Presentation of Diseases," serves as a comprehensive introduction to clinical medicine as well as a practical guide to the care of patients with these manifestations. Each section focuses on a particular group of disorders, examining the concepts of pathophysiology and differential diagnosis that must be considered in caring for patients with these common clinical presentations. Major symptoms are reviewed and correlated with specific disease states, and clinical approaches to patients presenting with these symptoms are summarized. There are eleven new chapters in this Part. Every chapter that appeared in the sixteenth edition has been updated, and two chapters have new authors. Among the e-chapters are atlases of rashes associated with fever; oral manifestations of disease; renal biopsies and urinary sediments; skin manifestations of internal disease; and peripheral blood and bone marrow. A new chapter on Hypercalcemia and Hypocalcemia provides a succinct overview of the causes, clinical presentations, and management of these conditions as a complement to the more extensive discussion of these topics in Part 15, "Endocrinology and Metabolism." New chapters discuss common clinical presentations such as menstrual disorders and pelvic pain, the pathogenesis and treatment of headache, the clinical approach to imbalance, and the causes of confusion and delirium.

Part 3, "Genetics and Disease," has been extensively updated, reflecting the remarkable impact of the human genome project and its implications for clinical medicine. The material included in this edition is strongly geared toward clinical practice, in which genetic information increasingly comes into play. A new chapter on gene transfer in clinical medicine addresses the principles and strategies for this novel, but still experimental, therapeutic area.

Part 4, "Regenerative Medicine," is a new part initiated for this edition. It contains chapters on Stem Cell Biology, Applications of Stem Cell Biology in Clinical Medicine, Hematopoietic Stem Cells, and Tissue Engineering. These chapters summarize the state of the science in these emerging fields and outline the future directions for clinical applications of stem cell biology in regenerative medicine.

Part 5, "Nutrition," covers topics critical to clinical medicine, whether dealing with undernutrition in the context of chronic starvation or acute illness or the implications of overfeeding in industrialized nations. New authors with global expertise in nutrition have prepared the chapters on protein-energy malnutrition and enteral and parenteral nutrition therapy. A new chapter on the Management of Obesity and a complementary chapter on the Biology of Obesity address the explosion of new knowledge about pathways that regulate body weight and composition and the urgent need to provide effective means to prevent and treat the global epidemic of obesity and its complications.

Copyright © 2008, 2005, 2001, 1998, 1994, 1991, 1987, 1983, 1980, 1977, 1974, 1970,1966, 1962, 1958 by The McGraw-Hill Companies, Inc. Click here for terms of use.

The core of *Harrison's* continues to encompass the disorders of the organ systems and is contained in Parts 6 through 17. These sections include succinct accounts of the pathophysiology of diseases involving the major organ systems as well as infectious diseases, with an emphasis on clinical manifestations, diagnostic procedures, differential diagnosis, and treatment strategies and guidelines.

Part 6, "Oncology and Hematology," includes 11 chapters by new authors, including a completely revised section on Disorders of Hemostasis. A new e-chapter on Thymoma has also been added. As novel therapies are being added at a record pace to the armamentarium for oncologic and hematologic disorders, the mechanisms of action, pharmacology, clinical uses, and toxicities of these new agents have been included. Recent progress in the treatment of renal cell cancer, colorectal cancer, and breast cancer is highlighted. Revised chapters include the impact of genetic factors on cancer development and the use of gene expression data to define prognostic disease subsets.

Part 7, "Infectious Diseases," presents an overview of the latest information on disease epidemiology, pathogenesis, and genetics while focusing on the needs of clinicians who must accurately diagnose and treat infections under time pressure and cost constraints. Abundant illustrations offer key information in an easily accessible format to assist clinicians with these challenges. The expert authors of each chapter make specific recommendations regarding therapeutic regimens, including the drug(s) of choice, doses, durations, and alternatives. Current trends in antimicrobial resistance are discussed fully in light of their impact on therapeutic choices. In line with the international emphasis of this edition, the infectious diseases section includes expanded information on disease prevalences, distributions, features, and management in different regions of the world.

A total of 17 chapters have been completely rewritten by new authors, covering the latest advances in the management of important diseases such as pneumonia, shigellosis, and rabies and of infections due to *Pseudomonas*, *Bartonella*, *Listeria*, corynebacteria, and parvovirus. The section on fungal infections is entirely new and encompasses the expertise of current authorities on specific mycoses. Health care–associated infections, an area of enormous significance in terms of patient care in general and antimicrobial resistance in particular, are addressed by Robert Weinstein in a thorough, highly practical chapter. Another topic of ever-increasing importance—infections with gram-negative enteric bacilli, including *Escherichia coli*—is dealt with by Thomas Russo and James Johnson in a substantially reworked and updated chapter. The superb chapter on human papillomaviruses by Richard Reichman includes the latest information and recommendations regarding the recently licensed and widely publicized HPV vaccine. Finally, the chapter on HIV infection and AIDS by Anthony S. Fauci and H. Clifford Lane has once again been completely revised, with an emphasis on therapeutic strategies. This chapter is widely considered to be a classic in the field; its clinically pragmatic focus in combination with its comprehensive and analytical approach to the pathogenesis of HIV disease has led to its use as the sole complete reference on HIV/AIDS in medical schools.

New in this edition is a chapter on babesiosis, an important emerging infection that can cause severe disease in immunodeficient and elderly patients. Three additional new chapters of substantial clinical relevance appear in the electronic version of the textbook: an atlas of rashes associated with fever, an atlas of blood smears showing the various stages of the parasites causing malaria and babesiosis, and a chapter detailing the pharmacology of antiparasitic agents.

Terrorist attacks in various forms have become a frightening reality throughout the world. Important among these is the threat of bioterror attacks involving microbes or their toxins, chemicals, and radiation. This has become of particular concern in light of the anthrax attacks in the United States shortly after the September 11, 2001, airplane attacks on the World Trade Center in New York City and the Pentagon in Washington, DC. In the sixteenth edition, the editors developed a new Part on Bioterrorism and Clinical Medicine. Part 8 in the current edition has been updated with descriptions of the most recent countermeasures that have been developed as part of the United States preparedness plan against bioterror attacks. Edited by *Harrison's* Anthony S. Fauci, these chapters are written succinctly and include easily readable charts, tables, and algorithms; their goal is to confer an understanding of the pathogenesis, diagnosis, treatment, and prognosis of the diseases in question.

Part 9, "Disorders of the Cardiovascular System," is now co-edited by two of the most preeminent experts in the field, Eugene Braunwald and Joseph Loscalzo, the newest addition to the team of *Harrison* editors. There are new chapters on the epidemiology of cardiovascular disease with an overview of the global nature of the growing pandemic, the basic biology of the cardiovascular system (written by Braunwald, Libby, and Loscalzo), and principles of electrophysiology. A new chapter on the metabolic syndrome summarizes the clinical features and complications of this disorder, which reflects the rapidly rising prevalence of obesity and insulin resistance. In addition, there are new e-chapters that provide atlases of basic electrocardiography, arrhythmias, noninvasive imaging, and percutaneous revascularization. Finally, every chapter has been revised to reflect the latest information on approaches to the diagnosis and treatment of specific cardiovascular diseases, and eight of these chapters have been written by new authors.

Part 10, "Disorders of the Respiratory System," includes a new e-chapter on chest imaging that provides an atlas of chest radiographs and computed tomographic studies of a wide range of chest diseases. In addition, three chapters have been written by new authors, including a superb chapter on asthma by Peter Barnes and an excellent chapter on pneumonia by Lionel Mandell.

With advances in health care delivery and pressures aimed at cost containment, critical care units account for a growing percentage of hospital beds. Part 11, "Critical Care Medicine," was first introduced as a separate Part for the sixteenth edition of *Harrison's*. It is devoted to the provision of optimal care in this medical setting of growing importance and deals with four main areas: respiratory critical care, shock and cardiac arrest, neurologic critical care, and a new section on oncologic emergencies.

Part 12, "Disorders of the Kidney and Urinary Tract," has undergone extensive revision and reorganization under the guidance of new editor Joseph Loscalzo. There is an outstanding new chapter on the cellular and molecular biology of the kidney by Eric Neilson, as well as a new e-chapter atlas of urinary sediments and renal pathology. In addition to a thorough updating of each revised chapter, five have new authors who bring a unique, contemporary perspective to their subject.

Part 13, "Disorders of the Gastrointestinal System," includes two new atlases of endoscopic findings, both static photographs and movies. New chapters have been added on mesenteric vascular insufficiency and common disorders of the colon and ano-rectum, and new authors have written two other chapters. The chapter on Cirrhosis and Its Complications has been completely rewritten by a new author, Bruce Bacon, who is also the new author for the chapter on Infiltrative, Genetic, and Metabolic Diseases Affecting the Liver. An Atlas of Liver Biopsies has been added as a new e-chapter.

Part 14, "Disorders of the Immune System, Connective Tissue, and Joints," has been extensively revised. The chapter on Introduction to the Immune System has been thoroughly updated. It has become a classic in its field and is often used as the textbook of immunology in postgraduate and medical school courses. This chapter combines an in-depth description and analysis of the principles of basic immunology with an easy flow into the application of these principles to clinical disease states. Its description of the relationship of innate to adaptive immunity is a model for understanding the intricacies of the human immune system. A new e-chapter written by Max Cooper on Primary Immunodeficiencies Associated with or Secondary to Other Diseases has been added to complement his printed book chapter on Primary Immunodeficiencies. The chapter on Systemic Sclerosis (Scleroderma) and Related Disorders has been rewritten by a new author. An Atlas of Clinical Imaging in the Vasculitis Syndromes has been added as a new e-chapter. The chapters on Sarcoidosis, Amyloidosis, Osteoarthritis, and Gout and Other Crystal Arthropathies have been rewritten by new authors. A highly skilled, academic, and clinical rheumatologist (Carol Langford) has joined the

team as an author and has co-authored the chapters on the Vasculitis Syndromes, Relapsing Polychondritis, Fibromyalgia, and Arthritis Associated with Systemic Disease and Other Arthritides.

Part 15, "Endocrinology and Metabolism," includes several new authors, including those for the chapter on pheochromocytoma, which highlights recent advances in the genetic causes of these catecholamine-secreting tumors, as well as updated strategies for diagnosis and management. The chapter on the Ovary has a new author who integrates traditional hypothalamic-pituitary regulation of the menstrual cycle with the identification of multiple ovarian growth factors that regulate follicle development. Identification of these pathways has provided insight into the causes of premature ovarian failure and infertility. There have been rapid changes in the clinical management of many endocrine diseases, especially diabetes, lipoprotein disorders, and the menopause. These and other chapters have been updated extensively. A new Atlas of Metabolic Disorders has been added as an e-chapter.

Part 16, "Neurologic Disorders," has been extensively rewritten to highlight the many advances that have taken place in the understanding, diagnosis, treatment, and prevention of neurologic and psychiatric diseases. Notable are new chapters on essential tremor and movement disorders, peripheral neuropathy, and neurologic problems in hospitalized patients. Many illustrative neuroimaging figures appear throughout the section, and a new atlas of neuroimaging findings has been added. Knowledge of the dementias, Parkinson's disease, and related neurodegenerative disorders has been transformed by new findings from genetics, modular imaging, cell biology, and clinical research. The very latest information has been included, providing a practical guide to diagnosis and appropriate use of the latest treatments. New therapies are also revolutionizing the care of patients with stroke and multiple sclerosis, and these are also discussed in an evidence-based fashion that will be useful to all practitioners and not only to specialists. Another new chapter, authored by Stephen Hyman and Eric Kandel, reviews progress in deciphering the pathogenesis of common psychiatric disorders and discusses the remaining challenges to development of more effective treatments.

Part 17, "Poisoning, Drug Overdose, and Envenomation," focuses on topics most relevant to internal medicine.

Part 18 is a new feature to *Harrison's* and represents four brand new e-chapters from our International Advisory Editors. Dr. Peter Barnes addresses the emerging use of pulmonary biomarkers in COPD. This state of the art summary will be useful to clinicians and researchers alike. Chagas' disease continues to cause significant morbidity in Central and South America, and the long period between infection and cardiovascular complications can make the etiologic aspects of its diagnosis difficult. The cardiovascular pathologies and sequelae, as well as current approaches to diagnosis and treatment, are clearly described by Dr. Sposito and Dr. Ramires. Chapter e38 by Dr. Reddy, Dr. Naik, and Dr. Roy addresses the potential benefits and challenges of a polypill for multiple cardiovascular risk factors, an issue of global interest in light of increases in cardiovascular disease worldwide. Interest in the mitochondrial role in human health and disease has advanced considerably in recent years, and Chapter e39 by Dr. Skorecki and Dr. Mandel sets forth the current understanding of the role of the mitochondria in a large number of diseases and approaches to diagnosis and treatment.

Within the last 10 years, the *Harrison's* collection of publications has expanded as information delivery technology has evolved. *Harrison's Online (HOL)* is now one of the standard informational resources used in medical centers throughout the United States. In addition to the full content of the parent text, HOL offers frequent updates from and links to the emerging scientific and clinical literature; an expanded collection of reference citations; audio recordings and Podcasts of lectures by authorities in the various specialties of medicine; and other helpful supplementary materials such as a complete database of pharmacologic therapeutics, self-assessment questions for examination and board review; and an expanded collection of clinical photographs. The brand new "e-chapters" on the enclosed DVD, including the video clips of cardiac and endoscopic imaging, are also available on *HOL*. Future iterations of *HOL* will include expanded use of such supplementary multimedia materials to illustrate further key concepts and clinical approaches discussed in the parent text.

In 2006, in recognition of the increasing time pressures placed on clinicians and the increasing use of electronic medical records systems, *Harrison's Practice of Medicine (HP)* made its debut. *HP* is a comprehensive database of specific clinical topics built from the ground up to provide authoritative guidance quickly at the point of care. *HP* is highly structured so that physicians and other health professionals can access the most salient features of any one of more than 700 diseases and clinical presentations within minutes. This innovative new application is updated regularly and includes fully integrated, detailed information on brand name and generic drugs. In addition, hyperlinks throughout *HP* enable quick access to the primary literature via PubMed. *HP* is available via the Internet and on PDA; samples of approximately 20 core topics from *HP* are included on the DVD packaged within this book.

The print publications within the *Harrison's* family are being revised for publication in new editions. The *Harrison's Manual of Medicine* is widely used by students and clinicians worldwide and, like the parent text, is available in print and digital formats. The PDA version of the *Harrison's Manual* provides full text coverage, the full complement of illustrations and tables from the print edition, and extensive cross-referencing between terms. In view of the requirements for continuing education for licensure and relicensure as well as emphasis on certification and recertification, a revision of the *Harrison's Self-Assessment and Board Review* will be published with this edition. This volume is again in the capable hands of Dr. Charles Wiener from Johns Hopkins. It consists of several hundred questions based on the seventeenth edition of *Harrison's*, along with answers and explanations for the answers.

Taken as a portfolio, *Harrison's* is now available in a wide variety of formats suitable for all levels of medical education and practice, and for all varieties of health care settings. It is gratifying that, whether in print or digital formats, the content within *Harrison's* remains so widely used and referenced by students and clinicians throughout medicine and health care across the globe.

We wish to express our appreciation to our many associates and colleagues, who, as experts in their fields, have offered us constructive criticisms and helpful suggestions. We acknowledge especially the contributions of the following individuals: Arv Vanagunas, Laura Kulik, Pat Lynch, Sundeep Khosla, Michael Bray, Mark D. Carlson, Daniel H. Lowenstein, Lawrence C. Madoff, Chung Owyang, Alice Pau, Mary Wright, and Gregory K. Folkers.

We thank in particular Kenneth and Elaine Kaye and Lindsey Baden, who gathered many high-quality illustrations of infectious disease manifestations. We also express our gratitude to Eileen J. Scott, who has applied her editorial expertise to the past six editions of *Harrison's,* and Alan Barnett, the text designer for this edition. This book could not have been edited without the dedicated help of our co-workers in the editorial offices of the individual editors. We are especially indebted to Patricia L. Duffey, Gregory K. Folkers, Sarah Matero, Julie B. McCoy, Elizabeth Robbins, Kathryn Saxon, Marie Scurti, Stephanie Tribuna, Karl Cremieux, and Kristina Shontz.

Finally, we continue to be highly indebted to the outstanding members of the McGraw-Hill organization: Mariapaz Ramos Englis, Senior Managing Editor, who will be retiring after serving the book and its Editors so well for four editions; Phil Galea and Catherine Saggese, Production Director and Manager, respectively; Jenna Esposito, the Editorial Assistant for this edition; James Halston, Digital Editing Manager; James F. Shanahan, Executive Editor; and Martin J. Wonsiewicz, Publisher, who recently left McGraw-Hill after serving as an extremely effective partner to the Editors for 10 years. They are an effective team who have given the Editors constant encouragement and sage advice. They have been instrumental in guiding the many changes instituted with this edition of *Harrison's* and in bringing this volume to fruition in a timely manner.

1 The Practice of Medicine

The Editors

THE MODERN-DAY PHYSICIAN

No greater opportunity, responsibility, or obligation can fall to the lot of a human being than to become a physician. In the care of the suffering, [the physician] needs technical skill, scientific knowledge, and human understanding.… Tact, sympathy, and understanding are expected of the physician, for the patient is no mere collection of symptoms, signs, disordered functions, damaged organs, and disturbed emotions. [The patient] is human, fearful, and hopeful, seeking relief, help, and reassurance.

–Harrison's Principles of Internal Medicine, 1950

The practice of medicine has changed in significant ways since the first edition of this book appeared in 1950. The advent of molecular biology with its enormous implications for the biological sciences (the sequencing of the human genome), sophisticated new imaging techniques, and advances in bioinformatics and information technology have contributed to an explosion of scientific information that has fundamentally changed the way we define, diagnose, treat, and prevent disease. This explosion of scientific knowledge is not at all static as it continues to intensify with time.

The widespread use of electronic medical records and the Internet have altered the way we practice medicine and exchange information. As today's physician struggles to integrate the copious amounts of scientific knowledge into everyday practice, it is important to remember that the ultimate goal of medicine is to treat the patient. Despite more than 50 years of scientific advances since the first edition of this text, it is critical to underscore that cultivating the intimate relationship that exists between physician and patient still lies at the heart of successful patient care.

The Science and Art of Medicine Science-based technology and deductive reasoning form the foundation for the solution to many clinical problems. Spectacular advances in biochemistry, cell biology, and genomics, coupled with newly developed imaging techniques, allow access to the innermost parts of the cell and provide a window to the most remote recesses of the body. Revelations about the nature of genes and single cells have opened the portal for formulating a new molecular basis for the physiology of systems. Increasingly, we are understanding how subtle changes in many different genes can affect the function of cells and organisms. We are beginning to decipher the complex mechanisms by which genes are regulated. We have developed a new appreciation of the role of stem cells in normal tissue function and in the development of cancer, degenerative disease, and other disorders. The knowledge gleaned from the science of medicine has already improved and undoubtedly will further improve our understanding of complex disease processes and provide new approaches to disease treatment and prevention. Yet skill in the most sophisticated application of laboratory technology and in the use of the latest therapeutic modality alone does not make a good physician.

When a patient poses challenging clinical problems, an effective physician must be able to identify the crucial elements in a complex history and physical examination, to order the appropriate laboratory tests, and to extract the key results from the crowded computer printouts of data to determine whether to "treat" or to "watch." Deciding whether a clinical clue is worth pursuing or should be dismissed as a "red herring" and weighing whether a proposed treatment entails a greater risk than the disease itself are essential judgments that the skilled clinician must make many times each day. This combination of medical knowledge, intuition, experience, and judgment defines the ***art of medicine***, which is as necessary to the practice of medicine as is a sound scientific base.

CLINICAL SKILLS

History-Taking The written history of an illness should include all the facts of medical significance in the life of the patient. Recent events should be given the most attention. The patient should, at some early point, have the opportunity to tell his or her own story of the illness without frequent interruption and, when appropriate, receive expressions of interest, encouragement, and empathy from the physician. Any event related by the patient, however trivial or seemingly irrelevant, may provide the key to solving the medical problem. In general, only patients who feel comfortable will offer complete information, and thus putting the patient at ease to the greatest extent possible contributes substantially to obtaining an adequate history.

An informative history is more than an orderly listing of symptoms; by listening to patients and noting the way in which they describe their symptoms, physicians can gain valuable insight into the problem. Inflections of voice, facial expression, gestures, and attitude, i.e., "body language," may reveal important clues to the meaning of the symptoms to the patient. Because patients vary in their medical sophistication and ability to recall facts, the reported medical history should be corroborated whenever possible. The social history can also provide important insights into the types of diseases that should be considered. The family history not only identifies rare Mendelian disorders within a family but often reveals risk factors for common disorders such as coronary heart disease, hypertension, or asthma. A thorough family history may require input from multiple relatives to ensure completeness and accuracy. However, once recorded, it can be readily updated. The process of history-taking provides an opportunity to observe the patient's behavior and to watch for features to be pursued more thoroughly during the physical examination.

The very act of eliciting the history provides the physician with the opportunity to establish or enhance the unique bond that forms the basis for the ideal patient-physician relationship. This process helps the physician develop an appreciation of the patient's perception of the illness, the patient's expectations of the physician and the health care system, and the financial and social implications of the illness to the patient. Although current health care settings may impose time constraints on patient visits, it is important not to rush the history-taking since the patient may get the impression that what he or she is relating is not of importance to the physician and therefore may hold back relevant information. The confidentiality of the patient-physician relationship cannot be overemphasized.

Physical Examination The purpose of the physical examination is to identify the physical signs of disease. The significance of these objective indications of disease is enhanced when they confirm a functional or structural change already suggested by the patient's history. At times, however, the physical signs may be the only evidence of disease.

The physical examination should be performed methodically and thoroughly, with consideration for the patient's comfort and modesty. Although attention is often directed by the history to the diseased organ or part of the body, the examination of a new patient must extend from head to toe in an objective search for abnormalities. Unless the physical examination is systematic and performed in a consistent manner from patient to patient, important segments may be inadvertently omitted. The results of the examination, like the details of the history, should be recorded at the time they are elicited, not hours later when they are subject to the distortions of memory. Skill in physical diagnosis is acquired with experience, but it is not merely technique that determines success in eliciting signs of disease. The detection of a few scattered petechiae, a faint diastolic murmur, or a small mass in the abdomen is not a question of keener eyes and ears or more sensitive fingers, but of a mind alert to these findings. Because physical

Copyright © 2008, 2005, 2001, 1998, 1994, 1991, 1987, 1983, 1980, 1977, 1974, 1970,1966, 1962, 1958 by The McGraw-Hill Companies, Inc. Click here for terms of use.

findings can change with time, the physical examination should be repeated as frequently as the clinical situation warrants. Because a large number of highly sensitive diagnostic tests are available, particularly imaging techniques, it may be tempting to put less emphasis on the physical examination. Indeed, many patients are seen for the first time after a series of diagnostic tests have already been performed and the results known. This should not deter the physician from performing a thorough physical examination since clinical findings are often present that have "escaped" the barrage of preexamination diagnostic tests.

Diagnostic Studies We have become increasingly reliant on a wide array of laboratory tests to solve clinical problems. However, accumulated laboratory data do not relieve the physician from the responsibility of carefully observing, examining, and studying the patient. It is also essential to appreciate the limitations of diagnostic tests. By virtue of their impersonal quality, complexity, and apparent precision, they often gain an aura of authority regardless of the fallibility of the tests themselves, the instruments used in the tests, and the individuals performing or interpreting them. Physicians must weigh the expense involved in the laboratory procedures relative to the value of the information they are likely to provide.

Single laboratory tests are rarely ordered. Rather, physicians generally request "batteries" of multiple tests, which often prove useful. For example, abnormalities of hepatic function may provide the clue to such nonspecific symptoms as generalized weakness and increased fatigability, suggesting the diagnosis of chronic liver disease. Sometimes a single abnormality, such as an elevated serum calcium level, points to a particular disease, such as hyperparathyroidism or underlying malignancy.

The thoughtful use of screening tests, such as low-density lipoprotein cholesterol, may be quite useful. A group of laboratory determinations can be carried out conveniently on a single specimen at relatively low cost. Screening tests are most informative when directed toward common diseases or disorders and when their results indicate the need for other useful tests or interventions that may be costly to perform. On the one hand, biochemical measurements, together with simple laboratory examinations such as blood count, urinalysis, and sedimentation rate, often provide a major clue to the presence of a pathologic process. On the other hand, the physician must learn to evaluate occasional abnormalities among the screening tests that may not necessarily connote significant disease. An in-depth workup following a report of an isolated laboratory abnormality in a person who is otherwise well is almost invariably wasteful and unproductive. Among the more than 40 tests that are routinely performed as screening, it would not be unusual for one or two of them to be slightly abnormal. If there is no suspicion of an underlying illness, these tests are ordinarily repeated to ensure that the abnormality does not represent a laboratory error. If an abnormality is confirmed, it is important to consider its potential significance in the context of the patient's condition and other test results.

The development of technically improved imaging studies with greater sensitivity and specificity is one of the most rapidly advancing areas of medicine. These tests provide remarkably detailed anatomic information that can be a pivotal factor in medical decision-making. Ultrasonography, a variety of isotopic scans, CT, MRI, and positron emission tomography have benefited patients by supplanting older, more invasive approaches and opening new diagnostic vistas. Cognizant of their capabilities and the rapidity with which they can lead to a diagnosis, it is tempting to order a battery of imaging studies. All physicians have had experiences in which imaging studies turned up findings leading to an unexpected diagnosis. Nonetheless, patients must endure each of these tests, and the added cost of unnecessary testing is substantial. A skilled physician must learn to use these powerful diagnostic tools judiciously, always considering whether the results will alter management and benefit the patient.

PRINCIPLES OF PATIENT CARE

Evidence-Based Medicine Evidence-based medicine refers to the concept that clinical decisions are formally supported by data, preferably data that are derived from prospectively designed, randomized, controlled clinical trials. This is in sharp contrast to anecdotal experience, which may often be biased. Unless they are attuned to the importance of using larger, more objective studies for making decisions, even the most experienced physicians can be influenced by recent encounters with selected patients. Evidence-based medicine has become an increasingly important part of the routine practice of medicine and has led to the publication of a number of practice guidelines.

Practice Guidelines Professional organizations and government agencies are developing formal clinical-practice guidelines to aid physicians and other caregivers in making diagnostic and therapeutic decisions that are evidence-based, cost-effective, and most appropriate to a particular patient and clinical situation. As the evidence base of medicine increases, guidelines can provide a useful framework for managing patients with particular diagnoses or symptoms. They can protect patients—particularly those with inadequate health care benefits—from receiving substandard care. Guidelines can also protect conscientious caregivers from inappropriate charges of malpractice and society from the excessive costs associated with the overuse of medical resources. There are, however, caveats associated with clinical practice guidelines since they tend to oversimplify the complexities of medicine. Furthermore, groups with differing perspectives may develop divergent recommendations regarding issues as basic as the need for periodic sigmoidoscopy in middle-aged persons. Finally, guidelines do not—and cannot be expected to—account for the uniqueness of each individual and his or her illness. The physician's challenge is to integrate into clinical practice the useful recommendations offered by experts without accepting them blindly or being inappropriately constrained by them.

Medical Decision-Making Medical decision-making is an important responsibility of the physician and occurs at each stage of the diagnostic and treatment process. It involves the ordering of additional tests, requests for consults, and decisions regarding treatment and prognosis. This process requires an in-depth understanding of the pathophysiology and natural history of disease. As described above, medical decision-making should be evidence-based so that patients derive the full benefit of the scientific knowledge available to physicians. Formulating a differential diagnosis requires not only a broad knowledge base but also the ability to assess the relative probabilities of various diseases. Application of the scientific method, including hypothesis formation and data collection, is essential to the process of accepting or rejecting a particular diagnosis. Analysis of the differential diagnosis is an iterative process. As new information or test results are acquired, the group of disease processes being considered can be contracted or expanded appropriately.

Despite the importance of evidence-based medicine, much of medical decision-making relies on good clinical judgment—a process that is difficult to quantify or even to assess qualitatively. Physicians must use their knowledge and experience as a basis for weighing known factors along with the inevitable uncertainties and the need to use sound judgment; this is particularly important when a relevant evidence base is not available. Several quantitative tools may be invaluable in synthesizing the available information, including diagnostic tests, Bayes' theorem, and multivariate statistical models. *Diagnostic tests* serve to reduce uncertainty about a diagnosis or prognosis in a particular individual and to help the physician decide how best to manage that individual's condition. The battery of diagnostic tests complements the history and the physical examination. The accuracy of a given test is ascertained by determining its sensitivity (true positive rate) and specificity (true negative rate) as well as the predictive value of a positive and negative result. *Bayes' theorem* uses information on a test's sensitivity and specificity, in conjunction with the pretest probability of a diagnosis, to determine mathematically the posttest probability of the diagnosis. More complex clinical problems can be approached with *multivariate statistical models*, which generate highly accurate information even when multiple factors are acting individually or together

to affect disease risk, progression, or response to treatment. Studies comparing the performance of statistical models with that of expert clinicians have documented equivalent accuracy, although the models tend to be more consistent. Thus, multivariate statistical models may be particularly helpful to less experienced clinicians. **See Chap. 3 for a more thorough discussion of decision-making in clinical medicine.**

Electronic Medical Records Our growing reliance on computers and the strength of information technology are playing an increasingly important role in medicine. Laboratory data are accessed almost universally through computers. Many medical centers now have electronic medical records, computerized order entry, and bar-coded tracking of medications. Some of these systems are interactive and provide reminders or warn of potential medical errors. In many ways, the health care system has lagged behind other industries in the adoption of information technology. Electronic medical records have extraordinary potential for providing rapid access to clinical information, imaging studies, laboratory results, and medications. This type of information is invaluable for ongoing efforts to enhance quality and improve patient safety. Ideally, patient records should be easily transferred across the health care system, providing reliable access to relevant data and historic information. However, technology limitations and concerns about privacy and cost continue to limit a broad-based utilization of electronic health records in most clinical settings. It should also be emphasized that information technology is merely a tool and can never replace the clinical decisions that are best made by the physician. In this regard, clinical knowledge and an understanding of the patient's needs, supplemented by quantitative tools, still seem to represent the best approach to decision-making in the practice of medicine.

Evaluation of Outcomes Clinicians generally use *objective* and readily measurable parameters to judge the outcome of a therapeutic intervention. For example, findings on physical or laboratory examination—such as the blood pressure level, the patency of a coronary artery on an angiogram, or the size of a mass on a radiologic examination—can provide critically important information. However, patients usually seek medical attention for *subjective* reasons; they wish to obtain relief from pain, to preserve or regain function, and to enjoy life. The components of a patient's health status or quality of life can include bodily comfort, capacity for physical activity, personal and professional function, sexual function, cognitive function, and overall perception of health. Each of these important areas can be assessed by means of structured interviews or specially designed questionnaires. Such assessments also provide useful parameters by which the physician can judge the patient's subjective view of his or her disability and the response to treatment, particularly in chronic illness. The practice of medicine requires consideration and integration of both objective and subjective outcomes.

Women's Health and Disease Although past epidemiologic studies and clinical trials have often focused predominantly on men, more recent studies have included more women, and some, like the Women's Health Initiative, have exclusively addressed women's health issues. Significant gender differences exist in diseases that afflict both men and women. Much is still to be learned in this arena, and ongoing studies should enhance our understanding of the mechanisms of gender differences in the course and outcome of certain diseases. **For a more complete discussion of women's health, see Chap. 6.**

Care of the Elderly The relative proportion of elderly individuals in the populations of developed nations has been growing considerably over the past few decades and will continue to grow. In this regard, the practice of medicine will continue to be greatly influenced by the health care needs of this growing elderly population. The physician must understand and appreciate the decline in physiologic reserve associated with aging; the diminished responses of the elderly to vaccinations such as those against influenza; the different responses of the elderly to common diseases; and disorders that occur commonly with aging, such as depression, dementia, frailty, urinary incontinence, and fractures. **For a more complete discussion of medical care for the elderly, see Chap. 9.**

Errors in the Delivery of Health Care A report from the Institute of Medicine called for an ambitious agenda to reduce medical-error rates and improve patient safety by designing and implementing fundamental changes in health care systems. Adverse drug reactions occur in at least 5% of hospitalized patients, and the incidence increases with use of a large number of drugs. No matter what the clinical situation, it is the responsibility of the physician to use powerful therapeutic measures wisely, with due regard for their beneficial action, potential dangers, and cost. It is also the responsibility of hospitals and health care organizations to develop systems to reduce risk and ensure patient safety. Medication errors can be reduced through the use of ordering systems that eliminate misreading of handwriting. Implementation of infection-control systems, enforcement of hand-washing protocols, and careful oversight of antibiotic use can minimize complications of nosocomial infections.

The Role of the Physician in the Informed Consent of the Patient The fundamental principles of medical ethics require physicians to act in the patient's best interest and to respect the patient's autonomy. This is particularly relevant to the issue of informed consent. Most patients possess only limited medical knowledge and must rely on their physicians for advice. Physicians must respect their patients' autonomy, fully discussing the alternatives for care and the risks, benefits, and likely consequences of each alternative.

Patients are required to sign a consent form for essentially any diagnostic or therapeutic procedure. In such cases, it is particularly important for the patient to understand clearly the risks and benefits of these procedures; this is the definition of *informed consent*. It is incumbent on the physician to explain the procedures in a clear and understandable manner and to ascertain that the patient comprehends both the nature of the procedure and the attendant risks and benefits. The dread of the unknown, inherent in hospitalization, can be mitigated by such explanations.

The Approach to Grave Prognoses and Death No problem is more distressing than the diagnosis of an incurable disease, particularly when premature death is inevitable. What should the patient and family be told? What measures should be taken to maintain life? What can be done to maintain the quality of life?

Although some would argue otherwise, there is no ironclad rule that the patient must immediately be told "everything," even if the patient is an adult with substantial family responsibilities. How much is told at a given point in time should depend on the individual's ability to deal with the possibility of imminent death; often this capacity grows with time, and, whenever possible, gradual rather than abrupt disclosure is the best strategy. A wise and insightful physician is often guided by an understanding of what a patient wants to know and when he or she wants to know it. The patient's religious beliefs may also be taken into consideration. The patient must be given an opportunity to talk with the physician and ask questions. Patients may find it easier to share their feelings about death with their physician, who is likely to be more objective and less emotional, than with family members. As William Osler wrote, "One thing is certain; it is not for you to don the black cap and, assuming the judicial function, take hope away from any patient." Even when the patient directly inquires, "Am I dying?" the physician must attempt to determine whether this is a request for information or for reassurance. Only open communication between the patient and the physician can resolve this question and guide the physician in what to say and how to say it.

The physician should provide or arrange for emotional, physical, and spiritual support and must be compassionate, unhurried, and open. There is much to be gained by the laying on of hands. Pain should be adequately controlled, human dignity maintained, and iso-

lation from family and close friends avoided. These aspects of care tend to be overlooked in hospitals, where the intrusion of life-sustaining apparati can so easily detract from attention to the whole person and encourage concentration instead on the life-threatening disease, against which the battle will ultimately be lost in any case. In the face of terminal illness, the goal of medicine must shift from *cure* to *care*, in the broadest sense of the term. In offering care to the dying patient, the physician must be prepared to provide information to family members and to deal with their grief and sometimes their feelings of guilt. It is important for the doctor to assure the family that everything possible has been done. **For a more complete discussion of end-of-life care, see Chap. 11.**

THE PATIENT-PHYSICIAN RELATIONSHIP

> *The significance of the intimate personal relationship between physician and patient cannot be too strongly emphasized, for in an extraordinarily large number of cases both the diagnosis and treatment are directly dependent on it. One of the essential qualities of the clinician is interest in humanity,* ***for the secret of the care of the patient is in caring for the patient****.*
>
> –Francis W. Peabody, 1881–1927

Physicians must never forget that patients are individual human beings with problems that all too often transcend their physical complaints. They are not "cases" or "admissions" or "diseases." This point is particularly important in this era of high technology in clinical medicine. Most patients are anxious and fearful. Physicians should instill confidence and should be reassuring but should never be arrogant. A professional attitude, coupled with warmth and openness, can do much to alleviate anxiety and to encourage patients to share all aspects of their medical history. Whatever the patient's attitude, the physician needs to consider the setting in which an illness occurs—in terms not only of the patients themselves but also of their familial, social, and cultural backgrounds. The ideal patient-physician relationship is based on thorough knowledge of the patient, on mutual trust, and on the ability to communicate.

The Dichotomy of Inpatient and Outpatient Internal Medicine The hospital environment has transformed dramatically over the past few decades. In more recent times, emergency departments and critical care units have evolved to identify and manage critically ill patients, allowing them to survive formerly fatal diseases. There is increasing pressure to reduce the length of stay in the hospital and to manage complex disorders in the outpatient setting. This transition has been driven not only by efforts to reduce costs but also by the availability of new outpatient technologies, such as imaging and percutaneous infusion catheters for long-term antibiotics or nutrition, and by evidence that outcomes are often improved by minimizing inpatient hospitalization. Hospitals now consist of multiple distinct levels of care, such as the emergency department, procedure rooms, overnight observation units, critical care units, and palliative care units, in addition to traditional medical beds. A consequence of this differentiation has been the emergence of new specialties such as emergency medicine, intensivists, hospitalists, and end-of-life care. Moreover, these systems frequently involve "hand-offs" from the outpatient to the inpatient environment, from the critical care unit to a general medicine floor, and from the hospital to the outpatient environment. Clearly, one of the important challenges in internal medicine is to maintain continuity of care and information flow during these transitions, which threaten the traditional one-to-one relationship between patient and physician. In the current environment, teams of physicians, specialists, and other health care professionals have often replaced the personal interaction between doctor and patient. The patient can benefit greatly from effective collaboration among a number of health care professionals; however, *it is the duty of the patient's principal or primary physician to provide cohesive guidance through an illness*. In order to meet this challenge, the primary physician must be familiar with the techniques, skills, and objectives of specialist physicians and allied health professionals. The primary physician must ensure that the patient will benefit from scientific advances and from the expertise of specialists when they are needed, while still retaining responsibility for the major decisions concerning diagnosis and treatment.

Appreciation of the Patient's Hospital Experience The hospital is an intimidating environment for most individuals. Hospitalized patients find themselves surrounded by air jets, buttons, and glaring lights; invaded by tubes and wires; and beset by the numerous members of the health care team—nurses, nurses' aides, physicians' assistants, social workers, technologists, physical therapists, medical students, house officers, attending and consulting physicians, and many others. They may be transported to special laboratories and imaging facilities replete with blinking lights, strange sounds, and unfamiliar personnel; they may be left unattended for periods of time; they may be obliged to share a room with other patients who have their own health problems. It is little wonder that patients may lose their sense of reality. Physicians who can appreciate the hospital experience from the patient's perspective and make an effort to develop a strong personal relationship with the patient whereby they may guide the patient through this experience can make a stressful situation more tolerable.

Trends in the Delivery of Health Care: A Challenge to the Humane Physician Many trends in the delivery of health care tend to make medical care impersonal. These trends, some of which have been mentioned already, include (1) vigorous efforts to reduce the escalating costs of health care; (2) the growing number of managed-care programs, which are intended to reduce costs but in which the patient may have little choice in selecting a physician or in seeing that physician consistently; (3) increasing reliance on technological advances and computerization for many aspects of diagnosis and treatment; (4) the need for numerous physicians to be involved in the care of most patients who are seriously ill; and (5) an increased number of malpractice suits, some of which are justifiable because of medical errors, but others of which reflect an unrealistic expectation on the part of many patients that their disease will be cured or that complications will not occur during the course of complex illnesses or procedures.

Given these changes in the medical care system, it is a major challenge for physicians to maintain the *humane* aspects of medical care. The American Board of Internal Medicine, working together with the American College of Physicians–American Society of Internal Medicine and the European Federation of Internal Medicine, has published a *Charter on Medical Professionalism* that underscores three main principles in physicians' contract with society: (1) the primacy of patient welfare, (2) patient autonomy, and (3) social justice. Medical schools have also increased their emphasis on physician professionalism in recent years **(Fig. 1-1)**. The humanistic qualities of a physician must encompass integrity, respect, and compassion. Availability, the expression of sincere concern, the willingness to take the time to explain all aspects of the illness, and a nonjudgmental attitude when dealing with patients whose cultures, lifestyles, attitudes, and values differ from those of the physician are just a few of the characteristics of the humane physician. Every physician will, at times, be challenged by patients who evoke strongly negative or positive emotional responses. Physicians should be alert to their own reactions to such patients and situations and should consciously monitor and control their behavior so that the patient's best interest remains the principal motivation for their actions at all times.

An important aspect of patient care involves an appreciation of the patient's "quality of life," a subjective assessment of what each patient values most. Such an assessment requires detailed, sometimes intimate knowledge of the patient, which can usually be obtained only through deliberate, unhurried, and often repeated conversations. Time pressures will always threaten these interactions, but they should not diminish the importance of understanding and seeking to fulfill the priorities of the patient.

THE TWENTY-FIRST CENTURY PHYSICIAN: EXPANDING FRONTIERS

The Era of Genomics In the spring of 2003, the complete sequencing of the human genome was announced, officially ushering in the genomic era. However, even before this landmark accomplishment, the practice of medicine had been evolving as a result of the insights gained from an understanding of the human genome as well as the genomes of a wide variety of microbes, whose genetic sequences were becoming widely available as a result of the breathtaking advances in sequencing techniques and informatics. Examples of the latter include the identification of a novel coronavirus as the etiologic agent of the severe acute respiratory syndrome (SARS) and the tracking of the evolution of a potentially pandemic influenza virus found in birds. Today, gene expression profiles are being used to guide therapy and inform prognosis for a number of diseases; the use of genotyping is providing a new means to assess the risk of certain diseases as well as variation in response to a number of drugs; we are understanding better the role of certain genes in the causality of certain common conditions such as obesity and allergies. Despite these advances, we are still in the infancy of understanding and utilizing the complexities of genomics in the diagnosis, prevention, and treatment of disease. Our task is complicated by the fact that phenotypes are generally determined not by genes alone but by the interplay of genetic and environmental factors. Indeed, we have just begun to scratch the surface of possibilities that the era of genomics will provide to the practice of medicine.

The rapidity of these advances may seem overwhelming to the practicing physician. However, he or she has an important role to play in ensuring that these powerful technologies and sources of new information are applied with sensitivity and intelligence to the patient. Since genomics is such a rapidly evolving field, physicians and other health care professionals must continue to educate themselves so that they can apply this new knowledge to the benefit of their patients' health and well-being. Genetic testing requires wise counsel based on an understanding of the value and limitations of the tests as well as the implications of their results for specific individuals. **For a more complete discussion of genetic testing, see Chap. 64.**

The Globalization of Medicine Physicians should be cognizant of diseases and health care services beyond local boundaries. Global travel has implications for disease spread, and it is not uncommon for diseases endemic to certain regions to be seen in other regions after a patient has traveled and returned from these regions. Patients have broader access to unique expertise or clinical trials at distant medical centers, and the cost of travel may be offset by the quality of care at these distant locations. As much as any other factor influencing global aspects of medicine, the Internet has transformed the transfer of medical information throughout the world. This change has been accompanied by the transfer of technological skills through telemedicine and international consultation for radiologic images and pathologic specimens. **For a complete discussion of global issues, see Chap. 2.**

Medicine on the Internet On the whole, the Internet has had a very positive effect on the practice of medicine; a wide range of information is available to physicians and patients through personal computers almost instantaneously at any time and from anywhere in the world. This medium holds enormous potential for delivering up-to-date information, practice guidelines, state-of-the-art conferences, journal contents, textbooks (including this text), and direct communications with other physicians and specialists, thereby expanding the depth and breadth of information available to the physician about the diagnosis and care of patients. Most medical journals are now accessible online, providing rapid and comprehensive sources of information. This medium also serves to lessen the information gap felt by physicians and health care providers in remote areas of the world by bringing them into direct and instant contact with the latest developments in medical care.

Patients, too, are turning to the Internet in increasing numbers to acquire information about their illnesses and therapies and to join Internet-based support groups. Physicians are increasingly faced with the prospect of dealing with patients who arrive with sophisticated information about their illness. In this regard, physicians are challenged in a positive way to keep themselves abreast of the latest relevant information while serving as an "editor" for the patients as they navigate through this seemingly endless source of information.

A critically important caveat is that virtually anything can be published on the Internet, with easy circumvention of the peer-review process that is an essential feature of quality publications. Physicians or patients who search the Internet for medical information must be aware of this danger. Notwithstanding this limitation, appropriate use of the Internet is revolutionizing information access for physicians and patients and in this regard is a great benefit that was not available to our predecessors.

Public Expectations and Accountability The level of knowledge and sophistication regarding health issues on the part of the general public has grown rapidly over the past few decades. As a result, expectations of the health care system in general and of physicians in particular have risen. Physicians are expected to master rapidly advancing fields (the *science* of medicine) while considering their patients' unique needs (the *art* of medicine). Thus, physicians are held accountable not only for the technical aspects of the care that they provide but also for their patients' satisfaction with the delivery and costs of care.

In many parts of the world, physicians are increasingly expected to account for the way in which they practice medicine by meeting certain standards prescribed by federal and local governments. The hospitalization of patients whose health care costs are reimbursed by the government and other third parties is subjected to utilization review. Thus, the physician must defend the cause for and duration of a patient's hospitalization if it falls outside certain "average" standards. Authorization for reimbursement is increasingly based on documentation of the nature and complexity of an illness, as reflected by recorded elements of the history and physical examination. There is a growing "pay for performance" movement, which seeks to link reimbursement to quality of care. The goal of this movement is to improve standards of health care and to contain spiraling health care costs. Physicians are also expected to give evidence of their continuing competence through mandatory continuing education, patient-record audits, maintenance of certification, or relicensing.

Medical Ethics and New Technologies The rapid pace of technological advances has profound implications for medical applications far beyond their traditional roles to prevent, treat, and cure disease. Cloning, genetic engineering, gene therapy, human-computer interfaces, nanotechnology, and designer drugs have the potential to modify inherited predispositions to disease, select desired characteristics in embryos, augment "normal" human performance, replace failing tissues, and sub-

stantially prolong life span. Because of their unique training, physicians have a responsibility to help shape the debate concerning the appropriate uses of, and limits that should be placed on, these new techniques.

The Physician as Perpetual Student It becomes all too apparent from the time we graduate from medical school that as physicians our lot is that of the "perpetual student" and the mosaic of our knowledge and experiences is eternally unfinished. This concept can be at the same time exhilarating and anxiety-provoking. It is exhilarating because we will continue to expand our knowledge that can be applied to our patients; it is anxiety-provoking because we realize that we will never know as much as we want or need to know. At best, we will translate this latter feeling into energy to continue to improve ourselves and realize our potential as physicians. In this regard, it is the responsibility of a physician to pursue new knowledge continually by reading, attending conferences and courses, and consulting colleagues and the Internet. This is often a difficult task for a busy practitioner; however, such a commitment to continued learning is an integral part of being a physician and must be given the highest priority.

Research, Teaching, and the Practice of Medicine The title *doctor* is derived from the Latin *docere*, "to teach," and physicians should share information and medical knowledge with colleagues, with students of medicine and related professions, and with their patients. The practice of medicine is dependent on the sum total of medical knowledge, which in turn is based on an unending chain of scientific discovery, clinical observation, analysis, and interpretation. Advances in medicine depend on the acquisition of new information through research, and improved medical care requires the transmission of this information. As part of broader societal responsibilities, the physician should encourage patients to participate in ethical and properly approved clinical investigations if they do not impose undue hazard, discomfort, or inconvenience. On the other hand, physicians engaged in clinical research must be alert to potential conflicts of interest between their research goals and their obligations to individual patients; the best interests of the patient must always take priority.

> *To wrest from nature the secrets which have perplexed philosophers in all ages, to track to their sources the causes of disease, to correlate the vast stores of knowledge, that they may be quickly available for the prevention and cure of disease—these are our ambitions.*
>
> –William Osler, 1849–1919

2 Global Issues in Medicine

Jim Yong Kim, Paul Farmer

WHY GLOBAL HEALTH?

Global health, it has been noted, is not a discipline; it is, rather, a collection of problems. No single review can do much more than lay out the leading problems faced in applying evidence-based medicine in settings of great poverty or across national boundaries. In this chapter, we first introduce the major international bodies engaged in addressing these problems; identify the more significant barriers to improving the health of people who to date have not, by and large, had access to modern medicines; and summarize population-based data regarding the most common health problems faced by people living in poverty. Examining specific problems—notably AIDS (Chap. 182), but also tuberculosis (TB, Chap. 158), malaria (Chap. 203), severe acute respiratory syndrome (SARS; Chap. 179), and key noncommunicable diseases—helps to sharpen the discussion of barriers to prevention, diagnosis, and care as well as means of overcoming them. We next discuss global health equity, drawing on notions of social justice that once were central to international public health but have fallen out of favor over the past several decades. We close by acknowledging the importance of cost-effectiveness analysis linked to national economic data, while at the same time underlining the need to address disparities of disease risk and access to care.

HISTORY OF GLOBAL HEALTH INSTITUTIONS

Concern about health across national boundaries dates back many centuries, predating the Black Plague and other pandemics. Before the advent of germ theory, when epidemic disease began to be understood to be the result of microbes rather than of "miasmas" or the wrath of a divine being, the chief social responses to such epidemics often included accusations that this or that human group was responsible for propagating the affliction in question. Similarly inaccurate and ineffective beliefs abounded when the arrival of European colonists led to catastrophic outbreaks of communicable diseases among indigenous populations in the Americas, and these viewpoints continued to hold sway during subsequent pandemics of cholera. Many historians trace modern public health and epidemiology to the day in 1851 when Dr. John Snow, having discerned the link between cholera outbreaks in London and water sources used by the afflicted populace, removed the handle of the Broad Street water pump. Thus one cholera epidemic was stopped, but it would still be years before the etiology of cholera was discovered.

A proper understanding of etiology was necessary to the birth not only of epidemiology but also of efforts to apply public health measures across administrative boundaries; indeed, without agreement upon etiology and case definitions, there could be no sound metrics upon which to base either assessments of disease burden or effective interventions. The close of the nineteenth century marked the birth and rapid growth of microbiology and the development of some of the first effective vaccines, which, along with measures to promote sanitation, were for decades the mainstay of modern public health. Before the development of effective antibiotics in the mid-twentieth century, international health endeavors consisted largely of the transnational application of a small number of lessons learned from local or regional campaigns. Perhaps the first organization founded explicitly to tackle cross-border health issues was the Pan American Sanitary Bureau, which was formed by 11 countries in the Americas in 1902. The primary goal of what was later to become the Pan American Health Organization was the control of infectious diseases across the Americas. Of special concern was yellow fever, which had been running a deadly course through much of South and Central America and posed a threat to the construction of the Panama Canal. The identification of a mosquito vector in 1901 led public and private health authorities to focus on mosquito control; a vaccine was developed in the 1930s.

Even in the early heyday of vaccine development, no global institutions tackled the health problems of the world's poor. Colonial powers did address (with varying degrees of effectiveness and sources of motivation) the ranking infectious killers in regions now known as the de-

veloping world, but universal standards or even aspirations for international public health and medicine were still far in the future. Although the League of Nations concerned itself with health issues such as malaria in the early twentieth century, and although various organs of the nascent United Nations—including the United Nations Development Program and the United Nations Children's Fund (UNICEF)—also addressed health issues, the World Health Organization (WHO) was the first truly global health institution. Since its founding in 1948, the WHO has witnessed dramatic shifts in population health and in its own stature as the premier global health institution. In line with a long-standing focus on communicable diseases that readily cross administrative and political borders, leaders in global health, under the aegis of the WHO, initiated the effort that led to what some see as the greatest success in international health: the eradication of smallpox. Historians of the smallpox campaign note the preconditions that made eradication possible: international consensus regarding the potential for success, an effective vaccine, and the apparent lack of a nonhuman reservoir for the often-lethal and highly infectious etiologic agent. The primary obstacle was the lack of effective delivery mechanisms for the vaccine in settings of poverty, where health personnel were scarce and health systems weak. Close collaborations across administrative and political borders were clearly necessary. Naysayers were surprised when the smallpox eradication campaign, which engaged public health officials throughout the world, proved successful at the height of the Cold War.

The optimism born of the world's first successful disease-eradication campaign invigorated the international health community, if only briefly. Global consensus regarding the right to primary health care for all was reached at the International Conference on Primary Health Care in Alma-Ata (in what is now Kazakhstan) in 1978. However, the declaration of this collective vision was not followed by substantial funding, nor did the apparent consensus reflect universal commitment to the right to health care. Moreover, as is too often the case, success paradoxically weakened commitment. Basic-science research that might lead to effective vaccines and therapies for TB and malaria faltered in the latter decades of the twentieth century after these diseases were brought under control in the affluent countries where most such research is conducted. U.S. Surgeon General William H. Stewart declared in the late 1960s that it was time to "close the book on infectious diseases," and attention was turned to the main health problems of countries that had already undergone an "epidemiological transition"; that is, the focus shifted from premature deaths due to infectious diseases toward deaths from complications of chronic noncommunicable diseases, including malignancies and complications of heart disease.

In 1982, the visionary leader of UNICEF, James P. Grant, frustrated by the lack of action around the Health for All initiative announced in Alma-Ata, launched a "child survival revolution" focused on four inexpensive interventions collectively known by the acronym GOBI: *g*rowth monitoring; *o*ral rehydration; *b*reast-feeding; and *i*mmunizations for TB, diphtheria, whooping cough, tetanus, polio, and measles. GOBI, which was later expanded to GOBI-FFF (to include *f*emale education, *f*ood, and *f*amily planning), was controversial from the start, but Grant's advocacy led to enormous improvements in the health of poor children worldwide. The Expanded Programme on Immunization was especially successful and is thought to have raised the proportion of children worldwide who were receiving critical vaccines by more than threefold—i.e., from <20% to almost 80% (the target level).

For many reasons (including, perhaps, the success of the UNICEF-led campaign for child survival), the influence of the WHO waned during the 1980s. In the early 1990s, many observers argued that, with its vastly superior financial resources and close if unequal relationships with the governments of poor countries, the World Bank had eclipsed the WHO as the most important multilateral institution working in the area of health. One of the stated goals of the World Bank was to help poor countries identify "cost-effective" interventions worthy of international public support. At the same time, the World Bank encouraged many of these nations to reduce public expenditures in health and education as part of (later discredited) structural adjustment programs (SAPs), which were imposed as a condition for access to credit and assistance through international financial institutions such as the Bank and the International Monetary Fund (IMF). One trend related, at least in part, to these expenditure-reduction policies was the resurgence in Africa of many diseases that colonial regimes had brought under control, including malaria, trypanosomiasis, and schistosomiasis. Tuberculosis, an eminently curable disease, remained the world's leading infectious killer of adults. Half a million women per year died in childbirth during the last decade of the twentieth century, and few of the world's largest philanthropic or funding institutions focused on global health.

AIDS, first described in 1981, precipitated a change. In the United States, the advent of this newly described infectious killer marked the culmination of a series of events that discredited the grand talk of "closing the book" on infectious diseases. In Africa, which would emerge as the global epicenter of the pandemic, HIV disease further weakened TB control programs, while malaria continued to take as many lives as ever. At the dawn of the twenty-first century, these three diseases alone killed an estimated 6 million people each year. New research, new policies, and new funding mechanisms were called for. Some of the requisite innovations have emerged in the past few years. The leadership of the WHO has been challenged by the rise of institutions such as the Global Fund to Fight AIDS, Tuberculosis, and Malaria; the Joint United Nations Program on HIV/AIDS (UNAIDS); and the Bill & Melinda Gates Foundation and by bilateral efforts such as the U.S. President's Emergency Plan for AIDS Relief (PEPFAR). Yet with its 193 member states and 147 country offices, the WHO remains preeminent in matters relating to the cross-border spread of infectious and other health threats. In the aftermath of the SARS epidemic of 2003, the International Health Regulations—which provide a legal foundation for the WHO's direct investigation of a wide range of global health problems, including pandemic influenza, in any member state—were strengthened and brought into force in May 2007.

Even as attention to and resources for health problems in resource-poor settings grow, the lack of coherence in and among global health institutions may seriously undermine efforts to forge a more comprehensive and effective response. While UNICEF had great success in launching and sustaining the child survival revolution, the end of James Grant's term at UNICEF upon his death in 1995 was followed by a lamentable shift of focus away from immunizations; predictably, coverage dropped. The WHO has gone through two recent leadership transitions and is still woefully underfunded despite the ever-growing need to engage a wider and more complex range of health issues. In another instance of the paradoxical impact of success, the rapid growth of the Gates Foundation, while clearly one of the most important developments in the history of global health, has led other foundations to question the wisdom of continuing to invest their more modest resources in this field. We may indeed be living in what some have called "the golden age of global health," but leaders of major organizations such as the WHO, the Global Fund, UNICEF, UNAIDS, and the Gates Foundation must work together to design an effective architecture that will make the most of the extraordinary opportunities that now exist. To this end, new and old players in global health must invest heavily in *discovery* (relevant basic science); in the *development* of new tools (preventive, diagnostic, and therapeutic); and in a new science of implementation, or *delivery*.

THE ECONOMICS OF GLOBAL HEALTH

Political and economic concerns have often guided global health interventions. As mentioned previously, early efforts to control yellow fever were tied to the completion of the Panama Canal. However, the precise nature of the link between economics and health remains a matter for debate. Some economists and demographers argue that economic development is the key to improving the health status of populations, while others maintain that ill health is the chief barrier to development in poor countries. In either case, investment in health care, and especially in the control of communicable diseases, should lead to in-

creased productivity. The question is where to find the necessary resources to start the predicted "virtuous cycle."

International financial institutions, including the World Bank and the IMF, have counseled limited investments and the capping of social expenditures in health and education. The socioeconomic argument was that a balanced budget and a "friendly investment climate"—that is, privatization, deregulation, decreased trade barriers, devalued currencies, and debt repayment—would favor development and thus improve health outcomes. The limitations on social-sector spending recommended for many poor countries by the World Bank and the IMF from the 1970s through the 1990s tended to confirm the opposite view. In the poorest countries, already-tiny health-sector budgets were further constricted. Moreover, health-sector spending in many poor countries channeled a majority of resources toward city hospitals that served mostly élites who were able to pay; consequently, in the past quarter-century, little spending went toward addressing the problems that most affected poor people in poor countries.

Since 1999, spurred by the leadership of the Gates Foundation and the growing interest in addressing novel and persistent challenges such as AIDS, spending on health in poor countries has increased, with $40 billion in new funds earmarked for the discovery and development of drugs and diagnostics targeting diseases of the poor; for comprehensive responses to the AIDS, TB, and malaria epidemics; for vaccine development and delivery; and even for improved methods of data collection in resource-poor settings. Nevertheless, in order to reach the United Nations' Millennium Development Goals, which include targets for poverty reduction, universal primary education, and gender equality, spending in the health sector will have to be further increased and sustained. To determine by how much and for how long, it is imperative that we improve our ability to assess the global burden of disease (GBD) and to plan interventions that more precisely match the need, which is glaring but often poorly understood. Refining metrics is an important task for global health: only recently have we had solid assessments of the GBD. Such assessments may serve as preliminaries or as correctives to effective interventions among the poor.

LIFE EXPECTANCY AND GLOBAL BURDEN OF DISEASE

Since the late 1980s, serious efforts have been made to calculate the GBD. The first GBD study, conducted in 1990, laid the foundation for the first report on *Disease Control Priorities in Developing Countries* (DCP1) and for the World Bank's 1993 World Development Report entitled *Investing in Health*. These efforts represented a major advance in our understanding of health status in developing countries. *Investing in Health* has been especially influential: it familiarized a broad audience with cost-effectiveness analysis for specific health interventions and with the notion of disability-adjusted life years (DALYs). The DALY, which has become a standard measure of the impact of a specific health condition on a population, combines in a single measure both absolute years of life lost and years lost due to disability for incident cases of a condition.

The second GBD analysis was carried out on health data from 2001. The latter report reflects growth in the available data on health in the poorest countries and in our capacity to measure the impact of specific conditions on a population. Yet, even in 2001, only 107 of 192 nations surveyed had reliable information on the causes of deaths within their own borders. It is essential to expand efforts to collect the most basic health data; this task falls to the WHO, national governments, and certain academic institutions. The lack of complete data has led to considerable uncertainty in estimates of overall mortality. The level of uncertainty ranges from as low as 1% for estimates of all-cause mortality in developed countries to well over 50% for disability resulting from diseases for which surveillance mechanisms are incomplete. As analytic methods and data quality have improved, however, important trends can be identified in a comparison of GBD estimates from 1990 and 2001.

Of the 56 million deaths worldwide in 2001, one-third were due to communicable diseases, maternal and perinatal conditions, and nutritional deficiencies. While the proportion of all deaths attributable to these causes was unchanged from 1990, the share of all deaths due to the communicable disease HIV/AIDS grew from just 2% to an astonishing 14%. If these deaths were excluded, the fraction of all deaths related to communicable diseases, maternal and perinatal conditions, and nutritional deficiencies dropped from one-third to one-fifth. Of the deaths making up that one-fifth of the total figure, 97% occurred in middle- and low-income countries. The leading cause of death among adults in 2001 was ischemic heart disease, accounting for 17.3% of all deaths in high-income countries and for 11.8% in middle- and low-income countries. In second place was cerebrovascular disease, which accounted for 9.9% of deaths in high-income countries and for 9.5% of deaths in middle- and low-income countries. While the third leading cause of death in high-income countries was tracheal, bronchial, and lung cancers (which accounted for 5.8% of all deaths), these conditions do not even register in the top 10 places in middle- and low-income countries. Of the 10 leading causes of death in poorer countries, 5 were communicable diseases; in high-income countries, however, only 1 communicable disease—lower respiratory infection—was ranked among the top 10 causes of death.

Nearly 20% (10.6 million) of the 56 million dead in 2001 were children <5 years of age who died of acute respiratory infections, measles, diarrhea, malaria, and HIV/AIDS (Fig. 2-1). Of these deaths, 99% occurred in middle- and low-income countries, and fully 40% occurred in sub-Saharan Africa. If stillbirths are counted, the number of childhood deaths rises to 13.5 million worldwide (~25% of all deaths worldwide), of which more than half (i.e., one-eighth of all deaths) occurred before the first birthday. Between 1990 and 2001, under-five childhood mortality dropped by ≥30% in high-income countries, Latin America, the Caribbean, the Middle East, North Africa, and the middle- and low-income countries of Europe and Central Asia. Notably, the total number of deaths from diarrheal diseases dropped from 2.4 million in 1990 to 1.6 million in 2001, probably as a result of the increased use of oral rehydration therapy in poor countries. Malaria and HIV infection were the only two conditions for which childhood death rates increased between 1990 and 2001.

Among persons 15–59 years of age (Fig. 2-2), noncommunicable diseases accounted for more than half of all deaths in all regions except South Asia and sub-Saharan Africa, where communicable diseases, maternal and perinatal conditions, and nutritional deficiencies together accounted for one-third and two-thirds of all deaths, respectively. The 15- to 59-year-olds with noncommunicable conditions in low- and middle-income countries faced a 30% greater risk of death from their conditions than did their peers in high-income countries. In this age group, injuries accounted for 25% of all deaths; Europe and Central Asia registered even higher rates, with injuries accounting for one-third of all deaths. Overall, death rates in this age group declined between 1990 and 2001 in all regions except Europe and Central Asia, where cardiovascular diseases and injuries have caused increased mortality, and sub-Saharan Africa, where the impact of HIV/AIDS in this age cohort has been particularly devastating.

Noncommunicable diseases accounted for almost 60% of all deaths in 2001 but, because of the later onset of these diseases, accounted for only 40% of years of life lost. In contrast, because they occur more often in younger people, injuries accounted for 12% of years of life lost but for only 9% of deaths. Overall, males had an 11% higher death rate than females as well as a 15% higher rate of years of life lost; these figures reflect the earlier age of death of males worldwide. Notably, almost half of the disease burden in middle- and low-income countries in 2001 derived from noncommunicable disease—an increase of 10% since 1990.

Compared with years of life lost, there is greater uncertainty in calculating years of life lived with disability for specific conditions. Best estimates from 2001 reveal that, while the prevalence of diseases common in older populations (e.g., dementia and musculoskeletal disease) was higher in high-income countries, the disability experienced as a result of cardiovascular diseases, chronic respiratory diseases, and the long-term impact of communicable diseases was greater in low- and middle-income countries. Thus, predictably, in most low- and middle-income

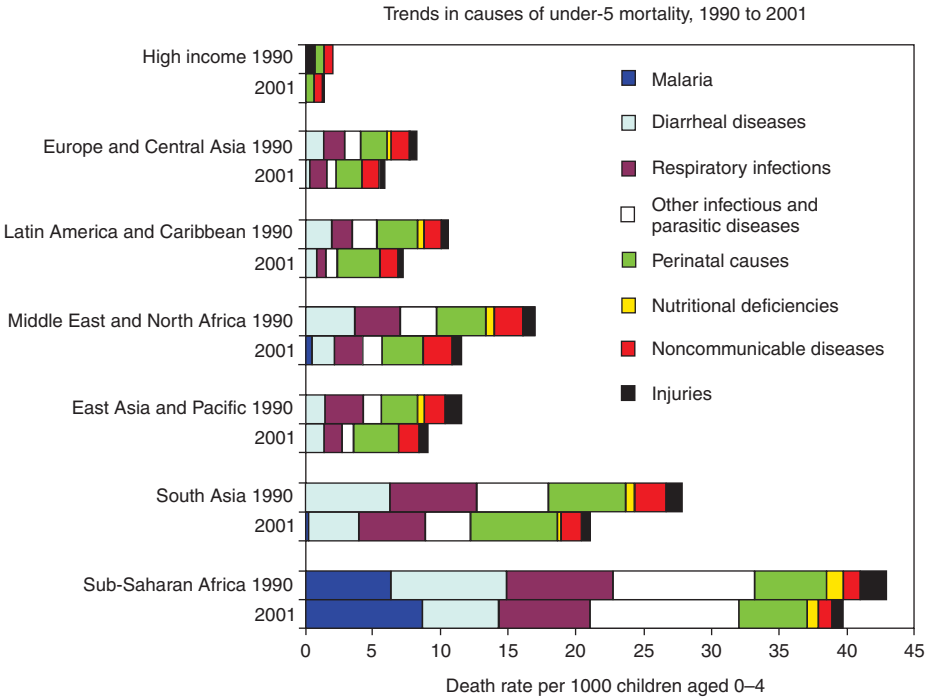

FIGURE 2-1 Death rates among children from birth through 4 years of age, by disease group and region, in 1990 and 2001. Cause-specific death rates for 1990, estimated from Murray and Lopez (1996), may not be completely comparable to those for 2001 because of changes in data availability and methods as well as some approximations in mapping 1990 estimates to the 2001 regions of East Asia and Pacific, South Asia, and Europe and Central Asia. For all geographic regions, high-income countries are excluded and are shown as a single group at the top of the graph. The geographic regions therefore refer to low- and middle-income countries only. *(Reprinted from Lopez et al, with permission from Elsevier.)*

countries, people both lived shorter lives and experienced disability and poor health for a greater proportion of their lives. Indeed, 45% of the overall burden of disease occurred in South Asia and sub-Saharan Africa, which together comprise only one-third of the global population.

In its analysis of risk factors for ill health, the GBD project found that undernutrition was the leading cause of loss of DALYs in both 1990 and 2001. In an era that has seen obesity become a major health concern in so many developed countries, the persistence of undernutrition is surely cause for great consternation. Our inability to feed the hungry indicts many years of failed development projects and must be addressed as a problem of the highest priority. Indeed, no health care initiative, however generously funded and scientifically justified, will be effective without adequate nutrition.

The GBD analysis was used as the basis for the second edition of *Disease Control Priorities in Developing Countries* (DCP2). Published in 2006, DCP2 is a document of stunning breadth and ambition, providing cost-effectiveness analyses for >100 interventions and including 21 chapters focused on strategies for strengthening health systems. Cost-effectiveness analyses that compare two relatively equal interventions and facilitate the best choices under constraint are important; however, as both resources and ambitions for global health grow, cost-effectiveness analyses (particularly those based on past conditions) must not hobble the increased worldwide commitment to provide resources and accessible services to all who need them. To illustrate this point, we turn in greater detail to AIDS, which has become, in the course of the last three decades, the world's leading infectious cause of death during adulthood.

AIDS

Chapter 182 provides an overview of the AIDS epidemic in the world today. Here we will limit ourselves to a discussion of AIDS in the developing world. Lessons learned in tackling AIDS in resource-constrained settings are highly relevant to discussions of other chronic diseases, including noncommunicable diseases, for which effective therapies have been developed. We highlight several of these lessons below.

In the United States, the availability of highly active antiretroviral therapy (ART) for AIDS has transformed this disease from an inescapably fatal destruction of cell-mediated immunity into a manageable chronic illness. In developing countries, treatment has been offered more broadly only since 2003, and only in the summer of 2006 did the number of patients receiving treatment exceed 25% of the number who currently need it. (It remains to be seen how many of

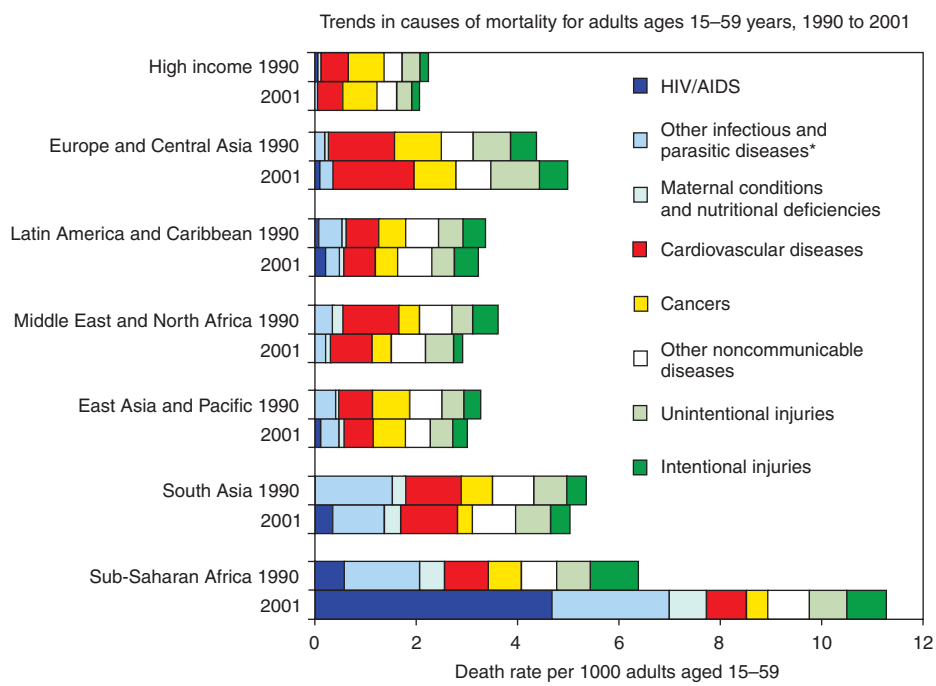

FIGURE 2-2 Death rates among persons 15–59 years old, by disease group and region, in 1990 and 2001. *Includes respiratory infections. Cause-specific death rates for 1990, estimated from Murray and Lopez (1996), may not be completely comparable to those for 2001 because of changes in data availability and methods as well as some approximations in mapping 1990 estimates to the 2001 regions of East Asia and Pacific, South Asia, and Europe and Central Asia. For all geographic regions, high-income countries are excluded and are shown as a single group at the top of the graph. The geographic regions therefore refer to low- and middle-income countries only. *(Reprinted from Lopez et al, with permission from Elsevier.)*

these fortunate few are receiving ART regularly and with the requisite social support.) Before 2003, many arguments were raised to justify not moving forward rapidly with ART programs for people living with HIV/AIDS in resource-limited settings. The standard litany included the price of therapy compared to the poverty of the patient, the complexity of the intervention, the lack of infrastructure for laboratory monitoring, and the lack of trained health care providers. Narrow cost-effectiveness arguments that created false dichotomies—prevention *or* treatment, rather than both—too often went unchallenged. The greatest obstacle at the time was the ambivalence, if not outright silence, of political leaders and experts in public health. The cumulative effect of these factors was to condemn to death tens of millions of poor people in developing countries who had become ill as a result of HIV infection.

The inequity between rich and poor countries in access to HIV treatment has rightly given rise to widespread moral indignation. In several middle-income countries, including Brazil, visionary programs have bridged the access gap. Other innovative projects pioneered by international nongovernmental organizations (NGOs) in diverse settings have clearly established that a very simple approach to ART, based on intensive community engagement and support, can achieve remarkable results. In 2000, the United Nations Accelerating Access Initiative finally brought the research-based and generic pharmaceutical industries into play, and AIDS drug prices have since fallen significantly. At the same time, easier-to-administer fixed-dose combination drugs have become more widely available.

Building on these lessons, the WHO advocated a public health approach to the treatment of people with AIDS in resource-limited settings. This approach, which was derived from models of care pioneered by the NGO Partners In Health and other groups, proposed standard first-line treatment regimens based on a simple five-drug formulary, with a more complex (and, up to now, more expensive) set of second-line options in reserve. Common clinical protocols were standardized, and intensive training packages for health and community workers were developed and implemented in many countries. These efforts were supported by unprecedented funding through the World Bank, the Global Fund, and PEPFAR. In 2003, the lack of access to ART was declared a global public-health emergency by the WHO and UNAIDS, and the two agencies launched the "3 by 5 initiative," setting an ambitious target: having 3 million people in developing countries on treatment by the end of 2005. Many countries have since set corresponding national targets and have worked to integrate ART into their national AIDS programs and health systems and to harness the synergies between HIV/AIDS treatment and prevention activities. The G8 (Gleneagles) 2005 communiqué endorsing universal access to HIV treatment by 2010 was another major step forward.

It is clear by now that the claims made for the efficacy of ART are well founded: in the United States, such therapy has prolonged life by an estimated 13 years per patient on average—a success rate that would compare favorably with that of almost any treatment for cancer or for complications of coronary artery disease. Further lessons with implications for policy and action have come from efforts that are now under way in the developing world. During the past decade, through experiences in >50 countries thus far, the world has seen that ambitious policy goals, adequate funding, and knowledge about implementation can dramatically transform the prospects of people living with HIV infection in developing nations.

TUBERCULOSIS

Chapter 158 offers a concise overview of the pathophysiology and treatment of TB, which is closely linked to HIV infection in much of the world. Indeed, a substantial proportion of the resurgence of TB registered in southern Africa may be attributed to HIV co-infection. Even before the advent of HIV, however, it was estimated that fewer than half of all cases of TB in developing countries were ever diagnosed, much less treated.

Primarily because of the common failure to diagnose and treat TB, international authorities devised a single strategy to reduce the burden of disease. The DOTS strategy (*d*irectly *o*bserved *t*herapy using *s*hort-course isoniazid- and rifampin-based regimens) was promoted in the early 1990s as highly cost-effective by the World Bank, the WHO, and other international bodies. Passive case-finding of smear-positive patients was central to the strategy, and an uninterrupted drug supply was, of course, deemed necessary for cure. DOTS was clearly effective for most uncomplicated cases of drug-susceptible TB, but it was not long before a number of shortcomings were identified. First, the diagnosis of TB based solely on smear microscopy—a method dating from the late nineteenth century—is not sensitive. Many patients with pulmonary TB and all patients with exclusively extrapulmonary TB are missed by smear microscopy, as are most children with active disease. Second, passive case-finding relies on the availability of health care services, which is uneven in settings where TB is most prevalent. Third, patients with multidrug-resistant (MDR) TB are by definition infected with strains of *Mycobacterium tuberculosis* resistant to isoniazid and rifampin; thus exclusive reliance on these drugs is ineffective in settings in which drug resistance is an established problem.

The crisis of antibiotic resistance registered in U.S. hospitals is not confined to the industrialized world or to bacterial infections. In some settings, a substantial minority of patients with TB are infected with strains resistant to at least one first-line anti-TB drug. As an effective DOTS-based response to MDR TB, global health authorities adopted DOTS-Plus, which adds the diagnostics and drugs necessary to manage drug-resistant disease. Even before DOTS-Plus could be brought to scale in resource-constrained settings, however, new strains of extensively drug-resistant (XDR) *M. tuberculosis* began to threaten the success of TB control programs in already-beleaguered South Africa, for example, where high rates of HIV infection have led to a doubling of TB incidence over the past decade.

TUBERCULOSIS AND AIDS AS CHRONIC DISEASES: LESSONS LEARNED

Strategies effective against MDR TB have implications for the management of drug-resistant HIV infection and even drug-resistant malaria, which, through repeated infections and a lack of effective therapy, has become a chronic disease in parts of Africa. Indeed, examining AIDS and TB together as chronic diseases allows us to draw a number of conclusions, many of them pertinent to global health in general (Fig. 2-3).

First, charging fees for AIDS prevention and care will pose insurmountable problems for people living in poverty, many of whom will always be unable to pay even modest amounts for services or medications. Like efforts to battle airborne TB, such services might best be seen as a public good for public health. Initially, this approach will require sustained donor contributions, but many African countries have recently set targets for increased national investments in health—a pledge that could render ambitious programs sustainable in the long run. Meanwhile, as local investments increase, the price of AIDS care is decreasing. The development of generic medications means that ART can now cost <$0.50 (U.S.) per day, and costs continue to decrease to affordable levels for public health bodies in developing countries.

Second, the effective scale-up of pilot projects will require the strengthening and sometimes rebuilding of health care systems, including those charged with delivering primary care. In the past, the lack of health care infrastructure has been cited as a barrier to providing ART in the world's poorest regions; however, AIDS resources, which are at last considerable, may be marshaled to rebuild public health systems in sub-Saharan Africa and other HIV-burdened regions—precisely the settings in which TB is resurgent.

Third, a lack of trained health care personnel, most notably doctors, is invoked as a reason for the failure to treat AIDS in poor countries. The lack is real, and the "brain drain," which is discussed below, continues. However, one reason doctors leave Africa is that they lack the tools to practice their trade there. AIDS funding provides an opportunity not only to recruit physicians and nurses to underserved regions but also to train community health workers to supervise care for AIDS and many other diseases within their home villages and neighborhoods. Such training should be undertaken even in places where physicians are abundant, since community-based, closely supervised care

FIGURE 2-3 An HIV/TB co-infected patient in Rwanda, before (***left***) and after (***right***) 6 months of treatment.

represents the highest standard of care for chronic disease, whether in the First World or the Third.

Fourth, extreme poverty makes it difficult for many patients to comply with therapy for chronic diseases, whether communicable or not. Indeed, poverty in its many dimensions is far and away the greatest barrier to the scale-up of treatment and prevention programs. It is possible to remove many of the social and economic barriers to adherence, but only with what are sometimes termed "wrap-around services": food supplements for the hungry, help with transportation to clinics, child care, and housing. In many rural regions of Africa, hunger is the major coexisting condition in patients with AIDS or TB, and these consumptive diseases cannot be treated effectively without adequate caloric intake.

Finally, there is a need for a renewed basic-science commitment to the discovery and development of vaccines; of more reliable, less expensive diagnostic tools; and of new classes of therapeutic agents. This need applies not only to the three leading infectious killers—against none of which an effective vaccine exists—but also to many other neglected diseases of poverty.

MALARIA

We turn now to the world's third largest infectious killer, which has taken its greatest toll among children, especially African children, living in poverty.

The Cost of Malaria Malaria's human toll is enormous. An estimated 250 million people suffer from malarial disease each year, and the disease annually kills between 1 million and 2.5 million people, mostly pregnant women and children under the age of 5. The poor disproportionately suffer the consequences of malaria: 58% of malaria deaths occur in the poorest 20% of the world's population, and 90% are registered in sub-Saharan Africa. The differential magnitude of this mortality burden is greater than that associated with any other disease. Likewise, the morbidity differential is greater for malaria than for diseases caused by other pathogens, as documented in a study from Zambia that revealed a 40% greater prevalence of parasitemia among children under 5 in the poorest quintile than in the richest.

Despite suffering the greatest consequences of malaria, the poor are precisely those least able to access effective prevention and treatment tools. Economists describe the complex interactions between malaria and poverty from an opposite but complementary perspective: they delineate ways in which malaria arrests economic development both for individuals and for whole nations. Microeconomic analyses focusing on direct and indirect costs estimate that malaria may consume up to 10% of a household's annual income. A Ghanaian study that categorized the population by income group highlighted the regressive nature of this cost: the burden of malaria represents only 1% of a wealthy family's income but 34% of a poor household's income.

At the national level, macroeconomic analyses estimate that malaria may reduce the per capita gross national product of a disease-endemic country by 50% relative to that of a non-malarial country. The causes of this drag include high fertility rates, impaired cognitive development of children, decreased schooling, decreased saving, decreased foreign investment, and restriction of worker mobility. Given this enormous cost, it is little wonder that an important review by the economists Sachs and Malaney concludes that "where malaria prospers most, human societies have prospered least."

Rolling Back Malaria In part because of differences in vector distribution and climate, resource-rich countries offer few blueprints for malaria control and treatment that are applicable in tropical (and resource-poor) settings. In 2001, African heads of state endorsed the WHO Roll Back Malaria (RBM) campaign, which prescribes strategies appropriate for sub-Saharan African countries. RBM recommends a three-pronged strategy to reduce malaria-related morbidity and mortality: the use of insecticide-treated bed nets (ITNs), combination antimalarial therapy, and indoor residual spraying.

ITNs are an efficacious and cost-effective public health intervention. A meta-analysis of controlled trials indicates that malaria incidence is reduced by 50% among persons who sleep under ITNs compared with that among those who do not use nets at all. Even untreated nets reduce malaria incidence by one-quarter. On an individual level, the utility of ITNs extends beyond protection from malaria. Several studies suggest that all-cause mortality is reduced among children under 5 to a greater degree than can be attributed to the reduction in malarial disease alone. Morbidity (specifically that due to anemia) predisposing children to diarrheal and respiratory illnesses and pregnant women to the delivery of low-birth-weight infants is also reduced in populations using ITNs. In some areas, ITNs offer a supplemental benefit by preventing transmission of lymphatic filariasis, cutaneous leishmaniasis, Chagas' disease, and tick-borne relapsing fever. At the community level, investigators suggest that the use of an ITN in just one household may reduce the number of mosquito bites in households up to several hundred meters away. The cost of ITNs per DALY saved is estimated at $10–$38 (U.S.), which qualifies ITNs as a "very efficient use of resources and [a] good candidate for public subsidy."[1]

Some RBM programs have had limited success, but overall the burden of malarial disease has continued to grow. In fact, annual malaria-attributable mortality increased between 1999 and 2003. While the RBM campaign's own report from that year is quick to note that morbidity and mortality data-collection methods in sub-Saharan Africa are inadequate and indicators may thus lag behind actual outcomes of ongoing campaigns, they nevertheless acknowledge that "RBM is acting against a background of increasing malaria burden."

Limited success in scaling-up ITN coverage reflects the inadequately acknowledged economic barriers that prevent the destitute sick from accessing critical preventive technologies. Despite proven efficacy and what are considered "reasonable costs," the 2003 RBM report reveals disappointing levels of ITN coverage. In 28 African countries surveyed, only 1.3% (range, 0.2–4.9%) of households owned at least one ITN, and <2% of children slept under an ITN. Why has the RBM campaign failed to achieve its goals? Do Africans not want to use bed nets? Do they not

[1]Nuwaha F: The challenge of chloroquine-resistant malaria in sub-Saharan Africa. Health Policy Plan 16:1, 2001.

recognize malaria as a health risk? Or have project managers and donors miscalculated most Africans' ability to obtain bed nets?

These are not rhetorical questions. The RBM strategy initially emphasized the importance of commercial markets as sources of ITNs for African populations. A precedent supporting this emphasis is the prior existence in countries such as Madagascar and Mali of local markets for untreated bed nets. Presumably, therefore, a demand for bed nets existed prior to the RBM campaign, as did a distribution system with points of sale. However, even with the application of subsidized social marketing strategies, this market approach has not resulted in large increases in coverage during the first years of the RBM campaign. Several studies have attempted to define willingness to pay (WTP) and actual payment for ITNs in African countries and thereby to determine why market-based strategies have been unsuccessful. Policy-makers often use WTP figures to determine appropriate pricing for social marketing projects and to project revenue and demand. A cross-sectional study in a rural Nigerian community administered two questionnaires, 1 month apart, to examine community members' WTP for ITNs, actual purchase of ITNs (with the second questionnaire accompanied by the opportunity to buy a subsidized ITN), and factors (such as socioeconomic status and recent history of malarial illness) contributing to hypothetical and actual ITN purchase. Among the 453 persons answering both surveys, the poorest quintile perceived a greater risk of malaria than the other quintiles (27.3% vs. 12.9–21.6%, $p < .05$). However, the poorest quintile was least likely to own a net, purchase a net, or express a hypothetical WTP. Even the most well-off quintile was willing to pay only 51% of the government-set price for an ITN. This finding suggests that even the relatively well-off may not be willing or able to pay for bed nets at set prices. The authors of this study concluded that reliance on the sale of nets alone may prove inadequate and that further studies are needed to define the degrees to which costs can be lowered and/or demand increased.

A 2002 study in highland Kenya compared the attitudes of people living in homesteads provided with heavily subsidized ITNs ($n = 190$) with those of residents of households that had no ITNs and had not been targeted by other health care initiatives ($n = 200$). Of all households, 97% expressed willingness to pay for ITNs. However, only 4% of those willing to pay offered spontaneously to meet the suggested price of 350 Kenyan shillings. After being prompted that "nets are expensive," 26% of respondents expressed willingness to pay the full price. This study did not offer nets for sale; therefore, the number of nets that would actually have been purchased is unknown. However, the study did contextualize the hypothetical WTP for ITNs by comparing their cost with other household costs: the price of one ITN is equal to the cost of sending three children to primary school for a year. By placing the nets' relative cost in context, the authors of this study call into question the likelihood that families in this district, over half of whom fall below the Kenyan poverty line, would actually be able to purchase ITNs.

Given the documented barriers to purchasing ITNs, especially among the poorest of the poor, many researchers and development professionals involved in malaria programs have called for the free distribution of ITNs, comparing their importance as a public health measure with that of childhood vaccination. The adoption of free ITN distribution strategies has been limited, however, by concerns about their feasibility and potential ITN misuse (for example, as nets for fishing). Evidence from a targeted free-distribution program discounts both concerns. In 2001, a Kenyan program sponsored by UNICEF sought to distribute 70,000 ITNs to pregnant women through antenatal clinics. Within 12 weeks, >50% of the ITNs had reached their intended recipients. A 1-year follow-up evaluation of 294 women who had received bed nets while pregnant—152 women from a high-transmission area and 142 from a low-transmission area—revealed that 84% of women in the high-transmission area used the ITNs throughout pregnancy. One year later, 77% continued to use the bed nets. In the low-transmission area, 57% of women used the ITNs during pregnancy, and 46% continued to use them a year later. These results contradict suppositions that free nets may not be used because recipients do not value them.

Given the scope and magnitude of the challenge posed by malaria, it is unlikely that any one strategy will work for every region or population within a country or across the world. Encouraging results from an employer-based ITN distribution system in Kenya highlight the potential role of public-private partnerships. Potential synergies between antimalaria programs and measles vaccine campaigns or possibly lymphatic filariasis eradication campaigns have been reported or suggested. Concerns about discomfort associated with sleeping under ITNs or about insecticide toxicities must be addressed through educational campaigns.

Meeting the challenge of malaria control will continue to require careful study of appropriate preventive and therapeutic strategies in the context of our increasingly sophisticated molecular understanding of the pathogen, vector, and host. However, an appreciation for the economic and structural devastation wrought by malaria—like that inflicted by diarrhea, AIDS, and TB—on the most vulnerable populations should heighten our commitment to the critical analysis of ways to implement proven strategies for the prevention and treatment of these diseases.

CHRONIC NONCOMMUNICABLE DISEASES

While the burden of communicable diseases—especially HIV infection, tuberculosis, and malaria—still accounts for the majority of deaths in resource-poor regions such as sub-Saharan Africa, close to 60% of all deaths worldwide in 2005 were due to chronic noncommunicable diseases (NCDs). Moreover, 80% of deaths attributable to NCDs occurred in low- and middle-income countries, where 85% of the global population lives. In 2005, 8.5 million people in the world died of an NCD before their 60th birthday—a figure exceeding the total number of deaths due to AIDS, TB, and malaria combined. By 2020, NCDs will account for 80% of the GBD and for 7 of every 10 deaths in developing countries. The recent rise in resources for and attention to communicable diseases is both welcome and long overdue, but developing countries are already carrying a "double burden" of communicable and noncommunicable diseases.

Cardiovascular Disease Unlike TB, HIV infection, and malaria—diseases caused by single pathogens that damage multiple organs—cardiovascular diseases reflect injury to a single organ system downstream of a variety of insults. The burden of chronic cardiovascular disease in low-income countries represents one consequence of decades of health system neglect; furthermore, cardiovascular research and investment have long focused on the ischemic conditions that are increasingly common in high- and middle-income countries. Meanwhile, despite awareness of its health impact during the early twentieth century, cardiovascular damage in response to infection and malnutrition has fallen out of view until recently.

The perception of cardiovascular diseases as a problem of elderly populations in middle- and high-income countries has contributed to their neglect by global health institutions. Even in Eastern Europe and Central Asia, where the collapse of the Soviet Union was followed by a catastrophic surge in cardiovascular disease deaths (mortality rates from ischemic heart disease nearly doubled between 1991 and 1994 in Russia, for example), the modest flows of overseas development assistance to the health sector focused on the communicable causes that accounted for <1 in 20 excess deaths during this period.

Predictions of an imminent rise in the share of deaths and disabilities due to NCDs in developing countries have led to calls for preventive policies to restrict tobacco use, improve diet, and increase exercise alongside the prescription of multidrug regimens for persons with high levels of vascular risk. Although this agenda could do much to prevent pandemic NCD, it will do little to help those with established heart disease stemming from non-atherogenic pathologies.

The epidemiology of heart failure reflects inequalities in risk factor prevalence and treatment. Heart failure as a consequence of pericardial, myocardial, endocardial, or valvular injury accounts for as many as 1 in 10 admissions to hospitals around the world. Countries have reported a remarkably similar burden of this condition at the health system level since the 1950s, but the causes of heart failure and the age of the people affected vary with resources and ecology. In populations with a high human-development index, coronary artery disease and hypertension among the elderly account for most cases of heart failure. Among the

world's poorest billion people, however, heart failure reflects poverty-driven exposure of children and young adults to rheumatogenic strains of streptococci and cardiotropic microorganisms (e.g., HIV, *Trypanosoma cruzi*, enteroviruses, *M. tuberculosis*), untreated high blood pressure, and nutrient deficiencies. The mechanisms of other causes of heart failure common in these populations—such as idiopathic dilated cardiomyopathy, peripartum cardiomyopathy, and endomyocardial fibrosis—remain unclear.

Of the 2.3 million annual cases of pediatric rheumatic heart disease, nearly half occur in sub-Saharan Africa. This disease leads to more than 33,000 cases of endocarditis, 252,000 strokes, and 680,000 deaths per year—almost all in developing countries. Researchers in Ethiopia have reported annual death rates as high as 12.5% in rural areas. In part because the prevention of rheumatic heart disease has not advanced since the disappearance of this disease in wealthy countries, no part of sub-Saharan Africa has yet eradicated rheumatic heart disease despite examples of success in Costa Rica, Cuba, and some Caribbean nations.

Strategies to eliminate rheumatic heart disease may depend on active case-finding confirmed by echocardiography among high-risk groups as well as efforts to extend access to surgical interventions among children with advanced valvular damage. Partnerships between established surgical programs and areas with limited or nonexistent facilities may help develop capacity and provide care to patients who would otherwise suffer an early and painful death. A long-term goal is the establishment of regional centers of excellence equipped to provide consistent, accessible, high-quality services.

In stark contrast to the extraordinary lengths to which patients in wealthy countries will go to treat ischemic cardiomyopathy, young patients with nonischemic cardiomyopathies in resource-poor settings have received little attention. These conditions account for as many as 25–30% of admissions for heart failure in sub-Saharan Africa and include poorly understood entities such as peripartum cardiomyopathy (which has an incidence in rural Haiti of 1 per 300 live births) and HIV cardiomyopathy. Multidrug regimens that include heart failure beta-blockers, ACE inhibitors, and other neurohormonal antagonists can dramatically reduce mortality risk and improve quality of life for these patients. Lessons learned in the scale-up of chronic care for HIV infection and TB may be illustrative as progress is made in establishing means to deliver cardiac therapies over a background of careful fluid management with diuretic drugs.

Because systemic investigation of the causes of stroke and heart failure in sub-Saharan Africa has begun only recently, little is known about the impact of elevated blood pressure in this portion of the continent. Modestly elevated blood pressure in the absence of tobacco use in populations with low rates of obesity may confer little risk of adverse events in the short run. In contrast, persistently elevated blood pressure above 180/110 goes largely undetected, untreated, and uncontrolled in this setting. In the Framingham cohort of men 45–74 years old, the prevalence of blood pressures above 210/120 declined from 1.8% in the 1950s to 0.1% in the 1990s with the introduction of effective antihypertensive agents. While debate continues about appropriate screening strategies and treatment thresholds, rural health centers staffed by nonphysicians must quickly gain access to essential antihypertensive medications.

In 1960, Paul Dudley White and colleagues reported on the prevalence of cardiovascular disease in the region near the Albert Schweitzer Hospital in Lambaréné, Gabon. Although the group found little evidence of myocardial infarction, they concluded that "*the high prevalence of mitral stenosis* [sic] is astonishing. . . . We believe strongly that it is a duty to help bring to these sufferers the benefits of better penicillin prophylaxis and of cardiac surgery when indicated. The same responsibility exists for those with correctable congenital cardiovascular defects."[2] Leaders from tertiary centers in sub-Saharan Africa and elsewhere have continued to call for prevention and treatment of the cardiovascular conditions of the poor. The reconstruction of health services in response to pandemic infectious disease offers an opportunity to identify and treat patients with organ damage and to undertake the prevention of cardiovascular and other chronic conditions of poverty.

Cancer Low- and middle-income countries accounted for 53% and 56%, respectively, of the 10 million cases and 7 million deaths due to cancer in 2000. By 2020, the total number of new cancer cases will rise by 29% in developed countries and by 73% in developing countries. Also by 2020, overall mortality from cancer will increase by 104%, and the increase will be fivefold higher in developing than in developed countries. "Western" lifestyle changes will be responsible for the increased incidence of cancers of the breast, colon, and prostate, but historic realities, sociocultural and behavioral factors, genetics, and poverty itself will also have a profound impact on cancer-related mortality and morbidity. While infectious causes are responsible for <10% of cancers in developed countries, they account for 25% of all malignancies in low- and middle-income countries. Infectious causes of cancer such as human papillomavirus (cervical cancer), hepatitis B virus (liver cancer), and *Helicobacter pylori* (stomach cancer) will continue to have a much larger impact in developing countries. Environmental and dietary factors, such as indoor air pollution and high-salt diets, also help account for increased rates of certain cancers (e.g., lung and stomach cancers). Tobacco use (both smoking and chewing) is the most important source of increased mortality from lung and oral cancers. In contrast to decreasing tobacco use in many developed countries, the number of smokers is growing in developing countries, especially among women and young people.

For many reasons, outcomes of malignancies are far worse in developing countries than in developed nations. Overstretched health systems in poor countries simply are not capable of early detection; 80% of patients already have incurable malignancies at diagnosis. Treatment of cancers is available for only a very small number of mostly wealthy citizens in the majority of poor countries, and, even when treatment is available, the range and quality of services are often substandard.

Diabetes The International Diabetes Federation reports that the number of diabetics in the world is expected to increase from 194 million in 2003 to 330 million by 2030, when 3 of every 4 sufferers will live in developing countries. Because diabetics are far more frequently under the age of 65 in developing nations, the complications of micro- and macrovascular disease take a far greater toll. In 2005, an estimated 1.1 million people died of diabetes-related illnesses, and >80% of these deaths occurred in low- and middle-income countries.

Obesity and Tobacco Use In 2004, the WHO released its Global Strategy on Diet, Physical Activity and Health, which focused on the population-wide promotion of healthy diet and regular physical activity in an effort to reduce the growing global problem of overweight and obesity. Passing this strategy at the World Health Assembly proved difficult because of strong opposition from the food industry and from a number of WHO member states, including the United States. While globalization has had many positive effects, one negative aspect has been the growth in both developed and developing countries of well-financed lobbies that have aggressively promoted unhealthy dietary changes and increased consumption of alcohol and tobacco. Foreign direct investment in tobacco, beverage, and food products in developing countries reached $327 million in 2002—a figure nearly five times greater than the amount spent during that year to address NCDs by bilateral funding agencies, the WHO, and the World Bank combined.

The Three Pillars of Prevention The WHO estimates that 80% of all cases of cardiovascular disease and type 2 diabetes as well as 40% of all cancers can be prevented through the three pillars of healthy diet, physical activity, and avoidance of tobacco. While there is some evidence that population-based measures can have some impact on these behaviors, it is sobering to note that increasing obesity levels have not been successfully reversed in any population, including those of high-income countries with robust diet industries. Nonetheless, in Mauri-

[2]Miller DC et al: Survey of cardiovascular disease among Africans in the vicinity of the Albert Schweitzer Hospital in 1960. Am J Cardiol 19:432, 1962.

tius, for example, a single policy measure that changed the type of cooking oil available to the population led to a fall in mean serum cholesterol levels. Tobacco avoidance may be the most important and most difficult behavioral modification of all. In the twentieth century, 100 million people died worldwide of tobacco-related diseases; it is projected that >1 billion people will die of these diseases in the twenty-first century, with the vast majority of these deaths in developing countries. Today, 80% of the world's 1.2 billion smokers live in low- and middle-income countries, and, while tobacco consumption is falling in most developed countries, it continues to rise at a rate of ~3.4% per year in developing countries. The WHO's Framework Convention on Tobacco Control was a major advance, committing all of its signatories to a set of policy measures that have been shown to reduce tobacco consumption. However, most developing countries have continued to take a passive approach to the control of smoking.

ENVIRONMENTAL HEALTH

In a recent publication that examined how specific diseases and injuries are affected by environmental risk, the WHO determined that ~24% of the total GBD, one-third of the GBD among children, and 23% of all deaths are due to modifiable environmental factors. Many of these factors lead to deaths from infectious diseases; others lead to deaths from malignancies. Increasingly, etiology and nosology are difficult to parse. As much as 94% of diarrheal disease, which is linked to unsafe drinking water and poor sanitation, can be attributed to environmental factors. Risk factors such as indoor air pollution due to use of solid fuels, exposure to second-hand tobacco smoke, and outdoor air pollution account for 20% of lower respiratory infections in developed countries and for as many as 42% of such infections in developing countries. Various forms of unintentional injury and malaria top the list of health problems to which environmental factors contribute. Some 4 million children die every year from causes related to unhealthy environments, and the number of infant deaths due to environmental factors in developing countries is 12 times that in developed countries.

MENTAL HEALTH

The WHO reports that some 450 million people worldwide are affected by mental, neurologic, or behavioral problems at any given time and that ~873,000 people die by suicide every year. Major depression is the leading cause of lost DALYs in the world today. One in four patients visiting a health service has at least one mental, neurologic, or behavioral disorder, but most of these disorders are neither diagnosed nor treated. Most low- and middle-income countries devote <1% of their already-paltry health expenditures to mental health.

Increasingly effective therapies exist for many of the major causes of mental disorder. Effective treatments for many neurologic diseases, including seizure disorders, have long been available. One of the greatest barriers to delivery of such therapies is the paucity of skilled personnel. Most sub-Saharan African countries have only a handful of psychiatrists, for example; most of them practice in cities and are unavailable within the public sector or to patients living in poverty. Of the few patients who are fortunate enough to see a psychiatrist or neurologist, fewer still are able to adhere to treatment regimens: several surveys of already-diagnosed patients ostensibly receiving daily therapy have revealed that, among the poor, few can take their medications as prescribed. The same barriers that prevent the poor from having reliable access to insulin or ART also prevent them from benefiting from antidepressant, antipsychotic, and antiepileptic agents. To alleviate this problem, some authorities are proposing the training of health workers to provide community-based adherence support, counseling services, and referrals for patients in need of mental health services.

World Mental Health: Problems and Priorities in Low-Income Countries offers a comprehensive analysis of the burden of mental, behavioral, and social problems in low-income countries and relates the mental health consequences of social forces such as violence, dislocation, poverty, and the disenfranchisement of women to current economic, political, and environmental concerns.

HEALTH SYSTEMS AND THE "BRAIN DRAIN"

A significant and oft-invoked barrier to effective health care in resource-poor settings is the lack of medical personnel. In what is termed the *brain drain*, many physicians and nurses emigrate from their home countries to pursue opportunities abroad, leaving behind health systems that are understaffed and ill-equipped to deal with the epidemic diseases that ravage local populations. The WHO recommends a minimum of 20 physicians and 100 nurses per 100,000 persons, but recent reports from that organization and others confirm that many countries, especially in sub-Saharan Africa, fall far short of those target numbers. More than half of these countries register fewer than 10 physicians per 100,000 population. In contrast, the United States and Cuba register 279 and 596 doctors per 100,000 population, respectively. Similarly, the majority of sub-Saharan African countries do not have even half of the WHO-recommended minimum number of nurses. In addition to these appalling national aggregates, further inequalities in health care staffing exist *within* countries. Rural-urban disparities in health care personnel mirror disparities of both wealth and health. In 1992, the poorest districts in southern Africa reported 5.5 doctors, 188.1 nurses, and 0.5 pharmacists per 100,000 population. The same survey found, in the richest districts, 35.6 doctors, 375.3 nurses, and 5.4 pharmacists per 100,000 population. Nearly 90% of Malawi's population is rural, but >95% of clinical officers were at urban facilities, and 47% of nurses were at tertiary care facilities. Even community health workers, trained to provide first-line services to rural populations, often transfer to urban districts. In 1989 in Kenya, for example, there were only 138 health workers per 100,000 persons in the rural North Eastern Province, whereas there were 688 per 100,000 in Nairobi.

In addition to inter- and intranational transfer of personnel, the AIDS epidemic contributes to personnel shortages across Africa. Although data on the prevalence of HIV infection among health professionals are scarce, the available numbers suggest substantial and adverse impacts on an already-overburdened health sector. In 1999, it was estimated that 17–32% of health care workers in Botswana had HIV disease, and this number is expected to increase in the coming years. A recent study that examined the fates of a small cohort of Ugandan physicians found that at least 22 of the 77 doctors who graduated from Makerere University Medical School in 1984 had died by 2004—most, presumably, of AIDS. Similar numbers have been registered in South Africa, where a small study by the Human Sciences Research Council found an HIV seroprevalence among health professionals similar to that among the general population—in this case, 15.7% of all health care workers surveyed. The shortage of medical personnel in the areas hardest hit by HIV has profound implications for prevention and treatment efforts in these regions. The cycle of health-sector impoverishment, brain drain, and lack of personnel to fill positions when they are available conspires against ambitious programs to bring ART to persons living with both AIDS and poverty. The president of Botswana recently declared that one of his country's main obstacles to rapid expansion of HIV/AIDS treatment is "a dearth of doctors, nurses, pharmacists, and other health workers."[3] In South Africa, the departure of nearly 600 pharmacists in 2001, coupled with standing vacancies for 32,000 nurses, has put continued strain on that relatively affluent country's ability to respond to calls for expanded treatment programs. In Malawi, only 28% of established nursing posts are filled. Furthermore, the education of medical trainees is jeopardized as the ranks of the health and academic communities continue to shrink as a result of migration or disease. The long-term implications are sobering.

A proper biosocial analysis of the brain drain reminds us that the flight of health personnel—almost always, as most reviews suggest, from poor to less-poor regions—is not simply a question of desire for more equitable remuneration. Epidemiologic trends and access to the tools of the trade are also relevant, as are working conditions in general. In many settings now losing skilled health personnel, the advent of HIV has led to a sharp rise in TB incidence; in the eyes of health care providers, other

[3]Dugger C: Botswana's brain drain cripples war on AIDS. New York Times A10 (13 November 2003).

opportunistic infections have also become insuperable challenges. Together, these forces have conspired to render the provision of proper care impossible, as the comments of a Kenyan medical resident suggest: "Regarding HIV/AIDS, it is impossible to go home and forget about it. Even the simplest opportunistic infections we have no drugs for. Even if we do, there is only enough for a short course. It is impossible to forget about it. . . . Just because of the numbers, I am afraid of going to the floors. It is a nightmare thinking of going to see the patients. You are afraid of the risk of infection, diarrhea, urine, vomit, blood. . . . It is frightening to think about returning."[4] Another resident noted, "Before training we thought of doctors as supermen. . . . [Now] we are only mortuary attendants."[5] Nurses and other providers are, of course, similarly affected.

Given the difficult conditions under which these health care personnel work, is it any surprise when the U.S. government's appointed Global AIDS Coordinator notes that there are more Ethiopian physicians practicing in Chicago than in all of Ethiopia? In Zambia, only 50 of the 600 doctors trained since the country's independence in 1964 remain in their home country. Nor is it surprising that a 1999 survey of medical students in Ghana in their final year of training revealed that 40 of 43 students planned to leave the country upon graduation. When providing care for the sick becomes a nightmare for those at the beginning of clinical training, physician burn-out soon follows among those who carry on in settings of impoverishment. In the public-sector institutions put in place to care for the poorest people, the confluence of epidemic disease, lack of resources with which to respond, and unrealistically high user fees has led to widespread burn-out among health workers. Patients and their families are those who pay most dearly for provider burn-out, just as they bear the burden of disease and—with the introduction of user fees—much of the cost of responding, however inadequately, to new epidemics and persistent plagues.

CONCLUSION: TOWARD A SCIENCE OF IMPLEMENTATION

Public-health strategies draw largely on quantitative methods—from epidemiology and biostatistics, but also from economics. Clinical practice, including internal medicine, draws on a rapidly expanding knowledge base but remains focused on individual patient care; clinical interventions are rarely population-based. In fact, neither public-health nor clinical approaches alone will prove adequate in addressing the problems of global health. There is a long way to go before evidence-based internal medicine is applied effectively among the world's poor. Complex infectious diseases such as AIDS and TB have proven difficult but not impossible to manage; drug resistance and a lack of effective health systems have further complicated such work. Beyond communicable disease, in the arena of chronic diseases (e.g., cardiovascular disease), global health is a nascent endeavor. Efforts to address any one of these problems in settings of great scarcity need to be integrated into broader efforts to strengthen failing health systems and to alleviate the growing personnel crisis within these systems.

For these reasons, scholarly work and practice in the field once known as international health and now often designated *global health equity* are changing rapidly. Such work is still informed by the tension between clinical practice and population-based interventions, between analysis and action. Once metrics are refined, how might they inform efforts to lessen the premature morbidity and mortality registered among the world's poor? As in the nineteenth century, human rights perspectives have proven helpful in turning attention to the problems of the destitute sick; such perspectives may also inform strategies of delivering care equitably. A number of university hospitals are developing training programs for physicians with interests in global health. In medical schools across the United States and in other wealthy countries, interest in global health has been exploding. An informal survey at Harvard Medical School in 2006 revealed that nearly one-quarter of the 160 entering students either had significant global health experience or were planning a career in global health. A similar sea-change among trainees has been reported at other medical schools. Half a century or even a decade ago, such high levels of interest would have been unimaginable.

Persistent epidemics, improved metrics, and growing interest have only recently been matched by an unprecedented investment in addressing the health problems of poor people in the developing world. Ours is a moment of opportunity. To ensure that the opportunity is not wasted, the basic facts need to be laid out for specialists and laypeople alike. More than 12 million people die each year simply because they live in poverty. An absolute majority of these premature deaths occur in Africa, with the poorer regions of Asia not far behind. Most of these deaths occur because the world's poorest do not have access to the fruits of science. They include deaths from vaccine-preventable illness; deaths during childbirth; deaths from infectious diseases that might be cured with access to antibiotics and other essential medicines; deaths from malaria that would have been prevented by bed nets and access to therapy; and deaths from water-borne illnesses. Other excess mortality is attributable to the inadequacy of efforts to develop new tools. Those funding the discovery and development of new tools typically neglect the concurrent need for strategies to make them available to the poor. Indeed, some would argue that the biggest challenge facing those who seek to address this outcome gap is the lack of practical means of distribution in the regions most heavily affected.

The development of tools must be followed in short order by their equitable distribution. When new preventive and therapeutic tools are developed without concurrent attention to delivery or implementation, we face what are sometimes termed *perverse effects:* even as new tools are developed, inequalities of outcome—less morbidity and mortality among those who can afford access, with sustained high morbidity and mortality among those who cannot—will grow in the absence of an equity plan to deliver the tools to those most at risk. Preventing such a future is the most important goal of global health.

3 Decision-Making in Clinical Medicine

Daniel B. Mark

To the medical student who requires 2 h to collect a patient's history and perform a physical examination, and several additional hours to organize them into a coherent presentation, the experienced clinician's ability to reach a diagnosis and decide on a management plan in a fraction of the time seems extraordinary. While medical knowledge and experience play a significant role in the senior clinician's ability to arrive at a differential diagnosis and plan quickly, much of the process involves skill in clinical decision-making. The first goal of this chapter is to provide an introduction to the study of clinical reasoning.

Equally bewildering to the student are the proper use of diagnostic tests and the integration of the results into the clinical assessment. The novice medical practitioner typically uses a "shotgun" approach to testing, hoping to hit a target without knowing exactly what that target is. The expert, on the other hand, usually has a specific target in mind and efficiently adjusts the testing strategy to it. The second goal of this chapter is to review briefly some of the crucial basic statistical concepts that govern the proper interpretation and use of diagnostic tests. Quantitative tools available to assist in clinical decision-making will also be discussed.

Evidence-based medicine is the term used to describe the integration of the best available research evidence with clinical judgment and experience in the care of patients. The third goal of this chapter is to provide a brief overview of some of the tools of evidence-based medicine.

CLINICAL DECISION-MAKING

CLINICAL REASONING

The most important clinical actions are not procedures or prescriptions but the judgments from which all other aspects of clinical medicine flow. In the modern era of large randomized trials and evidence-based medicine, it is easy to overlook the importance of this elusive mental activity and focus instead on the algorithmic practice guidelines constructed to improve care. One reason for this apparent neglect is that much more research has been done on how doctors *should* make decisions (e.g., using a Bayesian model, discussed below) than on how they actually *do*. Thus, much of what we know about clinical reasoning comes from empirical studies of nonmedical problem-solving behavior.

Despite the great technological advances of medicine over the last century, uncertainty still plays a pivotal role in all aspects of medical decision-making. We may know that a patient does not have long to live, but we cannot be certain how long. We may prescribe a potent new receptor blocker to reverse the course of a patient's illness, but we cannot be certain that the therapy will achieve the desired result and that result alone. Uncertainty in medical outcomes creates the need for probabilities and other mathematical/statistical tools to help guide decision-making. (These tools are reviewed later in the chapter.)

Uncertainty is compounded by the information overload that characterizes modern medicine. Today's experienced clinician needs close to 2 million pieces of information to practice medicine. Doctors subscribe to an average of seven journals, representing over 2500 new articles each year. Computers offer the obvious solution both for management of information and for better quantitation and management of the daily uncertainties of medical care. While the technology to computerize medical practice is available, many practical problems remain to be solved before patient information can be standardized and integrated with medical evidence on a single electronic platform.

The following three examples introduce the subject of clinical reasoning:

- A 46-year-old man presents to his internist with a chief complaint of hemoptysis. The physician knows that the differential diagnosis of hemoptysis includes over 100 different conditions, including cancer and tuberculosis. The examination begins with some general background questions, and the patient is asked to describe his symptoms and their chronology. By the time the examination is completed, and even before any tests are run, the physician has formulated a working diagnostic hypothesis and planned a series of steps to test it. In an otherwise healthy and nonsmoking patient recovering from a viral bronchitis, the doctor's hypothesis would be that the acute bronchitis is responsible for the small amount of blood-streaked sputum the patient observed. In this case, a chest x-ray may provide sufficient reassurance that a more serious disorder is not present.
- A second 46-year-old patient with the same chief complaint who has a 100-pack-year smoking history, a productive morning cough, and episodes of blood-streaked sputum may generate the principal diagnostic hypothesis of carcinoma of the lung. Consequently, along with the chest x-ray, the physician obtains a sputum cytology examination and refers this patient for fiberoptic bronchoscopy.
- A third 46-year-old patient with hemoptysis who is from a developing country is evaluated with an echocardiogram as well, because the physician thinks she hears a soft diastolic rumbling murmur at the apex on cardiac auscultation, suggesting rheumatic mitral stenosis.

These three simple vignettes illustrate two aspects of expert clinical reasoning: (1) the use of cognitive shortcuts as a way to organize the complex unstructured material that is collected in the clinical evaluation, and (2) the use of diagnostic hypotheses to consolidate the information and indicate appropriate management steps.

THE USE OF COGNITIVE SHORTCUTS

Cognitive shortcuts or rules of thumb, sometimes referred to as *heuristics*, can help solve complex problems, of the sort encountered daily in clinical medicine, with great efficiency. Clinicians rely on three basic types of heuristics. When assessing a particular patient, clinicians often weigh the probability that this patient's clinical features match those of the class of patients with the leading diagnostic hypotheses being considered. In other words, the clinician is searching for the diagnosis for which the patient appears to be a representative example; this cognitive shortcut is called the *representativeness heuristic*.

It may take only a few characteristics from the history for an expert clinician using the representativeness heuristic to arrive at a sound diagnostic hypothesis. For example, an elderly patient with new-onset fever, cough productive of copious sputum, unilateral pleuritic chest pain, and dyspnea is readily identified as fitting the pattern for acute pneumonia, probably of bacterial origin. Evidence of focal pulmonary consolidation on the physical examination will increase the clinician's confidence in the diagnosis because it fits the expected pattern of acute bacterial pneumonia. Knowing this allows the experienced clinician to conduct an efficient, directed, and therapeutically productive patient evaluation since there may be little else in the history or physical examination of direct relevance. The inexperienced medical student or resident, who has not yet learned the patterns most prevalent in clinical medicine, must work much harder to achieve the same result and is often at risk of missing the important clinical problem in a sea of compulsively collected but unhelpful data.

However, physicians using the representativeness heuristic can reach erroneous conclusions if they fail to consider the underlying prevalence of two competing diagnoses (i.e., the prior, or pretest, probabilities). Consider a patient with pleuritic chest pain, dyspnea, and a low-grade fever. A clinician might consider acute pneumonia and acute pulmonary embolism to be the two leading diagnostic alternatives. Using the representativeness heuristic, the clinician might judge both diagnostic candidates to be equally likely, although to do so would be wrong if pneumonia was much more prevalent in the underlying population. Mistakes may also result from a failure to consider that a pattern based on a small number of prior observations will likely be less reliable than one based on larger samples.

A second commonly used cognitive shortcut, the *availability heuristic*, involves judgments made on the basis of how easily prior similar

cases or outcomes can be brought to mind. For example, the experienced clinician may recall 20 elderly patients seen over the past few years who presented with painless dyspnea of acute onset and were found to have acute myocardial infarction. The novice clinician may spend valuable time seeking a pulmonary cause for the symptoms before considering and then confirming the cardiac diagnosis. In this situation, the patient's clinical pattern does not fit the expected pattern of acute myocardial infarction, but experience with this atypical presentation, and the ability to recall it, can help direct the physician to the diagnosis.

Errors with the availability heuristic can come from several sources of recall bias. For example, rare catastrophes are likely to be remembered with a clarity and force out of proportion to their value, and recent experience is, of course, easier to recall and therefore more influential on clinical judgments.

The third commonly used cognitive shortcut, the *anchoring heuristic*, involves estimating a probability by starting from a familiar point (the anchor) and adjusting to the new case from there. Anchoring can be a powerful tool for diagnosis but is often used incorrectly. For example, a clinician may judge the probability of coronary artery disease (CAD) to be very high after a positive exercise thallium test, because the prediction has been anchored to the test result ("positive test = high probability of CAD"). Yet, as discussed below, this prediction would be inaccurate if the clinical (pretest) picture of the patient being tested indicates a low probability of disease (e.g., a 30-year-old woman with no risk factors). As illustrated in this example, anchors are not necessarily the same as the pretest probability (see "Measures of Disease Probability and Bayes' Theorem," below).

DIAGNOSTIC HYPOTHESIS GENERATION

Cognitive scientists studying the thought processes of expert clinicians have observed that clinicians group data into packets, or "chunks," which are stored in their memories and manipulated to generate diagnostic hypotheses. Because short-term memory can typically hold only 7–10 items at a time, the number of packets that can be actively integrated into hypothesis-generating activities is similarly limited. The cognitive shortcuts discussed above play a key role in the generation of diagnostic hypotheses, many of which are discarded as rapidly as they are formed.

A diagnostic hypothesis sets a context for diagnostic steps to follow and provides testable predictions. For example, if the enlarged and quite tender liver felt on physical examination is due to acute hepatitis (the hypothesis), certain specific liver function tests should be markedly elevated (the prediction). If the tests come back normal, the hypothesis may need to be discarded or substantially modified.

One of the factors that make teaching diagnostic reasoning difficult is that expert clinicians do not follow a fixed pattern in patient examinations. From the outset, they are generating, refining, and discarding diagnostic hypotheses. The questions they ask in the history are driven by the hypotheses they are working with at the moment. Even the physical examination is driven by specific questions rather than a preordained checklist. While the student is palpating the abdomen of the alcoholic patient, waiting for a finding to strike him, the expert clinician is on a focused search mission. Is the spleen enlarged? How big is the liver? Is it tender? Are there any palpable masses or nodules? Each question focuses the attention of the examiner to the exclusion of all other inputs until answered, allowing the examiner to move on to the next specific question.

Negative findings are often as important as positive ones in establishing and refining diagnostic hypotheses. Chest discomfort that is not provoked or worsened by exertion in an active patient reduces the likelihood that chronic ischemic heart disease is the underlying cause. The absence of a resting tachycardia and thyroid gland enlargement reduces the likelihood of hyperthyroidism in a patient with paroxysmal atrial fibrillation.

The acuity of a patient's illness can play an important role in overriding considerations of prevalence and other issues described above. For example, clinicians are taught to consider aortic dissection routinely as a possible cause of acute severe chest discomfort along with myocardial infarction, even though the typical history of dissection is different from myocardial infarction and dissection is far less prevalent (Chap. 242). This recommendation is based on the recognition that a relatively rare but catastrophic diagnosis like aortic dissection is very difficult to make unless it is explicitly considered. If the clinician fails to elicit any of the characteristic features of dissection by history and finds equivalent blood pressures in both arms and no pulse deficits, he or she may feel comfortable in discarding the aortic dissection hypothesis. If, however, the chest x-ray shows a widened mediastinum, the hypothesis may be reinstated and a diagnostic test ordered [e.g., thoracic computed tomography (CT) scan, transesophageal echocardiogram] to evaluate it more fully. In nonacute situations, the prevalence of potential alternative diagnoses should play a much more prominent role in diagnostic hypothesis generation.

Generation of Diagnostic Hypotheses

Because the generation and evaluation of appropriate diagnostic hypotheses is a skill that not all clinicians possess to an equal degree, errors in this process can occur; in the patient with serious acute illness, these may lead to tragic consequences. Consider the following hypothetical example. A 45-year-old male patient with a 3-week history of a "flulike" upper respiratory infection (URI) presented to his physician with symptoms of dyspnea and a productive cough. Based on the presenting complaint, the clinician pulled out a "URI Assessment Form" to improve quality and efficiency of care. The physician quickly completed the examination components outlined on this structured form, noting in particular the absence of fever and a clear chest examination. He then prescribed an antibiotic for presumed bronchitis, showed the patient how to breathe into a paper bag to relieve his "hyperventilation," and sent him home with the reassurance that his illness was not serious. After a sleepless night with significant dyspnea unrelieved by breathing into a bag, the patient developed nausea and vomiting and collapsed. He was brought into the Emergency Department in cardiac arrest and could not be resuscitated. Autopsy showed a posterior wall myocardial infarction and a fresh thrombus in an atherosclerotic right coronary artery. What went wrong? The clinician decided, even before starting the history, that the patient's complaints were not serious. He therefore felt confident that he could perform an abbreviated and focused examination using the URI assessment protocol rather than considering the full range of possibilities and performing appropriate tests to confirm or refute his initial hypotheses. In particular, by concentrating on the "URI," the clinician failed to elicit the full dyspnea history, which would have suggested a far more serious disorder, and neglected to search for other symptoms that could have directed him to the correct diagnosis.

This example illustrates how patients can diverge from textbook symptoms and the potential consequences of being unable to adapt the diagnostic process to real-world challenges. The expert, while recognizing that common things occur commonly, approaches each evaluation on high alert for clues that the initial diagnosis may be wrong. Patients often provide information that "does not fit" with any of the leading diagnostic hypotheses being considered. Distinguishing real clues from false trails can only be achieved by practice and experience. A less-experienced clinician who tries to be too efficient (as in the above example) can make serious errors. Use of a rapid systematic clinical survey of symptoms and organ systems can help prevent the clinician from overlooking important but inapparent clues.

MAJOR INFLUENCES ON CLINICAL DECISION-MAKING

More than a decade of research on variations in clinician practice patterns has shed much light on forces that shape clinical decisions. The use of heuristic "shortcuts," as detailed above, provides a partial explanation, but several other key factors play an important role in shaping diagnostic hypotheses and management decisions. These factors can be grouped conceptually into three overlapping categories: (1) factors related to physicians' personal characteristics and practice style, (2) factors related to the practice setting, and (3) factors related to economic incentives.

Factors Related to Practice Style One of the key roles of the physician in medical care is to serve as the patient's agent to ensure that necessary care is provided at a high level of quality. Factors that influence this role include the physician's knowledge, training, and experience. It is obvious that physicians cannot practice evidence-based medicine (EBM; described later in the chapter) if they are unfamiliar with the evidence. As would be expected, specialists generally know the evidence in their field better than do generalists. Surgeons may be more enthusiastic about recommending surgery than medical doctors because their belief in the beneficial effects of surgery is stronger. For the same reason, invasive cardiologists are much more likely to refer chest pain patients for diagnostic catheterization than are noninvasive cardiologists or generalists. The physician beliefs that drive these different practice styles are based on personal experience, recollection, and interpretation of the available medical evidence. For example, heart failure specialists are much more likely than generalists to achieve target angiotensin-converting enzyme (ACE) inhibitor therapy in their heart failure patients because they are more familiar with what the targets are (as defined by large clinical trials), have more familiarity with the specific drugs (including dosages and side effects), and are less likely to overreact to foreseeable problems in therapy such as a rise in creatinine levels or symptomatic hypotension. Other intriguing research has shown a wide distribution of acceptance times of antibiotic therapy for peptic ulcer disease following widespread dissemination of the "evidence" in the medical literature. Some gastroenterologists accepted this new therapy before the evidence was clear (reflecting, perhaps, an aggressive practice style), and some gastroenterologists lagged behind (a conservative practice style, associated in this case with older physicians). As a group, internists lagged several years behind gastroenterologists.

The opinion of influential leaders can also have an important effect on practice patterns. Such influence can occur at both the national level (e.g., expert physicians teaching at national meetings) and the local level (e.g., local educational programs, "curbside consultations"). Opinion leaders do not have to be physicians. When conducting rounds with clinical pharmacists, physicians are less likely to make medication errors and more likely to use target levels of evidence-based therapies.

The patient's welfare is not the only concern that drives clinical decisions. The physician's perception about the risk of a malpractice suit resulting from either an erroneous decision or a bad outcome creates a style of practice referred to as *defensive medicine*. This practice involves using tests and therapies with very small marginal returns to preclude future criticism in the event of an adverse outcome. For example, a 40-year-old woman who presents with a long-standing history of intermittent headache and a new severe headache along with a normal neurologic examination has a very low likelihood of structural intracranial pathology. Performance of a head CT or magnetic resonance imaging (MRI) scan in this situation would constitute defensive medicine. On the other hand, the results of the test could provide reassurance to an anxious patient.

Practice Setting Factors Factors in this category relate to the physical resources available to the physician's practice and the practice environment. *Physician-induced demand* is a term that refers to the repeated observation that physicians have a remarkable ability to accommodate to and employ the medical facilities available to them. One of the foundational studies in outcomes research showed that physicians in Boston had an almost 50% higher hospital admission rate than did physicians in New Haven, despite there being no obvious differences in the health of the cities' inhabitants. The physicians in New Haven were not aware of using fewer hospital beds for their patients, nor were the Boston physicians aware of using less stringent criteria to admit patients. In both cities, physicians unconsciously adopted their practice styles to the available level of hospital beds.

Other environmental factors that can influence decision-making include the local availability of specialists for consultations and procedures, "high tech" facilities such as angiography suites, a heart surgery program, and MRI machines.

Economic Incentives Economic incentives are closely related to the other two categories of practice-modifying factors. Financial issues can exert both stimulatory and inhibitory influences on clinical practice. In general, physicians are paid on a fee-for-service, capitation, or salary basis. In fee-for-service, the more the physician does, the more the physician gets paid. The economic incentive in this case is to do more. When fees are reduced (discounted fee-for-service), doctors tend to increase the number of services billed for. Capitation, in contrast, provides a fixed payment per patient per year, encouraging physicians to take on more patients but to provide each patient with fewer services. Expensive services are more likely to be affected by this type of incentive than inexpensive preventive services. Salary compensation plans pay physicians the same regardless of the amount of clinical work performed. The incentive here is to see fewer patients.

In summary, expert clinical decision-making can be appreciated as a complex interplay between cognitive devices used to simplify large amounts of complex information interacting with physician biases reflecting education, training, and experience, all of which are shaped by powerful, sometimes perverse, external forces. In the next section, a set of statistical tools and concepts that can assist in making clinical decisions in the presence of uncertainty are reviewed.

QUANTITATIVE METHODS TO AID CLINICAL DECISION-MAKING

The process of medical decision-making can be divided into two parts: (1) defining the available courses of action and estimating the likely outcomes with each, and (2) assessing the desirability of the outcomes. The former task involves integrating key information about the patient along with relevant evidence from the medical literature to create the structure of a decision. The remainder of this chapter will review some quantitative tools available to assist the clinician in these activities.

QUANTITATIVE MEDICAL PREDICTIONS

Diagnostic Testing: Measures of Test Accuracy The purpose of performing a test on a patient is to reduce uncertainty about the patient's diagnosis or prognosis and to aid the clinician in making management decisions. Although diagnostic tests are commonly thought of as laboratory tests (e.g., measurement of serum amylase level) or procedures (e.g., colonoscopy or bronchoscopy), any technology that changes our understanding of the patient's problem qualifies as a diagnostic test. Thus, even the history and physical examination can be considered a form of diagnostic test. In clinical medicine, it is common to reduce the results of a test to a dichotomous outcome, such as positive or negative, normal or abnormal. In many cases, this simplification results in the waste of useful information. However, such simplification makes it easier to demonstrate some of the quantitative ways in which test data can be used.

The accuracy of diagnostic tests is defined in relation to an accepted "gold standard," which is presumed to reflect the true state of the patient (Table 3-1). To define the diagnostic performance of a new test, an appropriate population must be identified (ideally patients in whom the new test would be used) and both the new and the gold standard tests are applied to all subjects. The results of the two tests are then compared. The *sensitivity* or *true-positive rate* of the new test is the proportion of patients with disease (defined by the gold standard) who have a positive (new) test. This measure reflects how well the test identifies patients with disease. The proportion of patients with disease who have a negative test is the *false-negative rate* and is calculated as 1 – sensitivity. The proportion of patients without disease who have a negative test is the *specificity* or *true-negative rate*. This measure reflects how well the test correctly identifies patients without disease. The proportion of patients without disease who have a positive test is the *false-positive rate*, calculated as 1 – specificity. A perfect test would have a sensitivity of 100% and a specificity of 100% and would completely separate patients with disease from those without it.

Calculating sensitivity and specificity requires selection of a decision value for the test to define the threshold value at or above which the test is considered "positive." For any given test, as this cut point is moved to

TABLE 3-1 MEASURES OF DIAGNOSTIC TEST ACCURACY

	Disease Status	
Test Result	**Present**	**Absent**
Positive	True-positive (*TP*)	False-positive (*FP*)
Negative	False-negative (*FN*)	True-negative (*TN*)
Identification of Patients with Disease		
True-positive rate (sensitivity) = *TP*/(*TP*+*FN*) False-negative rate = *FN*/(*TP*+*FN*) True-positive rate = 1 – false-negative rate		
Identification of Patients without Disease		
True-negative rate (specificity) = *TN*/(*TN*+*FP*) False-positive rate = *FP*/(*TN*+*FP*) True-negative rate = 1 – false-positive rate		

TABLE 3-2 MEASURES OF DISEASE PROBABILITY

Pretest probability of disease = probability of disease before test is done. May use population prevalence of disease or more patient-specific data to generate this probability estimate.

Posttest probability of disease = probability of disease accounting for both pretest probability and test results. Also called predictive value of the test.

Bayes' theorem: Computational version:

$$\text{Posttest probability} = \frac{\text{Pretest probability} \times \text{test sensitivity}}{\text{Pretest probability} \times \text{test sensitivity} + (1 - \text{pretest probability}) \times \text{test false-positive rate}}$$

Example [with a pretest probability of 0.50 and a "positive" diagnostic test result (test sensitivity = 0.90, test specificity = 0.90)]:

$$\text{Posttest probability} = \frac{(0.50)(0.90)}{(0.50)(0.90) + (0.50)(0.10)} = 0.90$$

improve sensitivity, specificity typically falls and vice versa. This dynamic tradeoff between more accurate identification of subjects with disease versus those without disease is often displayed graphically as a receiver operating characteristic (ROC) curve (Fig. 3-1). An ROC curve plots sensitivity (*y*-axis) versus 1 – specificity (*x*-axis). Each point on the curve represents a potential cut point with an associated sensitivity and specificity value. The area under the ROC curve is often used as a quantitative measure of the information content of a test. Values range from 0.5 (no diagnostic information at all, test is equivalent to flipping a coin) to 1.0 (perfect test).

In the testing literature, ROC areas are often used to compare alternative tests that can be used for a particular diagnostic problem (Fig. 3-1). The test with the highest area (i.e., closest to 1.0) is presumed to be the most accurate. However, ROC curves are not a panacea for evaluation of diagnostic test utility. Like Bayes' theorem (discussed below), they are typically focused on only one possible test parameter (e.g., ST-segment response in a treadmill exercise test) to the exclusion of other potentially relevant data. In addition, ROC area comparisons do not simulate the way test information is actually used in clinical practice. Finally, biases in the underlying population used to generate the ROC curves (e.g., related to an unrepresentative test sample) can bias the ROC area and the validity of a comparison among tests.

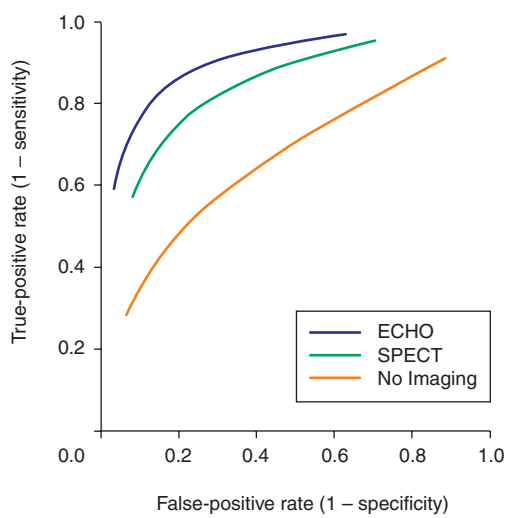

FIGURE 3-1 The receiver operating characteristic (ROC) curves for three diagnostic exercise tests for detection of CAD: exercise ECG, exercise SPECT, and exercise echo. Each ROC curve illustrates the trade-off that occurs between improved test sensitivity (accurate detection of patients with disease) and improved test specificity (accurate detection of patients without disease), as the test value defining when the test turns from "negative" to "positive" is varied. A 45° line would indicate a test with no information (sensitivity = specificity at every test value). The area under each ROC curve is a measure of the information content of the test. Moving to a test with a larger ROC area (e.g., from exercise ECG to exercise echo) improves diagnostic accuracy. However, these curves are not measured in the same populations and the effect of referral biases on the results cannot easily be discerned. *(From KE Fleischmann et al: JAMA 280:913, 1998, with permission.)*

Measures of Disease Probability and Bayes' Theorem Unfortunately, there are no perfect tests; after every test is completed, the true disease state of the patient remains uncertain. Quantitating this residual uncertainty can be done with Bayes' theorem. This theorem provides a simple mathematical way to calculate the posttest probability of disease from three parameters: the pretest probability of disease, the test sensitivity, and the test specificity (Table 3-2). The pretest probability is a quantitative expression of the confidence in a diagnosis before the test is performed. In the absence of more relevant information, it is usually estimated from the prevalence of the disease in the underlying population. For some common conditions, such as coronary artery disease (CAD), nomograms and statistical models have been created to generate better estimates of pretest probability from elements of the history and physical examination. The posttest probability, then, is a revised statement of the confidence in the diagnosis, taking into account what was known both before and after the test.

The term *predictive value* is often used as a synonym for the posttest probability. Unfortunately, clinicians commonly misinterpret reported predictive values as intrinsic measures of test accuracy. Studies of diagnostic tests compound the confusion by calculating predictive values on the same sample used to measure sensitivity and specificity. Since all posttest probabilities are a function of the prevalence of disease in the tested population, such calculations are clinically irrelevant unless the test is subsequently applied to populations with the same disease prevalence. For these reasons, the term *predictive value* is best avoided in favor of the more informative *posttest probability*.

To understand conceptually how Bayes' theorem estimates the posttest probability of disease, it is useful to examine a nomogram version of Bayes' theorem (Fig. 3-2). In this nomogram, the accuracy of the diagnostic test in question is summarized by the *likelihood ratio*, which is defined as the ratio of the probability of a given test result (e.g., "positive" or "negative") in a patient with disease to the probability of that result in a patient without disease.

For a positive test, the likelihood ratio is calculated as the ratio of the true-positive rate to the false-positive rate [or sensitivity/(1 – specificity)]. For example, a test with a sensitivity of 0.90 and a specificity of 0.90 has a likelihood ratio of 0.90/(1 – 0.90), or 9. Thus, for this hypothetical test, a "positive" result is 9 times more likely in a patient with the disease than in a patient without it. Most tests in medicine have likelihood ratios for a positive result between 1.5 and 20. Higher values are associated with tests that are more accurate at identifying patients with disease, with values of 10 or greater of particular note. If sensitivity is excellent but specificity is less so, the likelihood ratio will be substantially reduced (e.g., with a 90% sensitivity but a 60% specificity, the likelihood ratio is 2.25).

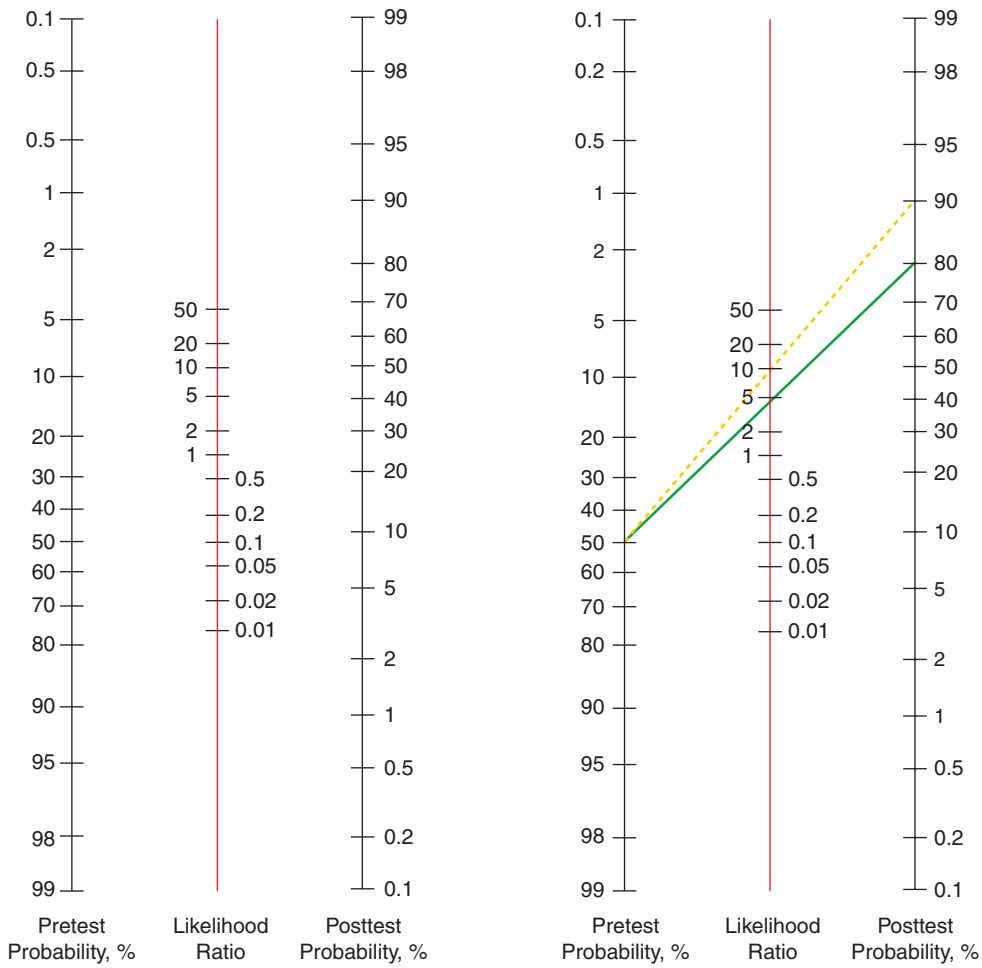

FIGURE 3-2 Nomogram version of Bayes' Theorem used to predict the posttest probability of disease (right-hand scale) using the pretest probability of disease (left-hand scale) and the likelihood ratio for a positive test (middle scale). See text for information on calculation of likelihood ratios. To use, place a straightedge connecting the pretest probability and the likelihood ratio and read off the posttest probability. The right-hand part of the figure illustrates the value of a positive exercise treadmill test (likelihood ratio 4, green line) and a positive exercise thallium SPECT perfusion study (likelihood ratio 9, broken yellow line) in the patient with a pretest probability of coronary artery disease of 50%. Treadmill results shown in solid line; thallium perfusion results in dashed line. *(From DB Mark: Screening Tests, in Atlas of Cardiovascular Risk Factors. Philadelphia, Current Medicine, LLC, 2006, with permission.)*

For a negative test, the corresponding likelihood ratio is the ratio of the false negative rate to the true negative rate [or (1 – sensitivity)/specificity]. The smaller the likelihood ratio (i.e., closer to 0) the better the test performs at ruling out disease. The hypothetical test we considered above with a sensitivity of 0.9 and a specificity of 0.9 would have a likelihood ratio for a negative test result of (1 – 0.9)/0.9 of 0.11, meaning that a negative result is almost 10 times more likely if the patient is disease-free than if he has disease.

Applications to Diagnostic Testing in CAD Consider two tests commonly used in the diagnosis of CAD, an exercise treadmill and an exercise single photon emission CT (SPECT) myocardial perfusion imaging test (Chap. 222). Meta-analysis has shown a positive treadmill ST-segment response to have an average sensitivity of 66% and an average specificity of 84%, yielding a likelihood ratio of 4.1 [0.66/(1 – 0.84)]. If we use this test on a patient with a pretest probability of CAD of 10%, the posttest probability of disease following a positive result rises to only about 30%. If a patient with a pretest probability of CAD of 80% has a positive test result, the posttest probability of disease is about 95%.

The exercise SPECT myocardial perfusion test is a more accurate test for the diagnosis of CAD. For our purposes, assume that the finding of a reversible exercise-induced perfusion defect has both a sensitivity and specificity of 90%, yielding a likelihood ratio for a positive test of 9.0 [0.90/(1 – 0.90)]. If we again test our low pretest probability patient and he has a positive test, using Fig. 3-2 we can demonstrate that the posttest probability of CAD rises from 10 to 50%. However, from a decision-making point of view, the more accurate test has not been able to improve diagnostic confidence enough to change management. In fact, the test has moved us from being fairly certain that the patient did not have CAD to being completely undecided (a 50:50 chance of disease). In a patient with a pretest probability of 80%, using the more accurate exercise SPECT test raises the posttest probability to 97% (compared with 95% for the exercise treadmill). Again, the more accurate test does not provide enough improvement in posttest confidence to alter management, and neither test has improved much upon what was known from clinical data alone.

If the pretest probability is low (e.g., 20%), even a positive result on a very accurate test will not move the posttest probability to a range high enough to rule in disease (e.g., 80%). Conversely, with a high pretest probability, a negative test will not adequately rule out disease. Thus, the largest gain in diagnostic confidence from a test occurs when the clinician is most uncertain before performing it (e.g., pretest probability between 30 and 70%). For example, if a patient has a pretest probability for CAD of 50%, a positive exercise treadmill test will move the posttest probability to 80% and a positive exercise SPECT perfusion test will move it to 90% (Fig. 3-2).

Bayes' theorem, as presented above, employs a number of important simplifications that should be considered. First, few tests have only two useful outcomes, positive or negative, and many tests provide numerous pieces of data about the patient. Even if these can be integrated into a summary result, multiple levels of useful information may be present (e.g., strongly positive, positive, indeterminate, negative, strongly negative). While Bayes' theorem can be adapted to this more detailed test result format, it is computationally complex to do so.

Finally, it has long been asserted that sensitivity and specificity are prevalence-independent parameters of test accuracy, and many texts still make this statement. This statistically useful assumption, however, is clinically simplistic. A treadmill exercise test, for example, has a sensitivity in a population of patients with one-vessel CAD of around 30%, whereas its sensitivity in severe three-vessel CAD approaches 80%. Thus, the best estimate of sensitivity to use in a particular decision will often vary, depending on the distribution of disease stages present in the tested population. A hospitalized population typically has a higher prevalence of disease and in particular a higher prevalence of more advanced disease than an outpatient population. As a consequence, test sensitivity will tend to be higher in hospitalized patients, whereas test specificity will be higher in outpatients.

Statistical Prediction Models Bayes' theorem, as presented above, deals with a clinical prediction problem that is unrealistically simple relative to most problems a clinician faces. Prediction models, based on multivariable statistical models, can handle much more complex problems and substantially enhance predictive accuracy for specific situations. Their particular advantage is the ability to take into account many overlapping pieces of information and assign a relative weight to each based on its unique contribution to the prediction in question. For example, a logistic regression model to predict the probability of CAD takes into account all of the relevant independent factors from the clinical examination and diagnostic testing instead of the small handful of data that clinicians can manage in their heads or with Bayes' theorem. However, despite this strength, the models are too complex computationally to use without a calculator or computer (although this limit may be overcome once medicine is practiced from a fully computerized platform).

To date, only a handful of prediction models have been properly validated. The importance of independent validation in a population separate from the one used to develop the model cannot be overstated. An unvalidated prediction model should be viewed with the same skepticism appropriate for a new drug or medical device that has not been through rigorous clinical trial testing.

When statistical models have been compared directly with expert clinicians, they have been found to be more consistent, as would be expected, but not significantly more accurate. Their biggest promise, then, would seem to be to make less-experienced clinicians more accurate predictors of outcome.

DECISION SUPPORT TOOLS

DECISION SUPPORT SYSTEMS

Over the past 35 years, many attempts have been made to develop computer systems to help clinicians make decisions and manage patients. Conceptually, computers offer a very attractive way to handle the vast information load that today's physicians face. The computer can help by making accurate predictions of outcome, simulating the whole decision process, or providing algorithmic guidance. Computer-based predictions using Bayesian or statistical regression models inform a clinical decision but do not actually reach a "conclusion" or "recommendation." Artificial intelligence systems attempt to simulate or replace human reasoning with a computer-based analogue. To date, such approaches have achieved only limited success. Reminder or protocol-directed systems do not make predictions but use existing algorithms, such as practice guidelines, to guide clinical practice. In general, however, decision support systems have shown little impact on practice. Reminder systems, although not yet in widespread use, have shown the most promise, particularly in correcting drug dosing and in promoting adherence to guidelines. The full impact of these approaches will only be evaluable when computers are fully integrated into medical practice.

DECISION ANALYSIS

Compared with the methods discussed above, decision analysis represents a completely different approach to decision support. Its principal application is in decision problems that are complex and involve a substantial risk, a high degree of uncertainty in some key area, or an idiosyncratic feature that does not "fit" the available evidence. Five general steps are involved. First, the decision problem must be clearly defined. Second, the elements of the decision must be made explicit. This involves specifying the alternatives being considered, their relevant outcomes, the probabilities attached to each outcome, and the relative desirability (called "utility") of each outcome. Cost can also be assigned to each branch of the decision tree, allowing calculation of cost effectiveness. Typically, the data to populate a decision model are derived from the literature, from unpublished sources, from expert opinion and from other secondary sources. Third, the decision model must be "evaluated" to determine the net long-term health benefits and costs of each strategy being considered. Fourth, the incremental health benefits and costs of the more effective strategies must be calculated. Finally, extensive sensitivity analyses must be used to examine the effects on the results of varying the starting assumptions through plausible alternative values.

An example decision tree created to evaluate strategies for screening for human immunodeficiency virus (HIV) infection is shown in Fig. 3-3. Up to 20,000 new cases of HIV infection are believed to be caused each year in the United States by infected individuals who are unaware of their illness. In addition, about 40% of HIV-positive patients progress to AIDS within a year of their diagnosis. Early identification offers the opportunity both to prevent progression to AIDS through use of serial CD4 counts and measurements of viral load linked to selective use of combination antiretroviral therapy and to encourage reduction of risky sexual behavior.

The Centers for Disease Control and Prevention (CDC) proposed in 2003 that routine HIV testing should be a part of standard medical care. In a decision-model exploration of this proposed strategy compared with usual care, assuming a 1% prevalence of unidentified HIV infection in the population, routine screening of a cohort of 43-year-old men and women increased life expectancy by 5.5 days and cost $194 per subject screened. The cost-effectiveness ratio for screening relative to usual care was $15,078 per quality-adjusted life year. Results were sensitive to assumptions about the effectiveness of behavior modification on subsequent sexual behavior, the benefits of early therapy of HIV infection and the prevalence and incidence of HIV infection in the population targeted. This model, which required over 75 separate data points, provides novel insights into a clinical management problem that has not been subjected to a randomized clinical trial.

The process of building and evaluating decision models is generally too complex for use in real-time clinical management. The potential for this tool therefore lies in the development of a set of published models addressing a particular decision or policy area that can serve to highlight key pressure points in the problem. Although many published models tend to focus excessively on providing an "answer," their better role is to enhance understanding of the most important questions that deserve particular attention in clinical decision-making.

EVIDENCE-BASED MEDICINE

The "art of medicine" is traditionally defined as a practice combining medical knowledge (including scientific evidence), intuition, and judgment in the care of patients (Chap. 1). Evidence-based medicine (EBM) updates this construct by placing a much-greater emphasis on the processes by which the clinician gains knowledge of the most up-to-date and relevant clinical research. The key processes of EBM can be summarized in four steps:

1. Formulating the management question to be answered
2. Searching the literature and on-line databases for applicable research data

TABLE 3-3 SELECTED TOOLS FOR FINDING THE EVIDENCE IN EVIDENCE-BASED MEDICINE

Name	Description	Web Address	Availability
Evidence-Based Medicine Reviews	Comprehensive electronic database that combines and integrates: 1. The Cochrane Database of Systematic Reviews 2. ACP Journal Club 3. The Database of Abstracts of Reviews of Effectiveness	*http://www.ovid.com*	Subscription required; available through medical center libraries and other institutions
Cochrane Library	Collection of EBM databases including The Cochrane Database of Systematic Reviews—full text articles reviewing specific health care topics	*http://www.cochrane.org*	Subscription required; abstracts of systematic reviews available free online; some countries have funding to provide free access to all residents
ACP Journal Club	Collection of summaries of original studies and systematic reviews; published bimonthly; all data since 1991 available on Web site, updated yearly	*http://www.acpjc.org*	Subscription required
Clinical Evidence	Monthly updated directory of concise overviews of common clinical interventions	*http://www.clinicalevidence.com*	Subscription required; free access for UK and for developing countries
MEDLINE	National Library of Medicine database with citations back to 1966	*http://www.nlm.nih.gov*	Free via Internet

Note: ACP, American College of Physicians; EBM, evidence-based medicine.

3. Appraising the evidence gathered with regard to its validity and relevance
4. Integrating this appraisal with knowledge about the unique aspects of the patient (including preferences)

Steps 2 and 3 are the heart of EBM as it is currently used in practice. The process of searching the world's research literature and appraising the quality and relevance of studies thus identified can be quite time-consuming and requires skills and training that most clinicians do not possess. Thus, the best starting point for most EBM searches is the identification of recent systematic overviews of the problem in question (Table 3-3).

Generally, the EBM tools listed in Table 3-3 provide access to research information in one of two forms. The first, primary research reports, is the original peer-reviewed research work that is published in medical journals. Initial access to this information in an EBM search may be gained through MEDLINE, which provides access to a huge amount of data in abstract form. However, it is often difficult, using MEDLINE, to locate reports that are on point in a sea of irrelevant or unhelpful information and being reasonably certain that important reports have not been overlooked. The second form, systematic reviews, comprehensively summarizes the available evidence on a particular topic up to a certain date and provides the interpretation of the reviewer. Explicit criteria are used to find all the relevant scientific research and grade its quality. The prototype for this kind of resource is the Cochrane Database of Systematic Reviews. One of the key components of a systematic review is a meta-analysis. In the next two sections, we will review some of the major types of clinical research reports available in the literature and the process of aggregating those data into meta-analyses.

Sources of Evidence: Clinical Trials and Registries The notion of learning from observation of patients is as old as medicine itself. Over the last 50 years, our understanding of how best to turn raw observation into useful evidence has evolved considerably. Case reports, personal anecdotal experience, and small single-center case series are now recognized as having severe limitations to validity and have no role in formulating modern standards of practice. The major tools used to develop reliable evidence consist of the randomized clinical trial and the large observational registry. A registry or database is typically focused on a disease or syndrome (e.g., cancer, CAD, heart failure), a clinical procedure (e.g., bone marrow transplantation, coronary revascularization), or an administrative process (e.g., claims data used for billing and reimbursement).

By definition, in observational data the care of the patient is not controlled by the investigator. Carefully collected *prospective* observational data can achieve a level of quality approaching that of major clinical trial data. At the other end of the spectrum, data collected retrospectively (e.g., chart review) are limited in form and content to what previous observers thought was important to record, which may not serve the research question under study particularly well. Data not specifically collected for research (e.g., claims data) will often have important limitations that cannot be overcome in the analysis phase of the research. Advantages to observational data include the ability to capture a broader population than is typically represented in clinical trials. In addition, observational data are the primary source of evidence for questions where a randomized trial cannot or will not be performed. For example, it may be difficult to randomize patients to test diagnostic or therapeutic strategies that are unproven but widely accepted in practice. In addition, we cannot randomize patients to a gender, racial/ethnic group, socioeconomic status, or country of residence. We are also not willing to randomize patients to a potentially harmful intervention, such as smoking or overeating to develop obesity.

The major difference between a well-done clinical trial and a well-done prospective observational study of a particular management strategy is the lack of protection from treatment selection bias in the latter. The underlying concept in the use of observational data to compare diagnostic or therapeutic strategies is that there is enough uncertainty in practice that similar patients will be managed differently by different physicians. In short, the assumption is that there is an element of randomness (in the sense of disorder rather than in the formal statistical sense) to clinical management. In such cases, statistical models can be used to adjust for important imbalances and "level the playing field" so that a fair comparison among treatment options can be made. When management is clearly not random (e.g., all eligible left main coronary artery disease patients are referred for coronary bypass surgery), the problem may be too confounded for statistical correction, and observational data may not provide reliable evidence.

In general, use of concurrent controls is vastly preferable to historical controls. For example, comparison of current surgical management of left main coronary artery disease with left main patients treated medically during the 1970s (the last time these patients were routinely treated with medicine alone) would be extremely misleading since the quality of "medical therapy" has made huge improvements in the interval.

Randomized controlled clinical trials include the careful prospective design features of the best observational data studies but also include the use of random allocation of treatment. This design provides the best protection against confounding due to treatment selection bias (a major aspect of internal validity). However, the randomized trial may not have good external validity if the process of recruitment into the trial resulted in the exclusion of many potentially eligible subjects.

Consumers of medical evidence need to be aware that randomized trials vary widely in their quality and applicability to practice. The process of designing such a trial often involves a great many compromises. For example, trials designed to gain FDA approval for an inves-

tigational drug or device will need to address certain regulatory requirements that may result in a different trial design from what practicing clinicians would find useful.

Meta-Analysis The Greek prefix *meta* signifies something at a later or higher stage of development. Meta-analysis is research done on research data for the purpose of combining and summarizing the available evidence quantitatively. Although it can be used to combine nonrandomized studies, meta-analysis is most valuable when used to summarize all of the randomized trials on a particular therapeutic problem. Ideally, unpublished trials should be identified and included to avoid publication bias (i.e., "positive" trials are more likely to be published). Furthermore, some of the best meta-analyses obtain and analyze the raw patient-level data from the individual trials rather than working only with what is available in the published reports of each trial. Not all published meta-analyses are reliable sources of evidence on a particular problem. Their methodology must be carefully scrutinized to ensure proper study design and analysis. The results of a well-done meta-analysis are likely to be most persuasive if it includes at least several large-scale, properly performed randomized trials. In cases where the available trials are small or poorly done, meta-analysis should not be viewed as a remedy for the deficiency in primary trial data.

Meta-analyses typically focus on summary measures of relative treatment benefit, such as odds ratios or relative risks. Clinicians should also examine what absolute risk reduction (ARR) can be expected from the therapy. A useful summary metric of absolute treatment benefit is the number needed to treat (NNT) to prevent one adverse outcome event (e.g., death, stroke). NNT is simply 1/ARR. For example, if a hypothetical therapy reduced mortality over a 5-year follow-up by 33% (the relative treatment benefit) from 12% (control arm) to 8% (treatment arm), the absolute risk reduction would be 12% – 8% = 4% and the NNT = $^1/_4$ or 25. Thus, we would need to treat 25 patients for 5 years to prevent 1 death. If we applied our hypothetical treatment to a lower-risk population, say with a 6% 5-year mortality, the 33% relative treatment benefit would reduce absolute mortality by 2% (from 6 to 4%) and the NNT for the same therapy in this different group of patients would be 50. Although not always made explicit, comparisons of NNT estimates from different studies need to take account of the duration of follow-up used to create each estimate.

Clinical Practice Guidelines According to the 1990 Institute of Medicine definition, clinical practice guidelines are "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances." This definition provides emphasis to several crucial features of modern guideline development. First, guidelines are created using the tools of EBM. In particular, the core of the development process is a systematic literature search followed by a review of the relevant peer-reviewed literature. Second, guidelines are usually focused around a clinical disorder (e.g., adult diabetes, stable angina pectoris) or a health care intervention (e.g., cancer screening). Third, guidelines are intended to "assist" decision-making, not to define explicitly what decisions should be made in a particular situation. The primary objective is to improve the quality of medical care by identifying areas where care should be standardized, based on compelling evidence.

Guidelines are narrative documents constructed by an expert panel whose composition is often chosen by interested professional organizations. These panels vary in the degree to which they represent all relevant stakeholders. The guideline documents consist of a series of specific management recommendations, a summary indication of the quantity and quality of evidence supporting each recommendation, and a narrative discussion of the recommendations. Many recommendations have little or no supporting evidence and, thus, reflect the expert consensus of the guideline panel. In part to protect against errors by individual panels, the final step in guideline construction is peer review, followed by a final revision in response to the critiques provided.

Guidelines are closely tied to the process of quality improvement in medicine through their identification of evidence-based best practices. Such practices can be used as quality indicators. Examples include the proportion of acute MI patients who receive aspirin upon admission to a hospital and the proportion of heart-failure patients with depressed ejection fraction who are on an ACE inhibitor. Routine measurement and reporting of such quality indicators can produce selective improvements in quality, since many physicians prefer not to be outliers.

CONCLUSIONS

In this era of EBM, it is tempting to think that all the difficult decisions practitioners face have been or soon will be solved and digested into practice guidelines and computerized reminders. However, EBM provides practitioners with an ideal rather than a finished set of tools with which to manage patients. The significant contribution of EBM has been to promote the development of more powerful and user-friendly EBM tools that can be accessed by the busy practitioners. This is an enormously important contribution that is slowly changing the way medicine is practiced. One of the repeated admonitions of EBM pioneers has been to replace reliance on the local "gray-haired expert" (who may be often wrong but is rarely in doubt) with a systematic search for and evaluation of the evidence. But EBM has not eliminated the need for subjective judgments. Each systematic review or clinical practice guideline presents the interpretation of "experts" whose biases remain largely invisible to the review's consumers. In addition, meta-analyses cannot generate evidence where there are no adequate randomized trials, and most of what clinicians confront in practice will never be thoroughly tested in a randomized trial. For the foreseeable future, excellent clinical reasoning skills and experience supplemented by well-designed quantitative tools and a keen appreciation for individual patient preferences will continue to be of paramount importance in the professional life of medical practitioners.

4 Screening and Prevention of Disease

Gary J. Martin

A primary goal of health care is to prevent disease or to detect it early enough that intervention will be more effective. Strategies for disease screening and prevention are driven by evidence that testing and intervention are practical and effective. Currently most screening tests are readily available and inexpensive. Examples include tests that are biochemical (e.g., cholesterol, glucose), physiologic (e.g., blood pressure, growth curves), radiologic (e.g., mammogram, bone densitometry), or tissue specimens (e.g., Pap smear, fine-needle aspirations). In the future, it is anticipated that genetic testing will play an increasingly important role for predicting disease risk (Chap. 64). However, such tests are not widely used except for individuals at risk for high-penetrance genes based on family or ethnic history (e.g., *BRCA1*, *BRCA2*). The identification of low-penetrance but high-frequency genes that cause common disorders such as diabetes, hypertension, or macular degeneration offers the possibility of new genetic tests. However, any new screening test, whether based on genetic or other methods, must be subjected to rigorous evaluation of its sensitivity, specificity, impact on disease, and cost-effectiveness. Physicians and patients are continuously introduced to new screening tests, often in advance of complete evaluation. For example, the use of whole-body CT imaging has been advocated as a means to screen for a variety of disorders. Though appealing in concept, there is currently no evidence to justify this approach, which is associated with high cost and a substantial risk of false-positive results.

This chapter will review the basic principles of screening and prevention in the primary care setting. Recommendations for specific disorders, such as cardiovascular disease, diabetes, or cancer, are provided in the chapters dedicated to these topics.

BASIC PRINCIPLES OF SCREENING

In general, screening is most effective when applied to relatively common disorders that carry a large disease burden (Table 4-1). The five leading causes of mortality in the United States are heart diseases, malignant neoplasms, accidents, cerebrovascular diseases, and chronic obstructive pulmonary disease. Thus, many prevention strategies are targeted at these conditions. From a global health perspective, these same conditions are priorities, but malaria, malnutrition, AIDS, tuberculosis, and violence carry a heavy disease burden (Chap. 2).

A primary goal of screening is the early detection of a risk factor or disease at a stage when it can be corrected or cured. For example, most cancers have a better prognosis when identified as premalignant lesions or when they are still resectable. Similarly, early identification of hypertension or hyperlipidemia allows therapeutic interventions that reduce the long-term risk of cardiovascular or cerebrovascular events. However, early detection does not necessarily influence survival. For example, in some studies of lung cancer screening, tumors are identified at an earlier stage, but overall mortality does not differ between screened and unscreened populations. The apparent improvement in 5-year survival rates can be attributed to the detection of smaller tumors rather than a real change in clinical course after diagnosis. Similarly, the detection of prostate cancer may not lead to a mortality difference because the disease is often indolent and competing morbidities, such as coronary artery disease, may ultimately cause mortality (Chap. 78).

Disorders with a long latency period increase the potential gains associated with detection. For example, cancer of the cervix has a long latency between dysplasia and invasive carcinoma, providing an opportunity for detection by routine screening. It is hoped that the introduction of new papilloma virus vaccines will provide additional disease prevention, ultimately reducing the reliance on screening for cervical cancer. For colon cancer, an adenomatous polyp progresses to invasive cancer over 4–12 years, providing an opportunity to detect early lesions by fecal occult blood testing (FOBT) or endoscopy. On the other hand, breast cancer screening in premenopausal women is more challenging because of the relatively short interval between development of a localized breast cancer and metastasis to regional nodes (estimated to be ~12 months).

METHODS OF MEASURING HEALTH BENEFITS

It is not practical to perform all possible screening procedures. For example, screening for laryngeal cancer in smokers is not currently recommended. It is necessary to examine the strength of evidence in favor of screening measures relative to the cost and risk of false-positive tests. For example, should ultrasound be used to screen for ovarian cancer in average-risk women? It is currently estimated that the unnecessary laparotomies triggered by finding benign ovarian masses would actually cause more harm than the benefit derived from detecting the occasional curable ovarian cancer.

A variety of endpoints are used to assess the potential gain from screening and prevention interventions:

1. *The number of subjects screened to alter the outcome in one individual.* It is estimated, for example, that 731 women ages 65–69 would need to be screened by dual-energy x-ray absorptiometry (DEXA) and then treated appropriately to prevent one hip fracture from osteoporosis.
2. *The absolute and relative impact of screening on disease outcome.* A meta-analysis of Swedish mammography trials (ages 40–70) found that ~1.2 fewer women per thousand would die from breast cancer if they were screened over a 12-year period. By comparison, ~3 lives per 1000 might be saved from colon cancer in a population (ages 50–75) screened with annual FOBT over a 13-year period. Based on this analysis, colon cancer screening may actually save more women's lives than mammography. The impact of FOBT (8.8/1000 versus 5.9/1000) might be stated either as 3 lives per 1000 or as a 30% reduction in colon cancer death; thus, it is important to consider both the relative and absolute impact on numbers of lives saved.
3. *The cost per year of life saved* is used to assess the effectiveness of many screening and prevention strategies. Typically, strategies that cost <$30,000–50,000 per year of life saved are considered "cost-effective" (Chap. 3). For example, using alendronate to treat 65-year-old women with osteoporosis approaches this threshold of approximately $30,000 per year of life saved.
4. *Increase in average life expectancy for a population.* Predicted increases in life expectancy for various screening procedures are listed in Table 4-2. It should be noted, however, that the life-expectancy increase is an average that applies to a population and not to an individual. In reality, the vast majority of the screened population does not derive any benefit and possibly incurs a slight risk from false-positive results. A small subset of patients, however, will benefit greatly from being screened. For example, Pap smears do not benefit the 98% of women who never develop cancer of the cervix. However, for the 2% who would develop localized cervical cancer, Pap smears may add as much as 25 years to their lives. Some studies suggest that a 1-month gain of life expectancy is a reasonable goal for a population-based preventive strategy.

The U.S. Preventive Services Task Force (USPSTF) provides recommendations for evidence-based screening (Table 4-3). In addition to these population-based guidelines, it is reasonable to consider family and social history to identify individuals with special risk (*www.ahrq.gov/clinic/uspstfix.htm*). For example, when there is a significant family history of breast, colon, or prostate cancer, it is prudent to initiate screening about 10 years before the age when the youngest

TABLE 4-1 LIFETIME CUMULATIVE RISK

Breast cancer for women	10%
Colon cancer	6%
Cancer of the cervix for women[a]	2%
Domestic violence for women	Up to 15%
Hip fracture for Caucasian women	16%

[a]Assuming an unscreened population.

TABLE 4-2 ESTIMATED AVERAGE INCREASE IN LIFE EXPECTANCY FOR A POPULATION

Screening Procedure	Average Increase
Mammography:	
Women, 40–50 years	0–5 days
Women, 50–70 years	1 month
Pap smears, age 18–65	2–3 months
Screening treadmill for a 50-year-old (asymptomatic) man	8 days
PSA and digital rectal exam for a man >50 years	Up to 2 weeks
Getting a 35-year-old smoker to quit	3–5 years
Beginning regular exercise for a 40-year-old man (30 min 3 times a week)	9 months to 2 years

Note: PSA, prostate-specific antigen.

family member developed cancer. Screening should also be considered for many other common disorders pending the development of further evidence. Three examples are screening for diabetes (using fasting blood glucose), domestic violence, and coronary artery disease in intermediate-risk asymptomatic individuals.

Cost-Effectiveness Screening techniques must be cost-effective if they are to be applied to large populations. Costs include not only the expense of testing but also time away from work and potential risks. When the risk-to-benefit ratio is less favorable, it is useful to provide information to patients and factor their perspectives into the decision-making process. For example, many expert groups, including the USPSTF, recommend an individualized discussion about prostate cancer screening, as the decision-making process is complex and relies heavily on personal issues. Although the early detection of prostate cancer may intuitively seem desirable, risks include false-positive results that can lead to anxiety and unnecessary surgery. Potential complications from surgery and radiation treatment include erectile dysfunction, urinary incontinence, and bowel dysfunction. Some men may decline screening, while others may be more willing to accept the risks of an early-detection strategy. Another example of shared decision-making is the choice of colon cancer screening techniques (Chap. 78). In controlled studies, the use of annual FOBT reduces colon cancer deaths by 15–30%. Flexible sigmoidoscopy reduces colon cancer deaths by ~60%. Colonoscopy offers the same, or greater, benefit than flexible sigmoidoscopy, but its use incurs additional costs and risks. These screening procedures have not been directly compared in the same population, but the estimated cost to society is similar: $10,000–25,000 per year of life saved. Thus, while one patient may prefer the ease of preparation, less time disruption, and the lower risk of flexible sigmoidoscopy, others may prefer the sedation and thoroughness of colonoscopy.

When considering the impact of screening tests, it is important to recognize that tobacco and alcohol use, diet, and exercise comprise the vast majority of factors that influence preventable deaths in developed countries. Perhaps the single greatest preventive health care measure is to help patients quit smoking (Chap. 390).

TABLE 4-4 COUNSELING TO PREVENT DISEASE

Topic	Chapter Reference
Tobacco cessation	375
Drug and alcohol use	372, 373
Nutrition to maintain caloric balance and vitamin intake	60
Calcium intake in women >18 years	333
Folic acid: Women of childbearing age	61
Oral health	28
Aspirin use to prevent cardiovascular disease in selected men >40 years and women >50 years	225
Chemoprevention of breast cancer in women at high risk	76
STDs and HIV prevention	115, 173
Physical activity	
Sun exposure	51
Injury prevention (loaded handgun, seat belts, bicycle helmet)	
Issues in the elderly	8
Polypharmacy	
Fall prevention	
Hot water heater <120°	
Vision, hearing, dental evaluations	
Immunizations (pneumococcal, influenza)	

Note: STDs, sexually transmitted diseases.

TABLE 4-3 CLINICAL PREVENTIVE SERVICES FOR NORMAL-RISK ADULTS RECOMMENDED BY THE U.S. PREVENTIVE SERVICES TASK FORCE

Test or Disorder	Population,[a] Years	Frequency	Chapter Reference
Blood pressure, height and weight	>18	Periodically	64
Cholesterol	Men > 35	Every 5 years	225
	Women > 45	Every 5 years	
Diabetes	>45 or earlier, if there are additional risk factors	Every 3 years	323
Pap smear[b]	Within 3 years of onset of sexual activity or 21–65	Every 1–3 years	67
Chlamydia	Women 18–25	Every 1–2 years	160
Mammography[a]	Women > 40	Every 1–2 years	67, 76
Colorectal cancer[a]	>50		67, 77
fecal occult blood and/or		Every year	
sigmoidoscopy or		Every 5 years	
colonoscopy		Every 10 years	
Osteoporosis	Women > 65; >60 at risk	Periodically	333
Abdominal aortic aneurysm (ultrasound)	Men 65–75 who have ever smoked	Once	
Alcohol use	>18	Periodically	372
Vision, hearing	>65	Periodically	25, 26
Adult immunization			107, 108
Tetanus-diptheria (Td)	>18	Every 10 years	
Varicella (VZV)	Susceptibles only, >18	Two doses	
Measles, mumps, rubella (MMR)	Women, childbearing age	One dose	
Pneumococcal	>65	One dose	
Influenza	>50	Yearly	
Human papillomavirus (HPV)	Up to age 26	If not done prior	

[a]Screening is performed earlier and more frequently when there is a strong family history. Randomized, controlled trials have documented that fecal occult blood testing (FOBT) confers a 15 to 30% reduction in colon cancer mortality. Although randomized trials have not been performed for sigmoidoscopy or colonoscopy, well-designed case-control studies suggest similar or greater efficacy relative to FOBT.

[b]In the future, Pap smear frequency may be influenced by HPV testing and the HPV vaccine.

Note: Prostate-specific antigen (PSA) testing is capable of enhancing the detection of early-stage prostate cancer, but evidence is inconclusive that it improves health outcomes. PSA testing is recommended by several professional organizations and is widely used in clinical practice, but it is not currently recommended by the U.S. Preventive Services Task Force (Chap. 81).

COMMONLY ENCOUNTERED ISSUES

Despite compelling evidence that prevention strategies can have major health care benefits, implementation of these services is challenging because of competing demands on physician and patient time and because of gaps in health care reimbursement. Moreover, efforts to reduce disease risk frequently involve behavior changes (e.g., weight loss, exercise, seatbelts) or managing addictive conditions (e.g., tobacco and alcohol use) that are often recalcitrant to intervention. Public education and economic incentives are often useful, in addition to counseling by health care providers (Table 4-4).

A number of techniques can assist the physician with the growing number of recommended screening tests. An appropriately configured electronic health record can provide reminder systems that make it easier for physicians to track and meet guidelines. Some systems provide patients with secure access to their medical records, providing an additional means to enhance adherence to routine screening. Systems that provide nurses and other staff with standing orders are effective for smoking prevention and immunizations. The Agency for Healthcare Research and Quality and the Centers for Disease Control and Prevention have developed flow sheets as part of their "Put Prevention into Practice" program (*http://www.ahcpr.gov/clinic/ppipix.htm*). Age-specific recommendations for screening and counseling are summarized in Table 4-5.

A routine health care examination should be performed every 1–3 years before age 50 and every year thereafter. History should include medication use (prescription and nonprescription), allergies, dietary history, use of alcohol and tobacco, sexual practices, and a thorough family history, if not obtained previously. Routine measurements should include assessments of height, weight (body mass index), and blood pressure, in addition to the relevant physical examination. The increasing incidence of skin cancer underscores the importance of screening for suspicious skin lesions. Hearing and vision should be tested after age 65, or earlier if the patient describes difficulties. Other gender- and age-specific examinations are listed in Table 4-3. Counseling and instruction about self-examination (e.g., skin, breast) can be provided during the routine examination.

Many patients see a physician for ongoing care of chronic illnesses, and this visit provides an opportunity to include a "measure of prevention" for other health problems. For example, the patient seen for management of hypertension or diabetes can have breast cancer screening incorporated into one visit and a discussion about colon cancer screening at the next visit. Other patients may respond more favorably to a clearly defined visit that addresses all relevant screening and prevention interventions. Because of age or comorbidities, it may be appropriate in some patients to abandon certain screening and prevention activities, although there are fewer data about when to "sunset" these services. The risk of certain cancers, like cancer of the cervix, ultimately declines, and it is reasonable to cease Pap smears after about age 65 if previous recent Pap smears have been negative. For breast, colon, and prostate cancer, it is reasonable to reevaluate the need for screening after about age 75. For some older patients with advanced diseases such as severe chronic obstructive pulmonary disease or congestive heart failure or who are immobile, the benefit of some screening procedures is low, and other priorities emerge when life expectancy is <10 years. This shift in focus needs to be done tactfully and allows greater focus on the conditions likely to impact quality and length of life.

TABLE 4-5 AGE-SPECIFIC CAUSES OF MORTALITY AND CORRESPONDING PREVENTATIVE OPTIONS

Age Group	Leading Causes of Age-Specific Mortality	Screening Prevention Interventions to Consider for Each Specific Population
15–24	1. Accident 2. Homicide 3. Suicide 4. Malignancy 5. Heart disease	• Counseling on routine seat belt use, bicycle/motorcycle/ATV helmets (1) • Counseling on diet and exercise (5) • Discuss dangers of alcohol use while driving, swimming, boating (1) • Ask about vaccination status (tetanus, diphtheria, hepatitis B, MMR, rubella, varicella, meningitis, HPV) • Ask about gun use and/or gun possession (2,3) • Assess for substance abuse history including alcohol (2,3) • Screen for domestic violence (2,3) • Screen for depression and/or suicidal/homicidal ideation (2,3) • Pap smear for cervical cancer screening, discuss STD prevention (4) • Recommend skin, breast, and testicular self-exams (4) • Recommend UV light avoidance and regular sun screen use (4) • Measurement of blood pressure, height, weight and body mass index (5) • Discuss health risks of tobacco use, consider emphasis of cosmetic and economic issues to improve quit rates for younger smokers (4,5) • *Chlamydia* screening and contraceptive counseling for sexually active females • HIV, hepatitis B, and syphilis testing if there is high-risk sexual behavior(s) or any prior history of sexually transmitted disease
25–44	1. Accident 2. Malignancy 3. Heart disease 4. Suicide 5. Homicide 6. HIV	*As above plus consider the following:* • Readdress smoking status, encourage cessation at every visit (2,3) • Obtain detailed family history of malignancies and begin early screening/prevention program if patient is at significant increased risk (2) • Assess all cardiac risk factors (including screening for diabetes and hyperlipidemia) and consider primary prevention with aspirin for patients at >3% 5-year risk of a vascular event (3) • Assess for chronic alcohol abuse, risk factors for viral hepatitis, or other risks for development of chronic liver disease • Begin breast cancer screening with mammography at age 40 (2)
45–64	1. Malignancy 2. Heart disease 3. Accident 4. Diabetes mellitus 5. Cerebrovascular disease 6. Chronic lower respiratory disease 7. Chronic liver disease and cirrhosis 8. Suicide	• Consider prostate cancer screen with annual PSA and digital rectal exam at age 50 (or possibly earlier in African Americans or patients with family history) (1) • Begin colorectal cancer screening at age 50 with either fecal occult blood testing, flexible sigmoidoscopy, or colonoscopy (1) • Reassess vaccination status at age 50 and give special consideration to vaccines against *Streptococcus pneumoniae*, influenza, tetanus, and viral hepatitis • Consider screening for coronary disease in higher risk patients (2,5)
≥65	1. Heart disease 2. Malignancy 3. Cerebrovascular disease 4. Chronic lower respiratory disease 5. Alzheimer's disease 6. Influenza and pneumonia 7. Diabetes mellitus 8. Kidney disease 9. Accidents 10. Septicemia	*As above plus consider the following:* • Readdress smoking status, encourage cessation at every visit (1,2,3) • One-time ultrasound for AAA in men 65–75 who have ever smoked • Consider pulmonary function testing for all long-term smokers to assess for development of chronic obstructive pulmonary disease (3,7) • Vaccinate all smokers against influenza and *S. pneumoniae* at age 50 (6) • Screen all postmenopausal women (and all men with risk factors) for osteoporosis • Reassess vaccination status at age 65, emphasis on influenza and *S. pneumoniae* (3,7) • Screen for dementia and depression (5) • Screen for visual and hearing problems, home safety issues, and elder abuse (9)

Note: The numbers in parentheses refer to areas of risk in the mortality column affected by the specified intervention.

5 Principles of Clinical Pharmacology

Dan M. Roden

Drugs are the cornerstone of modern therapeutics. Nevertheless, it is well recognized among physicians and among the lay community that the outcome of drug therapy varies widely among individuals. While this variability has been perceived as an unpredictable, and therefore inevitable, accompaniment of drug therapy, this is not the case. The goal of this chapter is to describe the principles of clinical pharmacology that can be used for the safe and optimal use of available and new drugs.

Drugs interact with specific target molecules to produce their beneficial and adverse effects. The chain of events between administration of a drug and production of these effects in the body can be divided into two components, both of which contribute to variability in drug actions. The first component comprises the processes that determine drug delivery to, and removal from, molecular targets. The resultant description of the relationship between drug concentration and time is termed *pharmacokinetics*. The second component of variability in drug action comprises the processes that determine variability in drug actions despite equivalent drug delivery to effector drug sites. This description of the relationship between drug concentration and effect is termed *pharmacodynamics*. As discussed further below, pharmacodynamic variability can arise as a result of variability in function of the target molecule itself or of variability in the broad biologic context in which the drug-target interaction occurs to achieve drug effects.

Two important goals of the discipline of clinical pharmacology are (1) to provide a description of conditions under which drug actions vary among human subjects; and (2) to determine mechanisms underlying this variability, with the goal of improving therapy with available drugs as well as pointing to new drug mechanisms that may be effective in the treatment of human disease. The first steps in the discipline were empirical descriptions of the influence of disease X on drug action Y or of individuals or families with unusual sensitivities to adverse drug effects. These important descriptive findings are now being replaced by an understanding of the molecular mechanisms underlying variability in drug actions. Thus, the effects of disease, drug coadministration, or familial factors in modulating drug action can now be reinterpreted as variability in expression or function of specific genes whose products determine pharmacokinetics and pharmacodynamics. Nevertheless, it is the personal interaction of the patient with the physician or other health care provider that first identifies unusual variability in drug actions; maintained alertness to unusual drug responses continues to be a key component of improving drug safety.

Unusual drug responses, segregating in families, have been recognized for decades and initially defined the field of *pharmacogenetics*. Now, with an increasing appreciation of common polymorphisms across the human genome, comes the opportunity to reinterpret descriptive mechanisms of variability in drug action as a consequence of specific DNA polymorphisms, or sets of DNA polymorphisms, among individuals. This approach defines the nascent field of *pharmacogenomics*, which may hold the opportunity of allowing practitioners to integrate a molecular understanding of the basis of disease with an individual's genomic makeup to prescribe personalized, highly effective, and safe therapies.

INDICATIONS FOR DRUG THERAPY

It is self-evident that the benefits of drug therapy should outweigh the risks. Benefits fall into two broad categories: those designed to alleviate a symptom and those designed to prolong useful life. An increasing emphasis on the principles of evidence-based medicine and techniques such as large clinical trials and meta-analyses have defined benefits of drug therapy in specific patient subgroups. Establishing the balance between risk and benefit is not always simple: for example, therapies that provide symptomatic benefits but shorten life may be entertained in patients with serious and highly symptomatic diseases such as heart failure or cancer. These decisions illustrate the continuing highly personal nature of the relationship between the prescriber and the patient.

Some adverse effects are so common and so readily associated with drug therapy that they are identified very early during clinical use of a drug. On the other hand, serious adverse effects may be sufficiently uncommon that they escape detection for many years after a drug begins to be widely used. The issue of how to identify rare but serious adverse effects (that can profoundly affect the benefit-risk perception in an individual patient) has not been satisfactorily resolved. Potential approaches range from an increased understanding of the molecular and genetic basis of variability in drug actions to expanded postmarketing surveillance mechanisms. None of these have been completely effective, so practitioners must be continuously vigilant to the possibility that unusual symptoms may be related to specific drugs, or combinations of drugs, that their patients receive.

Beneficial and adverse reactions to drug therapy can be described by a series of dose-response relations (Fig. 5-1). Well-tolerated drugs

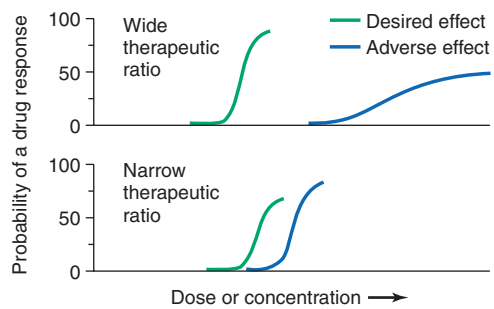

FIGURE 5-1 The concept of a therapeutic ratio. Each panel illustrates the relationship between increasing dose and cumulative probability of a desired or adverse drug effect. ***Top.*** A drug with a wide therapeutic ratio, i.e., a wide separation of the two curves. ***Bottom.*** A drug with a narrow therapeutic ratio; here, the likelihood of adverse effects at therapeutic doses is increased because the curves are not well separated. Further, a steep dose-response curve for adverse effects is especially undesirable, as it implies that even small dosage increments may sharply increase the likelihood of toxicity. When there is a definable relationship between drug concentration (usually measured in plasma) and desirable and adverse effect curves, concentration may be substituted on the abscissa. Note that not all patients necessarily demonstrate a therapeutic response (or adverse effect) at any dose, and that some effects (notably some adverse effects) may occur in a dose-independent fashion.

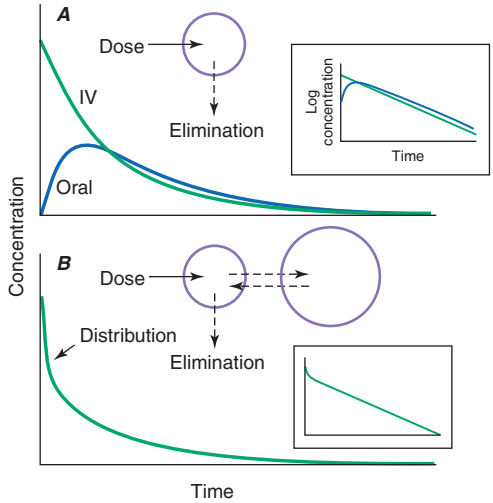

FIGURE 5-2 Idealized time-plasma concentration curves after a single dose of drug. *A.* The time course of drug concentration after an instantaneous IV bolus or an oral dose in the one-compartment model shown. The area under the time-concentration curve is clearly less with the oral drug than the IV, indicating incomplete bioavailability. Note that despite this incomplete bioavailability, concentration after the oral dose can be higher than after the IV dose at some time points. The inset shows that the decline of concentrations over time is linear on a log-linear plot, characteristic of first-order elimination, and that oral and IV drug have the same elimination (parallel) time course. ***B.*** The decline of central compartment concentration when drug is distributed both to and from a peripheral compartment and eliminated from the central compartment. The rapid initial decline of concentration reflects not drug elimination but distribution.

demonstrate a wide margin, termed the *therapeutic ratio*, *therapeutic index*, or *therapeutic window*, between the doses required to produce a therapeutic effect and those producing toxicity. In cases where there is a similar relationship between plasma drug concentration and effects, monitoring plasma concentrations can be a highly effective aid in managing drug therapy by enabling concentrations to be maintained above the minimum required to produce an effect and below the concentration range likely to produce toxicity. Such monitoring has been widely used to guide therapy with specific agents, such as certain antiarrhythmics, anticonvulsants, and antibiotics. Many of the principles in clinical pharmacology and examples outlined below, which can be applied broadly to therapeutics, have been developed in these arenas.

PRINCIPLES OF PHARMACOKINETICS

The processes of absorption, distribution, metabolism, and excretion—collectively termed *drug disposition*—determine the concentration of drug delivered to target effector molecules.

ABSORPTION

Bioavailability When a drug is administered orally, subcutaneously, intramuscularly, rectally, sublingually, or directly into desired sites of action, the amount of drug actually entering the systemic circulation may be less than with the intravenous route (Fig. 5-2*A*). The fraction of drug available to the systemic circulation by other routes is termed *bioavailability*. Bioavailability may be <100% for two reasons: (1) absorption is reduced, or (2) the drug undergoes metabolism or elimination prior to entering the systemic circulation.

When a drug is administered by a nonintravenous route, the peak concentration occurs later and is lower than after the same dose given by rapid intravenous injection, reflecting absorption from the site of administration (Fig. 5-2). The extent of absorption may be reduced because a drug is incompletely released from its dosage form, undergoes destruction at its site of administration, or has physicochemical properties such as insolubility that prevent complete absorption from its site of administration. Slow absorption is deliberately designed into "slow-release" or "sustained-release" drug formulations in order to minimize variation in plasma concentrations during the interval between doses.

"First-Pass" Effect When a drug is administered orally, it must transverse the intestinal epithelium, the portal venous system, and the liver prior to entering the systemic circulation (Fig. 5-3). Once a drug enters the enterocyte, it may undergo metabolism, be transported into the portal vein, or undergo excretion back into the intestinal lumen. Both excretion into the intestinal lumen and metabolism decrease systemic bioavailability. Once a drug passes this enterocyte barrier, it may also be taken up into the hepatocyte, where bioavailability can be further limited by metabolism or excretion into the bile. This elimination in intestine and liver, which reduces the amount of drug delivered to the systemic circulation, is termed *presystemic elimination*, or *first-pass elimination*.

Drug movement across the membrane of any cell, including enterocytes and hepatocytes, is a combination of passive diffusion and active transport, mediated by specific drug uptake and efflux molecules. The drug transport molecule that has been most widely studied is P-glycoprotein, the product of the normal expression of the *MDR1* gene. P-glycoprotein is expressed on the apical aspect of the enterocyte and on the canalicular aspect of the hepatocyte (Fig. 5-3); in both locations, it serves as an efflux pump, thus limiting availability of drug to the systemic circulation. P-glycoprotein is also an important component of the blood-brain barrier, discussed further below.

Drug metabolism generates compounds that are usually more polar and hence more readily excreted than parent drug. Metabolism takes place predominantly in the liver but can occur at other sites such as kidney, intestinal epithelium, lung, and plasma. "Phase I" metabolism involves chemical modification, most often oxidation accomplished by members of the cytochrome P450 (CYP) monooxygenase superfamily. CYPs that are especially important for drug metabolism (Table 5-1)

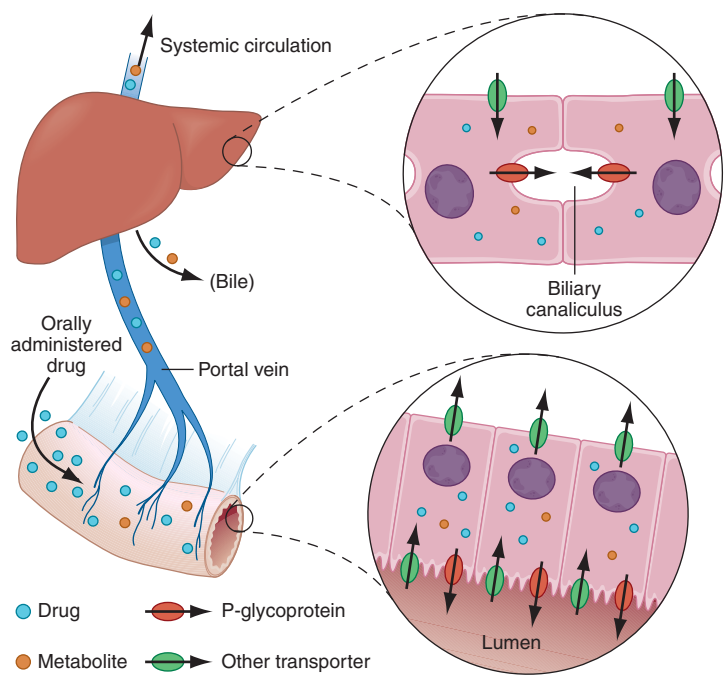

FIGURE 5-3 Mechanism of presystemic clearance. After drug enters the enterocyte, it can undergo metabolism, excretion into the intestinal lumen, or transport into the portal vein. Similarly, the hepatocyte may accomplish metabolism and biliary excretion prior to the entry of drug and metabolites to the systemic circulation. *[Adapted by permission from DM Roden, in DP Zipes, J Jalife (eds): Cardiac Electrophysiology: From Cell to Bedside, 4th ed. Philadelphia, Saunders, 2003. Copyright 2003 with permission from Elsevier.]*

TABLE 5-1 MOLECULAR PATHWAYS MEDIATING DRUG DISPOSITION

Molecule	Substrates[a]	Inhibitors[a]
CYP3A	Calcium channel blockers Antiarrhythmics (lidocaine, quinidine, mexiletine) HMG-CoA reductase inhibitors ("statins"; see text) Cyclosporine, tacrolimus Indinavir, saquinavir, ritonavir	Amiodarone Ketoconazole, itraconazole Erythromycin, clarithromycin Ritonavir
CYP2D6[b]	Timolol, metoprolol, carvedilol Phenformin Codeine Propafenone, flecainide Tricyclic antidepressants Fluoxetine, paroxetine	Quinidine (even at ultra-low doses) Tricyclic antidepressants Fluoxetine, paroxetine
CYP2C9[b]	Warfarin Phenytoin Glipizide Losartan	Amiodarone Fluconazole Phenytoin
CYP2C19[b]	Omeprazole Mephenytoin	
Thiopurine S-methyltransferase[b]	6-Mercaptopurine, azathioprine	
N-acetyltransferase[b]	Isoniazid Procainamide Hydralazine Some sulfonamides	
UGT1A1[b]	Irinotecan	
Pseudocholinesterase[b]	Succinylcholine	
P-glycoprotein	Digoxin HIV protease inhibitors Many CYP3A substrates	Quinidine Amiodarone Verapamil Cyclosporine Itraconazole Erythromycin

[a]Inhibitors affect the molecular pathway, and thus may affect substrate.
[b]Clinically important genetics variants described.
A listing of CYP substrates, inhibitors, and inducers is maintained at *http://medicine.iupui.edu/flockhart/table.htm*.

include CYP3A4, CYP3A5, CYP2D6, CYP2C9, CYP2C19, CYP1A2, and CYP2E1, and each drug may be a substrate for one or more of these enzymes. "Phase II" metabolism involves conjugation of specific endogenous compounds to drugs or their metabolites. The enzymes that accomplish phase II reactions include glucuronyl-, acetyl-, sulfo- and methyltransferases. Drug metabolites may exert important pharmacologic activity, as discussed further below.

Clinical Implications of Altered Bioavailability Some drugs undergo near-complete presystemic metabolism and thus cannot be administered orally. Nitroglycerin cannot be used orally because it is completely extracted prior to reaching the systemic circulation. The drug is therefore used by the sublingual or transdermal routes, which bypass presystemic metabolism.

Some drugs with very extensive presystemic metabolism can still be administered by the oral route, using much higher doses than those required intravenously. Thus, a typical intravenous dose of verapamil is 1–5 mg, compared to the usual single oral dose of 40–120 mg. Administration of low-dose aspirin can result in exposure of cyclooxygenase in platelets in the portal vein to the drug, but systemic sparing because of first-pass aspirin deacylation in the liver. This is an example of presystemic metabolism being exploited to therapeutic advantage.

DISTRIBUTION AND ELIMINATION

Most pharmacokinetic processes are first-order; i.e., the rate of the process depends on the amount of drug present. Clinically important exceptions are discussed below (see "Principles of Dose Selection"). In the simplest pharmacokinetic model (Fig. 5-2*A*), a drug bolus is administered instantaneously to a central compartment, from which drug elimination occurs as a first-order process. The first-order nature of drug elimination leads directly to the relationship describing drug concentration (C) at any time (t) following the bolus:

$$C = (\text{dose}/V_c) \cdot e^{(-0.69t/t_{1/2})}$$

where V_c is the volume of the compartment into which drug is delivered and $t_{1/2}$ is elimination half-life. As a consequence of this relationship, a plot of the logarithm of concentration vs time is a straight line (Fig. 5-2*A*, inset). *Half-life* is the time required for 50% of a first-order process to be complete. Thus, 50% of drug elimination is accomplished after one drug-elimination half-life, 75% after two, 87.5% after three, etc. In practice, first-order processes such as elimination are near-complete after four–five half-lives.

In some cases, drug is removed from the central compartment not only by elimination but also by distribution into peripheral compartments. In this case, the plot of plasma concentration vs time after a bolus may demonstrate two (or more) exponential components (Fig. 5-2*B*). In general, the initial rapid drop in drug concentration represents not elimination but drug distribution into and out of peripheral tissues (also first-order processes), while the slower component represents drug elimination; the initial precipitous decline is usually evident with administration by intravenous but not other routes. Drug concentrations at peripheral sites are determined by a balance between drug distribution to and redistribution from peripheral sites, as well as by elimination. Once the distribution process is near-complete (four to five distribution half-lives), plasma and tissue concentrations decline in parallel.

Clinical Implications of Half-Life Measurements The elimination half-life not only determines the time required for drug concentrations to fall to near-immeasurable levels after a single bolus; it is also the key determinant of the time required for steady-state plasma concentrations to be achieved after any change in drug dosing (Fig. 5-4). This applies to the initiation of chronic drug therapy (whether by multiple oral doses or by continuous intravenous infusion), a change in chronic drug dose or dosing interval, or discontinuation of drug.

Steady state describes the situation during chronic drug administration when the amount of drug administered per unit time equals drug eliminated per unit time. With a continuous intravenous infusion, plasma concentrations at steady state are stable, while with chronic oral drug administration, plasma concentrations vary during the dosing interval but the time-concentration profile between dosing intervals is stable (Fig. 5-4).

DRUG DISTRIBUTION

In a typical 70-kg human, plasma volume is ~3 L, blood volume is ~5.5 L, and extracellular water outside the vasculature is ~42 L. The volume of distribution of drugs extensively bound to plasma proteins but not to tissue components approaches plasma volume; warfarin is an example. By contrast, for drugs highly bound to tissues, the volume of distribution can be far greater than any physiologic space. For example, the volume of distribution of digoxin and tricyclic antidepressants is hundreds of liters, obviously exceeding total-body volume. Such drugs are not readily removed by dialysis, an important consideration in overdose.

Clinical Implications of Drug Distribution Digoxin accesses its cardiac site of action slowly, over a distribution phase of several hours. Thus,

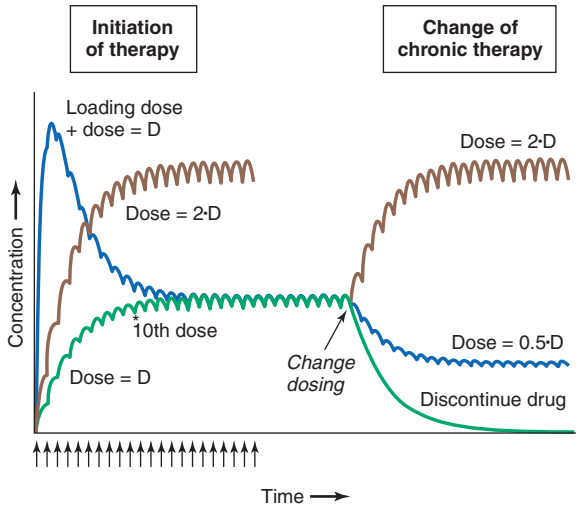

FIGURE 5-4 Drug accumulation to steady state. In this simulation, drug was administered (arrows) at intervals = 50% of the elimination half-life. Steady state is achieved during initiation of therapy after ~5 elimination half-lives, or 10 doses. A loading dose did not alter the eventual steady state achieved. A doubling of the dose resulted in a doubling of the steady state but the same time course of accumulation. Once steady state is achieved, a change in dose (increase, decrease, or drug discontinuation) results in a new steady state in ~5 elimination half-lives. *[Adapted by permission from DM Roden, in DP Zipes, J Jalife (eds): Cardiac Electrophysiology: From Cell to Bedside, 4th ed. Philadelphia, Saunders, 2003. Copyright 2003 with permission from Elsevier.]*

after an intravenous dose, plasma levels fall, but those at the site of action increase over hours. Only when distribution is near-complete does the concentration of digoxin in plasma reflect pharmacologic effect. For this reason, there should be a 6–8 h wait after administration before plasma levels of digoxin are measured as a guide to therapy.

Animal models have suggested, and clinical studies are confirming, that limited drug penetration into the brain, the "blood-brain barrier," often represents a robust P-glycoprotein–mediated efflux process from capillary endothelial cells in the cerebral circulation. Thus, drug distribution into the brain may be modulated by changes in P-glycoprotein function.

LOADING DOSES For some drugs, the indication may be so urgent that the time required to achieve steady-state concentrations may be too long. Under these conditions, administration of "loading" dosages may result in more rapid elevations of drug concentration to achieve therapeutic effects earlier than with chronic maintenance therapy (Fig. 5-4). Nevertheless, the time required for true steady state to be achieved is still determined only by elimination half-life. This strategy is only appropriate for drugs exhibiting a defined relationship between drug dose and effect.

Disease can alter loading requirements: in congestive heart failure, the central volume of distribution of lidocaine is reduced. Therefore, lower-than-normal loading regimens are required to achieve equivalent plasma drug concentrations and to avoid toxicity.

RATE OF INTRAVENOUS ADMINISTRATION Although the simulations in Fig. 5-2 use a single intravenous bolus, this is very rarely appropriate in practice because side effects related to transiently very high concentrations can result. Rather, drugs are more usually administered orally or as a slower intravenous infusion. Some drugs are so predictably lethal when infused too rapidly that special precautions should be taken to prevent accidental boluses. For example, solutions of potassium for intravenous administration >20 meq/L should be avoided in all but the most exceptional and carefully monitored circumstances. This minimizes the possibility of cardiac arrest due to accidental increases in infusion rates of more concentrated solutions.

While excessively rapid intravenous drug administration can lead to catastrophic consequences, transiently high drug concentrations after intravenous administration can occasionally be used to advantage. The use of midazolam for intravenous sedation, for example, depends upon its rapid uptake by the brain during the distribution phase to produce sedation quickly, with subsequent egress from the brain during the redistribution of the drug as equilibrium is achieved.

Similarly, adenosine must be administered as a rapid bolus in the treatment of reentrant supraventricular tachycardias (Chap. 226) to prevent elimination by very rapid ($t_{1/2}$ of seconds) uptake into erythrocytes and endothelial cells before the drug can reach its clinical site of action, the atrioventricular node.

PLASMA PROTEIN BINDING

Many drugs circulate in the plasma partly bound to plasma proteins. Since only unbound (free) drug can distribute to sites of pharmacologic action, drug response is related to the free rather than the total circulating plasma drug concentration.

Clinical Implications of Altered Protein Binding For drugs that are normally highly bound to plasma proteins (>90%), small changes in the extent of binding (e.g., due to disease) produce a large change in the amount of unbound drug, and hence drug effect. The acute-phase reactant α_1-acid glycoprotein binds to basic drugs, such as lidocaine or quinidine, and is increased in a range of common conditions, including myocardial infarction, surgery, neoplastic disease, rheumatoid arthritis, and burns. This increased binding can lead to reduced pharmacologic effects at therapeutic concentrations of total drug. Conversely, conditions such as hypoalbuminemia, liver disease, and renal disease can decrease the extent of drug binding, particularly of acidic and neutral drugs, such as phenytoin. Here, plasma concentration of free drug is increased, so drug efficacy and toxicity are enhanced if total (free + bound) drug concentration is used to monitor therapy.

CLEARANCE

When drug is eliminated from the body, the amount of drug in the body declines over time. An important approach to quantifying this reduction is to consider that drug concentration at the beginning and end of a time period are unchanged, and that a specific volume of the body has been "cleared" of the drug during that time period. This defines clearance as volume/time. Clearance includes both drug metabolism and excretion.

Clinical Implications of Altered Clearance • ***ADJUSTING DRUG DOSAGES*** While elimination half-life determines the time required to achieve steady-state plasma concentrations (C_{ss}), the *magnitude* of that steady state is determined by clearance (Cl) and dose alone. For a drug administered as an intravenous infusion, this relationship is

$$Css = \text{dosing rate}/Cl \qquad \text{or} \qquad \text{dosing rate} = Cl \times Css$$

When drug is administered orally, the average plasma concentration within a dosing interval ($C_{avg,ss}$) replaces C_{ss}, and bioavailability (F) must be included:

$$F \times \text{dosing rate} = Cl \times C_{avg,ss}$$

Genetic variants, drug interactions, or diseases that reduce the activity of drug-metabolizing enzymes or excretory mechanisms may lead to decreased clearance and hence a requirement for downward dose adjustment to avoid toxicity. Conversely, some drug interactions and genetic variants increase CYP expression, and hence increased drug dosage may be necessary to maintain a therapeutic effect.

THE CONCEPT OF HIGH-RISK PHARMACOKINETICS When drugs utilize a single pathway exclusively for elimination, any condition that inhibits that pathway (be it disease-related, genetic, or due to a drug interaction) can lead to dramatic changes in drug concentrations and thus increase the risk of concentration-related drug toxicity. For example, administration of drugs that inhibit P-glycoprotein reduces digoxin clearance, since P-glycoprotein is the major mediator of digoxin elimination; the risk of digoxin toxicity is high with this drug interaction unless digoxin dosages

are reduced. Conversely, when drugs undergo elimination by multiple drug metabolizing or excretory pathways, absence of one pathway (due to a genetic variant or drug interaction) is much less likely to have a large impact on drug concentrations or drug actions.

ACTIVE DRUG METABOLITES

From an evolutionary point of view, drug metabolism probably developed as a defense against noxious xenobiotics (foreign substances, e.g., from plants) to which our ancestors inadvertently exposed themselves. The organization of the drug uptake and efflux pumps and the location of drug metabolism in the intestine and liver prior to drug entry to the systemic circulation (Fig. 5-3) support this idea of a primitive protective function.

However, drug metabolites are not necessarily pharmacologically inactive. Metabolites may produce effects similar to, overlapping with, or distinct from those of the parent drug. For example, *N*-acetylprocainamide (NAPA) is a major metabolite of the antiarrhythmic procainamide. While it exerts antiarrhythmic effects, its electrophysiologic properties differ from those of the parent drug. Indeed, NAPA accumulation is the usual explanation for marked QT prolongation and torsades des pointes ventricular tachycardia (Chap. 226) during therapy with procainamide. Thus, the common laboratory practice of adding procainamide to NAPA concentrations to estimate a total therapeutic effect is inappropriate.

Prodrugs are inactive compounds that require metabolism to generate active metabolites that mediate the drug effects. Examples include many angiotensin-converting enzyme (ACE) inhibitors, the angiotensin receptor blocker losartan, the antineoplastic irinotecan, and the analgesic codeine (whose active metabolite morphine probably underlies the opioid effect during codeine administration). Drug metabolism has also been implicated in bioactivation of procarcinogens and in generation of reactive metabolites that mediate certain adverse drug effects (e.g., acetaminophen hepatotoxicity, discussed below).

PRINCIPLES OF PHARMACODYNAMICS

Once a drug accesses a molecular site of action, it alters the function of that molecular target, with the ultimate result of a drug effect that the patient or physician can perceive. For drugs used in the urgent treatment of acute symptoms, little or no delay is anticipated (or desired) between the drug-target interaction and the development of a clinical effect. Examples of such acute situations include vascular thrombosis, shock, malignant hypertension, or status epilepticus.

For many conditions, however, the indication for therapy is less urgent, and a delay between the interaction of a drug with its pharmacologic target(s) and a clinical effect is common. Pharmacokinetic mechanisms that can contribute to such a delay include uptake into peripheral compartments or accumulation of active metabolites. Commonly, the clinical effect develops as a downstream consequence of the initial molecular effect the drug produces. Thus, administration of a proton-pump inhibitor or an H_2-receptor blocker produces an immediate increase in gastric pH but ulcer healing that is delayed. Cancer chemotherapy inevitably produces delayed therapeutic effects, often long after drug is undetectable in plasma and tissue. Translation of a molecular drug action to a clinical effect can thus be highly complex and dependent on the details of the pathologic state being treated. These complexities have made pharmacodynamics and its variability less amenable than pharmacokinetics to rigorous mathematical analysis. Nevertheless, some clinically important principles can be elucidated.

A drug effect often depends on the presence of underlying pathophysiology. Thus, a drug may produce no action or a different spectrum of actions in unaffected individuals compared to patients. Further, concomitant disease can complicate interpretation of response to drug therapy, especially adverse effects. For example, high doses of anticonvulsants such as phenytoin may cause neurologic symptoms, which may be confused with the underlying neurologic disease. Similarly, increasing dyspnea in a patient with chronic lung disease receiving amiodarone therapy could be due to drug, underlying disease, or an intercurrent cardiopulmonary problem. Thus the presence of chronic lung disease may alter the risk-benefit ratio in a specific patient to argue against the use of amiodarone.

The concept that a drug interacts with a specific molecular receptor does not imply that the drug effect will be constant over time, even if stable drug and metabolite concentrations are maintained. The drug-receptor interaction occurs in a complex biologic milieu that it can vary to modulate the drug effect. For example, ion channel blockade by drugs, an important anticonvulsant and antiarrhythmic effect, is often modulated by membrane potential, itself a function of factors such as extracellular potassium or local ischemia. Thus, the effects of these drugs may vary depending on the external milieu. Receptors may be up- or down-regulated by disease or by the drug itself. For example, β-adrenergic blockers upregulate β-receptor density during chronic therapy. While this effect does not usually result in resistance to the therapeutic effect of the drugs, it may produce severe agonist–mediated effects (such as hypertension or tachycardia) if the blocking drug is abruptly withdrawn.

PRINCIPLES OF DOSE SELECTION

The desired goal of therapy with any drug is to maximize the likelihood of a beneficial effect while minimizing the risk of adverse effects. Previous experience with the drug, in controlled clinical trials or in postmarketing use, defines the relationships between dose (or plasma concentration) and these dual effects and provides a starting point for initiation of drug therapy.

Figure 5-1 illustrates the relationships among dose, plasma concentrations, efficacy, and adverse effects and carries with it several important implications:

1. *The target drug effect should be defined when drug treatment is started.* With some drugs, the desired effect may be difficult to measure objectively, or the onset of efficacy can be delayed for weeks or months; drugs used in the treatment of cancer and psychiatric disease are examples. Sometimes a drug is used to treat a symptom, such as pain or palpitations, and here it is the patient who will report whether the selected dose is effective. In yet other settings, such as anticoagulation or hypertension, the desired response is more readily measurable.

2. *The nature of anticipated toxicity often dictates the starting dose.* If side effects are minor, it may be acceptable to start at a dose highly likely to achieve efficacy and downtitrate if side effects occur. However, this approach is rarely if ever justified if the anticipated toxicity is serious or life-threatening; in this circumstance, it is more appropriate to initiate therapy with the lowest dose that may produce a desired effect.

3. *The above considerations do not apply if these relationships between dose and effects cannot be defined.* This is especially relevant to some adverse drug effects (discussed in further detail below) whose development is not readily related to drug dose.

4. *If a drug dose does not achieve its desired effect, a dosage increase is justified only if toxicity is absent and the likelihood of serious toxicity is small.* For example, a small percentage of patients with strong seizure foci require plasma levels of phenytoin >20 μg/mL to control seizures. Dosages to achieve this effect may be appropriate, if tolerated. Conversely, clinical experience with flecainide suggests that levels >1000 ng/mL, or dosages >400 mg/d, may be associated with an increased risk of sudden death; thus dosage increases beyond these limits are ordinarily not appropriate, even if the higher dosage appears tolerated.

Other mechanisms that can lead to failure of drug effect should also be considered; drug interactions and noncompliance are common examples. This is one situation in which measurement of plasma drug concentrations, if available, can be especially useful. Noncompliance is an especially frequent problem in the long-term treatment of diseases such as hypertension and epilepsy, occurring in ≥25% of patients in therapeutic environments in which no special effort is made to involve patients in the responsibility for their own health. Multidrug regimens

with multiple doses per day are especially prone to noncompliance.

Monitoring response to therapy, by physiologic measures or by plasma concentration measurements, requires an understanding of the relationships between plasma concentration and anticipated effects. For example, measurement of QT interval is used during treatment with sotalol or dofetilide to avoid marked QT prolongation that can herald serious arrhythmias. In this setting, evaluating the electrocardiogram at the time of anticipated peak plasma concentration and effect (e.g., 1–2 h postdose at steady state) is most appropriate. Maintained high aminoglycoside levels carry a risk of nephrotoxicity, so dosages should be adjusted on the basis of plasma concentrations measured at trough (predose). On the other hand, ensuring aminoglycoside efficacy is accomplished by adjusting dosage so that peak drug concentrations are above a minimal antibacterial concentration. For dose adjustment of other drugs (e.g., anticonvulsants), concentration should be measured at its lowest during the dosing interval, just prior to a dose at steady state (Fig. 5-4), to ensure a maintained therapeutic effect.

CONCENTRATION OF DRUGS IN PLASMA AS A GUIDE TO THERAPY

Factors such as interactions with other drugs, disease-induced alterations in elimination and distribution, and genetic variation in drug disposition combine to yield a wide range of plasma levels in patients given the same dose. Hence, if a predictable relationship can be established between plasma drug concentration and beneficial or adverse drug effect, measurement of plasma levels can provide a valuable tool to guide selection of an optimal dose. This is particularly true when there is a narrow range between the plasma levels yielding therapeutic and adverse effects, as with digoxin, theophylline, some antiarrhythmics, aminoglycosides, cyclosporine, and anticonvulsants. On the other hand, if drug access to important sites of action outside plasma is highly variable, monitoring plasma concentration may not provide an accurate guide to therapy (Fig. 5-5*A*).

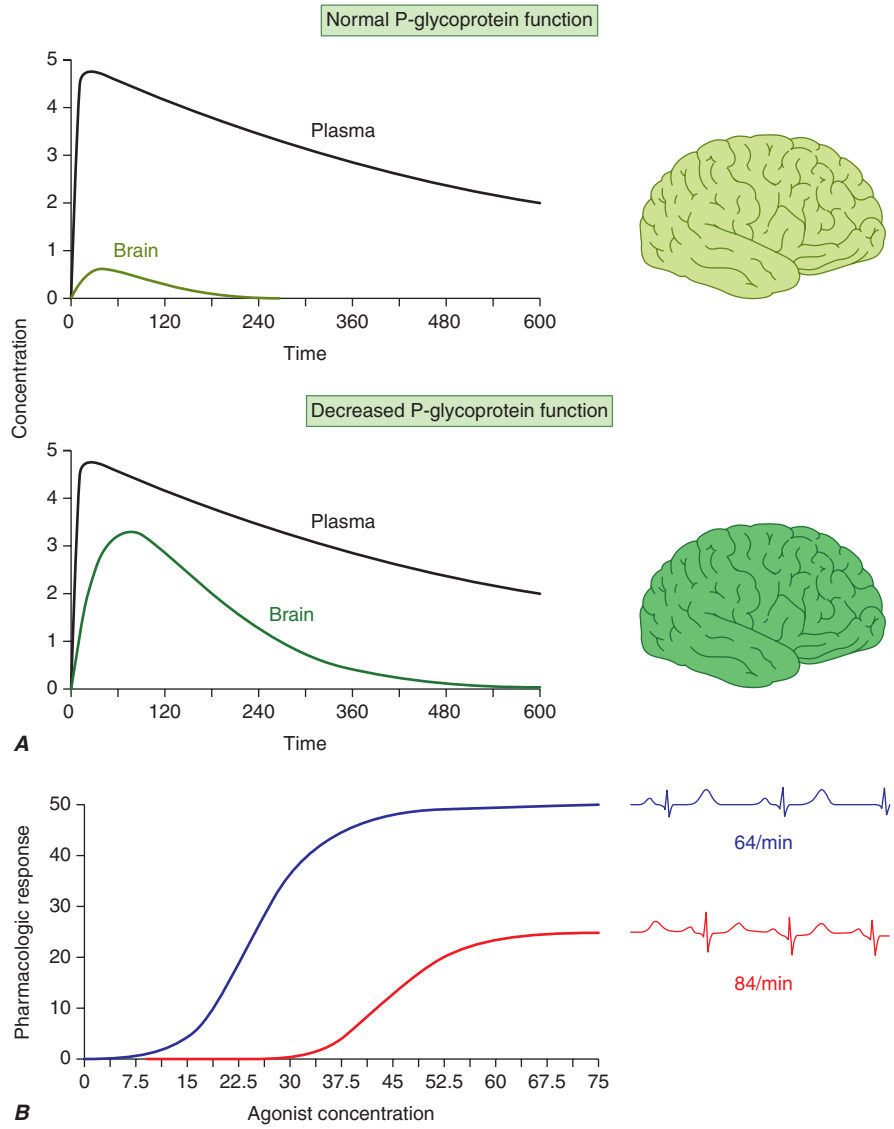

FIGURE 5-5 ***A.*** The efflux pump P-glycoprotein excludes drugs from the endothelium of capillaries in the brain, and so constitutes a key element of the blood-brain barrier. Thus, reduced P-glycoprotein function (e.g., due to drug interactions or genetically determined variability in gene transcription) increases penetration of substrate drugs into the brain, even when plasma concentrations are unchanged. ***B.*** The graph shows an effect of a β_1-receptor polymorphism on receptor function in vitro. Patients with the hypofunctional variant may display greater heart-rate slowing or blood pressure lowering on exposure to receptor blocking agents.

The common situation of first-order elimination implies that average, maximum, and minimum steady-state concentrations are related linearly to the dosing rate. Accordingly, the maintenance dose may be adjusted on the basis of the ratio between the desired and measured concentrations *at steady state*; for example, if a doubling of the steady-state plasma concentration is desired, the dose should be doubled. In some cases, elimination becomes saturated at high doses, and the process then occurs at a fixed amount per unit time (zero order). For drugs with this property (e.g., phenytoin and theophylline), plasma concentrations change disproportionately more than the alteration in the dosing rate. In this situation, changes in dose should be small to minimize the degree of unpredictability, and plasma concentration monitoring should be used to ensure that dose modification achieves the desired level.

DETERMINATION OF MAINTENANCE DOSE

An increase in dosage is usually best achieved by changing the drug dose but not the dosing interval, e.g., by giving 200 mg every 8 h instead of 100 mg every 8 h. However, this approach is acceptable only if the resulting maximum concentration is not toxic and the trough value does not fall below the minimum effective concentration for an undesirable period of time. Alternatively, the steady state may be changed by altering the frequency of intermittent dosing but not the size of each dose. In this case, the magnitude of the fluctuations around the average steady-state level will change—the shorter the dosing interval, the smaller the difference between peak and trough levels.

Fluctuation within a dosing interval is determined by the relationship between the dosing interval and the drug's half-life. If the dosing interval is equal to the drug's half-life, fluctuation is about twofold, which is usually acceptable. With drugs that have a low therapeutic ratio, dosage changes should be conservative (<50% dose change) and not more frequent than every three–four half-lives. Other drugs, such as many antihypertensives, have little dose-related toxicity, so the therapeutic ratio is large. Even if drug is eliminated rapidly, it can be given infrequently. Thus, 75 mg of captopril will result in reduced blood pressure for up to 12 h, even though captopril elimination half-life is about 2 h; this is because the dose raises the concentration of drug in plasma many times higher than the threshold for its pharmacologic effect.

EFFECTS OF DISEASE ON DRUG CONCENTRATION AND RESPONSE

RENAL DISEASE

Renal excretion of parent drug and metabolites is generally accomplished by glomerular filtration and by specific drug transporters, only now being identified. If a drug or its metabolites are primarily excreted through the kidneys and increased drug levels are associated with adverse effects, drug dosages must be reduced in patients with renal dysfunction to avoid toxicity. The antiarrhythmics dofetilide and sotalol undergo predominant renal excretion and carry a risk of QT prolongation and arrhythmias if doses are not reduced in renal disease. Thus, in end-stage renal disease, sotalol can be given as 40 mg after dialysis (every second day), compared to the usual daily dose, 80–120 mg every 12 h. The narcotic analgesic meperidine undergoes extensive hepatic metabolism, so that renal failure has little effect on its plasma concentration. However, its metabolite, normeperidine, does undergo renal excretion, accumulates in renal failure, and probably accounts for the signs of central nervous system excitation, such as irritability, twitching, and seizures, that appear when multiple doses of meperidine are administered to patients with renal disease. Protein binding of some drugs (e.g., phenytoin) may be altered in uremia, so measuring free drug concentration may be desirable.

In non-end-stage renal disease, changes in renal drug clearance are generally proportional to those in creatinine clearance, which may be measured directly or estimated from the serum creatinine (Chap. 272). This estimate, coupled with the knowledge of how much drug is normally excreted renally vs nonrenally, allows an estimate of the dose adjustment required. In practice, most decisions involving dosing adjustment in patients with renal failure use published recommended adjustments in dosage or dosing interval based on the severity of renal dysfunction indicated by creatinine clearance. Any such modification of dose is a first approximation and should be followed by plasma concentration data (if available) and clinical observation to further optimize therapy for the individual patient.

LIVER DISEASE

In contrast to the predictable decline in renal clearance of drugs in renal insufficiency, the effects of diseases like hepatitis or cirrhosis on drug disposition range from impaired to increased drug clearance, in an unpredictable fashion. Standard tests of liver function are not useful in adjusting doses. First-pass metabolism may decrease—and thus oral bioavailability increases—as a consequence of disrupted hepatocyte function, altered liver architecture, and portacaval shunts. The oral availability for high-first-pass drugs such as morphine, meperidine, midazolam, and nifedipine is almost doubled in patients with cirrhosis, compared to those with normal liver function. Therefore the size of the oral dose of such drugs should be reduced in this setting.

HEART FAILURE AND SHOCK

Under conditions of decreased tissue perfusion, the cardiac output is redistributed to preserve blood flow to the heart and brain at the expense of other tissues (Chap. 227). As a result, drugs may be distributed into a smaller volume of distribution, higher drug concentrations will be present in the plasma, and the tissues that are best perfused (the brain and heart) will be exposed to these higher concentrations. If either the brain or heart is sensitive to the drug, an alteration in response will occur. As well, decreased perfusion of the kidney and liver may impair drug clearance. Thus, in severe congestive heart failure, in hemorrhagic shock, and in cardiogenic shock, response to usual drug doses may be excessive, and dosage reduction may be necessary. For example, the clearance of lidocaine is reduced by about 50% in heart failure, and therapeutic plasma levels are achieved at infusion rates of 50% or less than those usually required. The volume of distribution of lidocaine is also reduced, so loading regimens should be reduced.

DRUG USE IN THE ELDERLY

In the elderly, multiple pathologies and medications used to treat them result in more drug interactions and adverse effects. Aging also results in changes in organ function, especially of the organs involved in drug disposition. Initial doses should be less than the usual adult dosage and should be increased slowly. The number of medications, and doses per day, should be kept as low as possible.

Even in the absence of kidney disease, renal clearance may be reduced by 35–50% in elderly patients. Dosage adjustments are therefore necessary for drugs that are eliminated mainly by the kidneys. Because muscle mass and therefore creatinine production are reduced in older individuals, a normal serum creatinine concentration can be present even though creatinine clearance is impaired; dosages should be adjusted on the basis of creatinine clearance, as discussed above. Aging also results in a decrease in the size of, and blood flow to, the liver and possibly in the activity of hepatic drug-metabolizing enzymes; accordingly, the hepatic clearance of some drugs is impaired in the elderly. As with liver disease, these changes are not readily predicted.

Elderly patients may display altered drug sensitivity. Examples include increased analgesic effects of opioids, increased sedation from benzodiazepines and other CNS depressants, and increased risk of bleeding while receiving anticoagulant therapy, even when clotting parameters are well controlled. Exaggerated responses to cardiovascular drugs are also common because of the impaired responsiveness of normal homeostatic mechanisms. Conversely, the elderly display decreased sensitivity to β-adrenergic receptor blockers.

Adverse drug reactions are especially common in the elderly because of altered pharmacokinetics and pharmacodynamics, the frequent use of multidrug regimens, and concomitant disease. For example, use of long half-life benzodiazepines is linked to the occurrence of hip fractures in elderly patients, perhaps reflecting both a risk of falls from these drugs (due to increased sedation) and the increased incidence of osteoporosis in elderly patients. In population surveys of the noninstitutionalized elderly, as many as 10% had at least one adverse drug reaction in the previous year.

GENETIC DETERMINANTS OF THE RESPONSE TO DRUGS

PRINCIPLES OF GENETIC VARIATION AND HUMAN TRAITS

(See also Chaps. 62 and 64) Variants in the human genome resulting in variation in level of expression or function of molecules important for pharmacokinetics and pharmacodynamics are increasingly recognized. These may be mutations (very rare variants, often associated with disease) or polymorphisms, variants that are much more common in a population. Variants may occur at a single nucleotide [known as single nucleotide polymorphism (SNP)] or involve insertion or deletion of one or more nucleotides. They may be in the exons (coding regions) or introns (noncoding intervening sequences). Exonic polymorphisms may or may not alter the encoded protein, and variant proteins may or may not display altered function. Similarly, polymorphisms in intronic regions may or may not alter gene expression and protein level.

As variation in the human genome is increasingly well documented, associations are being described between polymorphisms and various traits (including response to drug therapy). Some of these rely on well-developed chains of evidence, including in vitro studies demonstrating variant protein function, familial aggregation of the variant allele with the trait, and association studies in large populations. In other cases, the associations are less compelling. Identifying "real" associations is one challenge that must be overcome before the concept of genotyping to identify optimal drugs (or dosages) in individual patients prior to prescribing can be considered for widespread clinical practice. Nevertheless, the appeal of using genomic information to guide therapy is considerable.

Rates of drug efficacy and adverse effects often vary among ethnic groups. Many explanations for such differences are plausible; genomic approaches have now established that functionally important variants determining differences in drug response often display differing distributions among ethnic groups. This finding may have importance for drug use among ethnic groups, as well as in drug development.

GENETICALLY DETERMINED DRUG DISPOSITION AND VARIABLE EFFECTS

The concept that genetically determined variations in drug metabolism might be associated with variable drug levels, and hence effect, was advanced at the end of the nineteenth century, and the first exam-

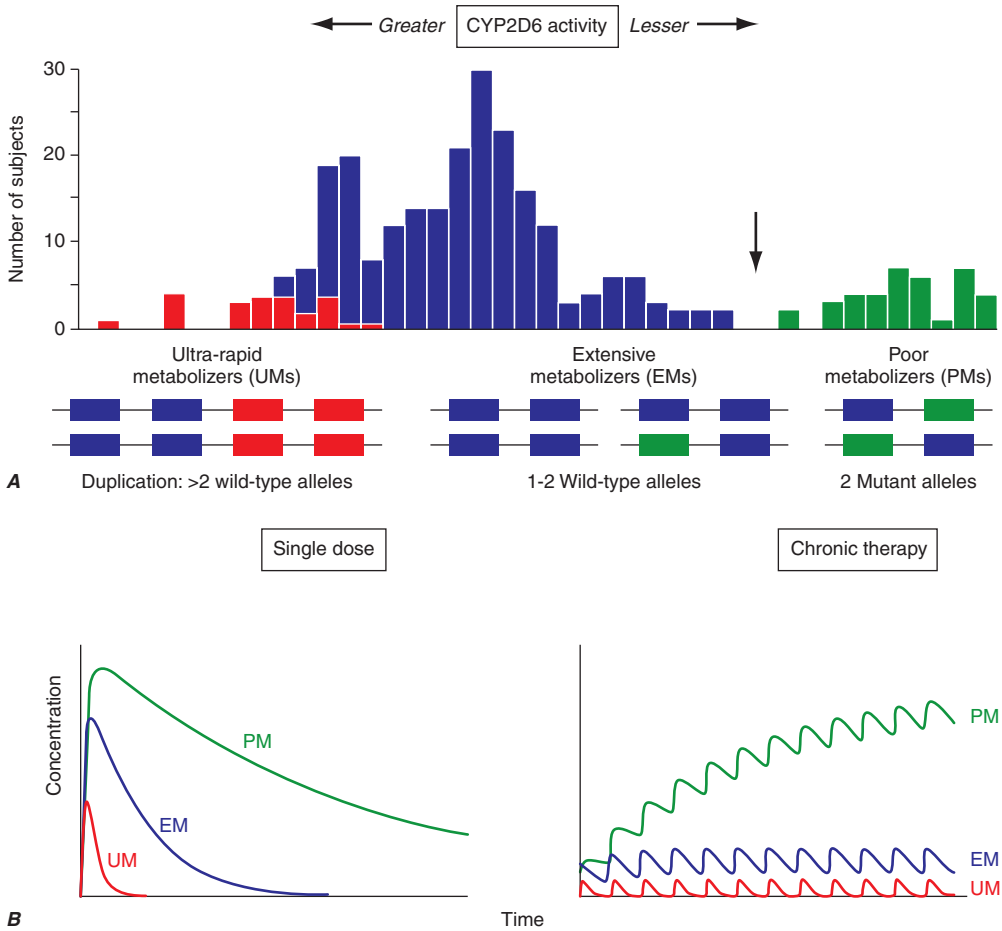

FIGURE 5-6 ***A.*** CYP2D6 metabolic activity was assessed in 290 subjects by administration of a test dose of a probe substrate and measurement of urinary formation of the CYP2D6-generated metabolite. The heavy arrow indicates a clear antimode, separating poor metabolizer subjects (PMs, green), with two loss-of-function CYP2D6 alleles, indicated by the intron-exon structures below the bar chart. Individuals with one or two functional alleles are grouped together as extensive metabolizers (EMs, blue). Also shown are ultrarapid metabolizers (UMs), with 2–12 functional copies of the gene (red), displaying the greatest enzyme activity. *(Adapted by permission from M-L Dahl et al: J Pharmacol Exp Ther 274:516, 1995.)* ***B.*** These simulations show the predicted effects of CYP2D6 genotype on disposition of a substrate drug. With a single dose (*left*), there is an inverse "gene-dose" relationship between the number of active alleles and the areas under the time-concentration curves (smallest in UM subjects; highest in PM subjects); this indicates that clearance is greatest in UM subjects. In addition, elimination half-life is longest in PM subjects. The right panel shows that these single dose differences are exaggerated during chronic therapy: steady-state concentration is much higher in PM subjects (decreased clearance), as is the time required to achieve steady state (longer elimination half-life).

ples of familial clustering of unusual drug responses due to this mechanism were noted in the mid-twentieth century. Clinically important genetic variants have been described in multiple molecular pathways of drug disposition (Table 5-1). A distinct multimodal distribution of drug disposition (as shown in Fig. 5-6) argues for a predominant effect of variants in a single gene in the metabolism of that substrate. Individuals with two alleles (variants) encoding for nonfunctional protein make up one group, often termed *poor metabolizers* (PM phenotype); many variants can produce such a loss of function, complicating the use of genotyping in clinical practice. Individuals with one functional allele make up a second (*intermediate metabolizers*) and may or may not be distinguishable from those with two functional alleles (*extensive metabolizers*, EMs). *Ultra-rapid metabolizers* with especially high enzymatic activity (occasionally due to gene duplication; Fig. 5-6) have also been described for some traits. Many drugs in widespread use can inhibit specific drug disposition pathways (Table 5-1), and so EM individuals receiving such agents can respond like PM patients (*phenocopying*). Polymorphisms in genes encoding drug uptake or drug efflux transporters may be another contributor to variability in drug delivery to target sites and, hence, drug effects. However, loss-of-function alleles in these genes have not yet been described.

CYP Variants CYP3A4 is the most abundant hepatic and intestinal CYP and is also the enzyme responsible for metabolism of the greatest number of drugs in therapeutic use. CYP3A4 activity is highly variable (up to an order of magnitude) among individuals, but the underlying mechanisms are not yet well understood. A closely related gene, encoding CYP3A5 (which shares substrates with CYP3A4), does display loss-of-function variants, especially in African-derived populations. CYP3A refers to both enzymes.

CYP2D6 is second to CYP3A4 in the number of commonly used drugs that it metabolizes. CYP2D6 is polymorphically distributed, with about 7% of European- and African-derived populations (but very few Asians) displaying the PM phenotype (Fig. 5-6). Dozens of loss-of-function variants in the CYP2D6 gene have been described; the PM phenotype arises in individuals with two such alleles. In addition, ultrarapid metabolizers with multiple functional copies of the CYP2D6 gene have been identified, particularly among northern Africans.

CYP2D6 represents the main metabolic pathway for a number of drugs (Table 5-1). Codeine is biotransformed by CYP2D6 to the potent active metabolite morphine, so its effects are blunted in PMs and exaggerated in ultrarapid metabolizers. In the case of drugs with beta-blocking properties metabolized by CYP2D6, including ophthalmic timolol and the sodium channel–blocking antiarrhythmic propafenone, PM subjects display greater signs of beta blockade (including bradycardia and bronchospasm) than EMs. Further, in EM subjects, propafenone elimination becomes zero-order at higher doses; so, for example, a tripling of the dose may lead to a tenfold increase in drug concentration. The oral hypoglycemic agent phenformin was withdrawn because it occasionally caused profound lactic acidosis; this likely arose as a result of high concentrations in CYP2D6 PMs. Ultrarapid metabolizers may require very high dosages of tricyclic antidepressants to achieve a therapeutic effect and, with codeine, may display transient euphoria and nausea due to very rapid generation of morphine. Tamoxifen undergoes CYP2D6-mediated biotransformation to an active metabolite, so its efficacy may be in part related to this polymorphism. In addition, the widespread use of selective serotonin reuptake inhibitors (SSRIs) to treat tamoxifen-related hot flashes may also alter the drug's effects since many SSRIs (fluoxetine, paroxetine) are also CYP2D6 inhibitors.

The PM phenotype for CYP2C19 is common (20%) among Asians and rarer (3–5%) in European-derived populations. The impact of polymorphic CYP2C19-mediated metabolism has been demonstrated with the proton pump inhibitor omeprazole, where ulcer cure rates with

"standard" dosages were markedly lower in EM patients (29%) than in PMs (100%). Thus, understanding the importance of this polymorphism would have been important in developing the drug, and knowing a patient's CYP2C19 genotype should improve therapy.

There are common allelic variants of *CYP2C9* that encode proteins with loss of catalytic function. These variant alleles are associated increased rates of neurologic complications with phenytoin and of hypoglycemia with glipizide. The angiotensin-receptor blocker losartan is a prodrug that is bioactivated by CYP2C9; as a result, PMs and those receiving inhibitor drugs may display little response to therapy.

Transferase Variants One of the most extensively studied phase II polymorphisms is the PM trait for thiopurine S-methyltransferase (TPMT). TPMT bioinactivates the antileukemic drug 6-mercaptopurine. Further, 6-mercaptopurine is itself an active metabolite of the immunosuppressive azathioprine. Homozygotes for alleles encoding the inactive TPMT (1 in 300 individuals) predictably exhibit severe and potentially fatal pancytopenia on standard doses of azathioprine or 6-mercaptopurine. On the other hand, homozygotes for fully functional alleles may display less anti-inflammatory or antileukemic effect with the drugs.

N-acetylation is catalyzed by hepatic *N*-acetyl transferase (NAT), which represents the activity of two genes, *NAT-1* and *NAT-2*. Both enzymes transfer an acetyl group from acetyl coenzyme A to the drug; NAT-1 activity is generally constant, while polymorphisms in *NAT-2* result in individual differences in the rate at which drugs are acetylated and thus define "rapid acetylators" and "slow acetylators." Slow acetylators make up ~50% of European- and African-derived populations but are less common among Asians.

Slow acetylators have an increased incidence of the drug-induced lupus syndrome during procainamide and hydralazine therapy and of hepatitis with isoniazid. Induction of CYPs (e.g., by rifampin) also increases the risk of isoniazid-related hepatitis, likely reflecting generation of reactive metabolites of acetylhydrazine, itself an isoniazid metabolite.

Individuals homozygous for a common promoter polymorphism that reduces transcription of uridine diphosphate glucuronosyltransferase (*UGT1A1*) have benign hyperbilirubinemia (Gilbert's syndrome; Chap. 297). This variant has also been associated with diarrhea and increased bone marrow depression with the antineoplastic prodrug irinotecan, whose active metabolite is normally detoxified by this UGT1A1-mediated glucuronidation.

VARIABILITY IN THE MOLECULAR TARGETS WITH WHICH DRUGS INTERACT

As molecular approaches identify specific gene products as targets of drug action, polymorphisms that alter the expression or function of these drug targets—and thus modulate their actions in patients—are also being recognized. Multiple polymorphisms identified in the β_2-adrenergic receptor appear to be linked to specific phenotypes in asthma and congestive heart failure, diseases in which β_2-receptor function might be expected to determine prognosis. Polymorphisms in the β_2-receptor gene have also been associated with response to inhaled β_2-receptor agonists, while those in the β_1-adrenergic receptor gene have been associated with variability in heart rate slowing and blood pressure lowering (Fig. 5-5*B*). In addition, in heart failure, a common polymorphism in the β_1-adrenergic receptor gene has been implicated in variable clinical outcome during therapy with the beta blocker bucindolol. Response to the 5-lipoxygenase inhibitor zileuton in asthma has been linked to polymorphisms that determine the expression level of the 5-lipoxygenase gene. Herceptin, which potentiates anthracycline-related cardiotoxicity, is ineffective in breast cancers that do not express the herceptin receptor; thus, "genotyping" the tumor is a mechanism to avoid potentially toxic therapy in patients who would derive no benefit.

Drugs may also interact with genetic pathways of disease, to elicit or exacerbate symptoms of the underlying conditions. In the porphyrias, CYP inducers are thought to increase the activity of enzymes proximal to the deficient enzyme, exacerbating or triggering attacks (Chap. 352). Deficiency of glucose-6-phosphate dehydrogenase (G6PD), most often in individuals of African or Mediterranean descent, increases risk of hemolytic anemia in response to primaquine and a number of other drugs that do not cause hemolysis in patients with normal amounts of the enzyme (Chap. 101). Patients with mutations in the ryanodine receptor, which controls intracellular calcium in skeletal muscle and other tissues, may be asymptomatic until exposed to certain general anesthetics, which trigger the syndrome of malignant hyperthermia. Certain antiarrhythmics and other drugs can produce marked QT prolongation and torsades des pointes (Chap. 226), and in some patients this adverse effect represents unmasking of previously subclinical congenital long QT syndrome.

POLYMORPHISMS THAT MODULATE THE BIOLOGIC CONTEXT WITHIN WHICH THE DRUG-TARGET INTERACTIONS OCCUR

The interaction of a drug with its molecular target is translated into a clinical action in a complex biologic milieu that is itself often perturbed by disease. Thus, polymorphisms that determine variability in this biology may profoundly influence drug response, although the genes involved are not themselves directly targets of drug action. Polymorphisms in genes important for lipid homeostasis (such as the ABCA1 transporter and the cholesterol ester transport protein) modulate response to 3-hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitors, "statins." In one large study, the combination of diuretic use combined with a variant in the adducin gene (encoding a cytoskeletal protein important for renal tubular sodium absorption) decreased stroke or myocardial infarction risk, while neither factor alone had an effect. Common polymorphisms in ion channel genes that are not themselves the target of QT-prolonging drugs may nevertheless influence the extent to which those drugs affect the electrocardiogram and produce arrhythmias. These findings not only point to new mechanisms for understanding drug action, but also can be used for drug development. For example, a set of polymorphisms in the gene encoding 5-lipoxygenase activating protein (FLAP) has been identified as a risk factor for myocardial infarction in an Icelandic population, and an initial clinical trial of a FLAP inhibitor was conducted only in subjects with the high risk allele.

MULTIPLE VARIANTS MODULATING DRUG EFFECTS

As this discussion makes clear, for each drug with a defined mechanism of action and disposition pathways, a set of "candidate genes," in which polymorphisms may mediate variable clinical responses, can be identified. Indeed, polymorphisms in multiple genes have been associated with variability in the effect of a single drug. CYP2C9 loss-of-function variants are associated with a requirement for lower maintenance doses of the vitamin K antagonist anticoagulant warfarin. In rarer (<2%) individuals homozygous for these variant alleles, maintenance warfarin dosages may be difficult to establish, and the risk of bleeding complications appears increased. In addition to *CYP2C9*, variants in the promoter region of *VKORC1*, encoding a vitamin K epoxide reductase, predict warfarin dosages; these promoter variants are in tight *linkage disequilibrium*, i.e. genotyping at one polymorphic site within this *haplotype block* provides reliable information on the identity of genotypes at other linked sites (Chap. 62). Thus, variability in response to warfarin can be linked to both coding region polymorphisms in CYP2C9 and promoter haplotypes in the warfarin target *VKORC1*.

As genotyping technologies improve and data sets of patients with well-documented drug responses are accumulated, it is becoming possible to interrogate hundreds of polymorphisms in dozens of candidate genes. This approach has been applied to implicate linked noncoding polymorphisms in the HMG-CoA reductase gene as predicting efficacy of HMG-CoA reductase inhibitors, and in variants in the gene-encoding corticotrophin-releasing hormone receptor 1 as predicting efficacy of inhaled steroids in asthma.

Technologies are now evolving to interrogate hundreds of thousands of SNPs across the genome, or to rapidly resequence each patient's genome. These approaches, which have been applied to identify new genes modulating disease susceptibility (Chap. 62), may be applicable to the problem of identifying genomic predictors of variable drug effects.

PROSPECTS FOR INCORPORATING GENETIC INFORMATION INTO CLINICAL PRACTICE

The examples of associations between specific genotypes and drug responses raise the tantalizing prospect that patients will undergo routine genotyping for loci known to modulate drug levels or response prior to receiving a prescription. Indeed, clinical tests for some of the polymorphisms described above, including those in *TPMT*, *UGT1A1*, *CYP2D6*, and *CYP2C19*, have been approved by the U.S. Food and Drug Administration (FDA). The twin goals are to identify patients likely to exhibit adverse effects and those most likely to respond well. Obstacles that must be overcome before this vision becomes a reality include replication of even the most compelling associations, demonstrations of cost-effectiveness, development of readily useable genotyping technologies, and ethical issues involved in genotyping. While these barriers seem daunting, the field is very young and evolving rapidly. Indeed, one major result of understanding of the role of genetics in drug action has been improved screening of drugs during the development process to reduce the likelihood of highly variable metabolism or unanticipated toxicity (such as torsades des pointes).

INTERACTIONS BETWEEN DRUGS

Drug interactions can complicate therapy by increasing or decreasing the action of a drug; interactions may be based on changes in drug disposition or in drug response in the absence of changes in drug levels. *Interactions must be considered in the differential diagnosis of any unusual response occurring during drug therapy*. Prescribers should recognize that patients often come to them with a legacy of drugs acquired during previous medical experiences, often with multiple physicians who may not be aware of all the patient's medications. A meticulous drug history should include examination of the patient's medications and, if necessary, calls to the pharmacist to identify prescriptions. It should also address the use of agents not often volunteered during questioning, such as over-the-counter (OTC) drugs, health food supplements, and topical agents such as eye drops. Lists of interactions are available from a number of electronic sources. While it is unrealistic to expect the practicing physician to memorize these, certain drugs consistently run the risk of generating interactions, often by inhibiting or inducing specific drug elimination pathways. Examples are presented below and in Table 5-2. Accordingly, when these drugs are started or stopped, prescribers must be especially alert to the possibility of interactions.

TABLE 5-2 DRUGS WITH A HIGH RISK OF GENERATING PHARMACOKINETIC INTERACTIONS

Drug	Mechanism	Examples
Antacids Bile acid sequestrants	Reduced absorption	Antacids/tetracyclines Cholestryamine/digoxin
Proton pump inhibitors H_2-receptor blockers	Altered gastric pH	Ketoconazole absorption decreased
Rifampin Carbamazepine Barbiturates Phenytoin St. John's wort Glutethimide	Induction of hepatic metabolism	Decreased concentration and effects of warfarin quinidine cyclosporine losartan oral contraceptives methadone
Tricyclic antidepressants Fluoxetine Quinidine	Inhibitors of CYP2D6	Increased β-blockade Decreased codeine effect
Cimetidine	Inhibitor of multiple CYPs	Increased concentration and effects of warfarin theophylline phenytoin
Ketoconazole, itraconazole Erythromycin, clarithromycin Calcium channel blockers Ritonavir	Inhibitor of CYP3A	Increased concentration and toxicity of some HMG-CoA reductase inhibitors cyclosporine cisapride, terfenadine (now withdrawn) Increased concentration and effects of indinavir (with ritonavir) Decreased clearance and dose requirement for cyclosporine (with calcium channel blockers)
Allopurinol	Xanthine oxidase inhibitor	Azathioprine and 6-mercaptopurine toxicity
Amiodarone	Inhibitor of many CYPs and of P-glycoprotein	Decreased clearance (risk of toxicity) for warfarin digoxin quinidine
Gemfibrazol (and other fibrates)	CYP3A inhibition	Rhabdomyolysis when co-prescribed with some HMG-CoA reductase inhibitors
Quinidine Amiodarone Verapamil Cyclosporine Itraconazole Erythromycin	P-glycoprotein inhibition	Risk of digoxin toxicity
Phenylbutazone Probenecid Salicylates	Inhibition of renal tubular transport	Salicylates → increased risk of methotrexate toxicity

PHARMACOKINETIC INTERACTIONS CAUSING DECREASED DRUG EFFECTS

Gastrointestinal absorption can be reduced if a drug interaction results in drug binding in the gut, as with aluminum-containing antacids, kaolin-pectin suspensions, or bile acid sequestrants. Drugs such as histamine H_2 receptor antagonists or proton pump inhibitors that alter gastric pH may decrease the solubility and hence absorption of weak bases such as ketoconazole.

Expression of some genes responsible for drug elimination, notably *CYP3A* and *MDR1*, can be markedly increased by "inducing" drugs, such as rifampin, carbamazepine, phenytoin, St. John's wort, and glutethimide and by smoking, exposure to chlorinated insecticides such as DDT (CYP1A2), and chronic alcohol ingestion. Administration of inducing agents lowers plasma levels over 2–3 weeks as gene expression is increased. If a drug dose is stabilized in the presence of an inducer that is subsequently stopped, major toxicity can occur as clearance returns to preinduction levels and drug concentrations rise. Individuals vary in the extent to which drug metabolism can be induced, likely through genetic mechanisms.

Interactions that inhibit the bioactivation of prodrugs will similarly decrease drug effects. The analgesic effect of codeine depends on its metabolism to morphine via CYP2D6. Thus, the CYP2D6 inhibitor quinidine reduces the analgesic efficacy of codeine in EMs.

Interactions that decrease drug delivery to intracellular sites of action can decrease drug effects: tricyclic antidepressants can blunt the antihypertensive effect of clonidine by decreasing its uptake into adrenergic neurons. Reduced CNS penetration of multiple HIV protease inhibitors (with the attendant risk of facilitating viral replication in a sanctuary site) appears attributable to P-glycoprotein-mediated exclusion of the drug from the CNS; indeed, inhibition of P-glycoprotein has been proposed as a therapeutic approach to enhance drug entry to the CNS (Fig. 5-5*A*).

PHARMACOKINETIC INTERACTIONS CAUSING INCREASED DRUG EFFECTS

The most common mechanism here is inhibition of drug elimination. In contrast to induction, new protein synthesis is not involved, and the effect develops as drug and any inhibitor metabolites accumulate (a

function of their elimination half-lives). Since shared substrates of a single enzyme can compete for access to the active site of the protein, many CYP substrates can also be considered inhibitors. However, some drugs are especially potent as inhibitors (and occasionally may not even be substrates) of specific drug-elimination pathways, and so it is in the use of these agents that clinicians must be most alert to the potential for interactions (Table 5-2). Commonly implicated interacting drugs of this type include cimetidine, erythromycin and some other macrolide antibiotics (clarithromycin but not azithromycin), ketoconazole and other azole antifungals, the antiretroviral agent ritonavir, and high concentrations of grapefruit juice (Table 5-2). The consequences of such interactions will depend on the drug whose elimination is being inhibited; high-risk drugs are those for which alternate pathways of elimination are not available and for which drug accumulation increases the risk of serious toxicity (see "The Concept of High-Risk Pharmacokinetics," above). Examples include CYP3A inhibitors increasing the risk of cyclosporine toxicity or of rhabdomyolysis with some HMG-CoA reductase inhibitors (lovastatin, simvastatin, atorvastatin), and P-glycoprotein inhibitors increasing risk of digoxin toxicity.

Phenytoin, an inducer of many systems, including CYP3A, inhibits CYP2C9. CYP2C9 metabolism of losartan to its active metabolite is inhibited by phenytoin, with potential loss of antihypertensive effect.

The antiviral ritonavir is a very potent CYP3A4 inhibitor that has been added to anti-HIV regimens, not because of its antiviral effects but because it decreases clearance, and hence increases efficacy, of other anti-HIV agents. Grapefruit (but not orange) juice inhibits CYP3A, especially at high doses; patients receiving drugs where even modest CYP3A inhibition may increase the risk of adverse effects (e.g., cyclosporine, some HMG-CoA reductase inhibitors) should therefore avoid grapefruit juice.

CYP2D6 is markedly inhibited by quinidine, a number of neuroleptic drugs (chlorpromazine and haloperidol), and the SSRIs fluoxetine and paroxetine. Clinical consequences of fluoxetine's interaction with CYP2D6 substrates may not be apparent for weeks after the drug is started, because of its very long half-life and slow generation of a CYP2D6-inhibiting metabolite.

6-Mercaptopurine, the active metabolite of azathioprine, is metabolized not only by TPMT but also by xanthine oxidase. When allopurinol, a potent inhibitor of xanthine oxidase, is administered with standard doses of azathioprine or 6-mercaptopurine, life-threatening toxicity (bone marrow suppression) can result.

A number of drugs are secreted by the renal tubular transport systems for organic anions. Inhibition of these systems can cause excessive drug accumulation. Salicylate, for example, reduces the renal clearance of methotrexate, an interaction that may lead to methotrexate toxicity. Renal tubular secretion contributes substantially to the elimination of penicillin, which can be inhibited (to increase its therapeutic effect) by probenecid. Similarly, inhibition of the tubular cation transport system by cimetidine decreases the renal clearance of dofetilide and of procainamide and its active metabolite NAPA.

DRUG INTERACTIONS NOT MEDIATED BY CHANGES IN DRUG DISPOSITION

Drugs may act on separate components of a common process to generate effects greater than either has alone. Antithrombotic therapy with combinations of antiplatelet agents (glycoprotein IIb/IIIa inhibitors, aspirin, clopidogrel) and anticoagulants (warfarin, heparins) are often used in the treatment of vascular disease, although such combinations carry an increased risk of bleeding.

Nonsteroidal anti-inflammatory drugs (NSAIDs) cause gastric ulcers, and in patients treated with warfarin, the risk of bleeding from a peptic ulcer is increased almost threefold by concomitant use of an NSAID.

Indomethacin, piroxicam, and probably other NSAIDs antagonize the antihypertensive effects of β-adrenergic receptor blockers, diuretics, ACE inhibitors, and other drugs. The resulting elevation in blood pressure ranges from trivial to severe. This effect is not seen with aspirin and sulindac but has been found with the cyclooxygenase 2 (COX-2) inhibitor celecoxib.

Torsades des pointes during administration of QT-prolonging antiarrhythmics (quinidine, sotalol, dofetilide) occur much more frequently in patients receiving diuretics, probably reflecting hypokalemia. In vitro, hypokalemia not only prolongs the QT interval in the absence of drug but also potentiates drug block of ion channels that results in QT prolongation. Also, some diuretics have direct electrophysiologic actions that prolong QT.

The administration of supplemental potassium leads to more frequent and more severe hyperkalemia when potassium elimination is reduced by concurrent treatment with ACE inhibitors, spironolactone, amiloride, or triamterene.

The pharmacologic effects of sildenafil result from inhibition of the phosphodiesterase type 5 isoform that inactivates cyclic GMP in the vasculature. Nitroglycerin and related nitrates used to treat angina produce vasodilation by elevating cyclic GMP. Thus, coadministration of these nitrates with sildenafil can cause profound hypotension, which can be catastrophic in patients with coronary disease.

Sometimes, combining drugs can increase overall efficacy and/or reduce drug-specific toxicity. Such therapeutically useful interactions are described in chapters dealing with specific disease entities, elsewhere in this text.

ADVERSE REACTIONS TO DRUGS

The beneficial effects of drugs are coupled with the inescapable risk of untoward effects. The morbidity and mortality from these untoward effects often present diagnostic problems because they can involve every organ and system of the body; these may be mistaken for signs of underlying disease.

Adverse reactions can be classified in two broad groups. One type results from exaggeration of an intended pharmacologic action of the drug, such as increased bleeding with anticoagulants or bone marrow suppression with antineoplastics. The other type of adverse reactions ensues from toxic effects unrelated to the intended pharmacologic actions. The latter effects are often unanticipated (especially with new drugs) and frequently severe and result from recognized as well as undiscovered mechanisms.

Drugs may increase the frequency of an event that is common in a general population, and this may be especially difficult to recognize; the increase in myocardial infarctions with the COX-2 inhibitor rofecoxib is an excellent example. Drugs can also cause rare and serious adverse effects, such as hematologic abnormalities, arrhythmias, or hepatic or renal dysfunction. Prior to regulatory approval and marketing, new drugs are tested in relatively few patients who tend to be less sick and to have fewer concomitant diseases than those patients who subsequently receive the drug therapeutically. Because of the relatively small number of patients studied in clinical trials and the selected nature of these patients, rare adverse effects are generally not detected prior to a drug's approval, and physicians therefore need to be cautious in the prescription of new drugs and alert for the appearance of previously unrecognized adverse events.

Elucidating mechanisms underlying adverse drug effects can assist development of safer compounds or allow a patient subset at especially high risk to be excluded from drug exposure. National adverse reaction reporting systems, such as those operated by the FDA (suspected adverse reactions can be reported online at *http://www.fda.gov/medwatch/report/hcp.htm*) and the Committee on Safety of Medicines in Great Britain, can prove useful. The publication or reporting of a newly recognized adverse reaction can in a short time stimulate many similar such reports of reactions that previously had gone unrecognized.

Occasionally, "adverse" effects may be exploited to develop an entirely new indication for a drug. Unwanted hair growth during minoxidil treatment of severely hypertensive patients led to development of the drug for hair growth. Sildenafil was initially developed as an antianginal, but its effects to alleviate erectile dysfunction not only led to a new drug indication but also to increased understanding of the role of type 5 phosphodiesterase in erectile tissue. These examples further reinforce the concept that prescribers must remain vigilant to the possibility that unusual symptoms may reflect unappreciated drug effects.

Some 25–50% of patients make errors in self-administration of prescribed medicines, and these errors can be responsible for adverse drug effects. Similarly, patients commit errors in taking OTC drugs by not reading or following the directions on the containers. Physicians must recognize that providing directions with prescriptions does not always guarantee compliance.

In hospital, drugs are administered in a controlled setting, and patient compliance is, in general, ensured. Errors may occur nevertheless—the wrong drug or dose may be given or the drug may be given to the wrong patient—and improved drug distribution and administration systems are addressing this problem.

EPIDEMIOLOGY

Patients receive, on average, 10 different drugs during each hospitalization. The sicker the patient, the more drugs are given, and there is a corresponding increase in the likelihood of adverse drug reactions. When <6 different drugs are given to hospitalized patients, the probability of an adverse reaction is ~5%, but if >15 drugs are given, the probability is >40%. Retrospective analyses of ambulatory patients have revealed adverse drug effects in 20%. Serious adverse reactions are also well recognized with "herbal" remedies and OTC compounds: examples include kava-associated hepatotoxicity, L-tryptophan-associated eosinophilia-myalgia, and phenylpropanolamine-associated stroke, each of which has caused fatalities.

A small group of widely used drugs accounts for a disproportionate number of reactions. Aspirin and other NSAIDs, analgesics, digoxin, anticoagulants, diuretics, antimicrobials, glucocorticoids, antineoplastics, and hypoglycemic agents account for 90% of reactions, although the drugs involved differ between ambulatory and hospitalized patients.

TOXICITY UNRELATED TO A DRUG'S PRIMARY PHARMACOLOGIC ACTIVITY

Cytotoxic Reactions Drugs or more commonly reactive metabolites generated by CYPs can covalently bind to tissue macromolecules (such as proteins or DNA) to cause tissue toxicity. Because of the reactive nature of these metabolites, covalent binding often occurs close to the site of production, typically the liver.

The most common cause of drug-induced hepatotoxicity is acetaminophen overdosage. Normally, reactive metabolites are detoxified by combining with hepatic glutathione. When glutathione becomes exhausted, the metabolites bind instead to hepatic protein, with resultant hepatocyte damage. The hepatic necrosis produced by the ingestion of acetaminophen can be prevented or attenuated by the administration of substances such as *N*-acetylcysteine that reduce the binding of electrophilic metabolites to hepatic proteins. The risk of acetaminophen-related hepatic necrosis is increased in patients receiving drugs such as phenobarbital or phenytoin that increase the rate of drug metabolism or ethanol that exhaust glutathione stores. Such toxicity has even occurred with therapeutic dosages, so patients at risk through these mechanisms should be warned.

Immunologic Mechanisms Most pharmacologic agents are small molecules with low molecular weights (<2000) and thus are poor immunogens. Generation of an immune response to a drug therefore usually requires in vivo activation and covalent linkage to protein, carbohydrate, or nucleic acid.

Drug stimulation of antibody production may mediate tissue injury by several mechanisms. The antibody may attack the drug when the drug is covalently attached to a cell and thereby destroy the cell. This occurs in penicillin-induced hemolytic anemia. Antibody-drug-antigen complexes may be passively adsorbed by a bystander cell, which is then destroyed by activation of complement; this occurs in quinine- and quinidine-induced thrombocytopenia. Heparin-induced thrombocytopenia arises when antibodies against complexes of platelet factor 4 peptide and heparin generate immune complexes that activate platelets; thus, the thrombocytopenia is accompanied by "paradoxical" thrombosis and is treated with thrombin inhibitors. Drugs or their reactive metabolites may alter a host tissue, rendering it antigenic and eliciting autoantibodies. For example, hydralazine and procainamide (or their reactive metabolites) can chemically alter nuclear material, stimulating the formation of antinuclear antibodies and occasionally causing lupus erythematosus. Drug-induced pure red cell aplasia (Chap. 102) is due to an immune-based drug reaction. Red cell formation in bone marrow cultures can be inhibited by phenytoin and purified IgG obtained from a patient with pure red cell aplasia associated with phenytoin.

Serum sickness (Chap. 311) results from the deposition of circulating drug-antibody complexes on endothelial surfaces. Complement activation occurs, chemotactic factors are generated locally, and an inflammatory response develops at the site of complex entrapment. Arthralgias, urticaria, lymphadenopathy, glomerulonephritis, or cerebritis may result. Foreign proteins (vaccines, streptokinase, therapeutic antibodies) and antibiotics are common causes. Many drugs, particularly antimicrobial agents, ACE inhibitors, and aspirin, can elicit anaphylaxis with production of IgE, which binds to mast cell membranes. Contact with a drug antigen initiates a series of biochemical events in the mast cell and results in the release of mediators that can produce the characteristic urticaria, wheezing, flushing, rhinorrhea, and (occasionally) hypotension.

Drugs may also elicit cell-mediated immune responses. Topically administered substances may interact with sulfhydryl or amino groups in the skin and react with sensitized lymphocytes to produce the rash characteristic of contact dermatitis. Other types of rashes may also result from the interaction of serum factors, drugs, and sensitized lymphocytes.

DIAGNOSIS AND TREATMENT OF ADVERSE DRUG REACTIONS

The manifestations of drug-induced diseases frequently resemble those of other diseases, and a given set of manifestations may be produced by different and dissimilar drugs. Recognition of the role of a drug or drugs in an illness depends on appreciation of the possible adverse reactions to drugs in any disease, on identification of the temporal relationship between drug administration and development of the illness, and on familiarity with the common manifestations of the drugs. Many associations between particular drugs and specific reactions have been described, but there is always a "first time" for a novel association, and any drug should be suspected of causing an adverse effect if the clinical setting is appropriate.

Illness related to a drug's intended pharmacologic action is often more easily recognized than illness attributable to immune or other mechanisms. For example, side effects such as cardiac arrhythmias in patients receiving digitalis, hypoglycemia in patients given insulin, and bleeding in patients receiving anticoagulants are more readily related to a specific drug than are symptoms such as fever or rash, which may be caused by many drugs or by other factors.

Electronic sources of adverse drug reactions can be useful. However, exhaustive compilations often provide little sense of perspective in terms of frequency and seriousness, which can vary considerably among patients.

Eliciting a drug history from patients is important for diagnosis. Attention must be directed to OTC drugs and herbal preparations as well as to prescription drugs. Each type can be responsible for adverse drug effects, and adverse interactions may occur between OTC drugs and prescribed drugs. Loss of efficacy of oral contraceptives or cyclosporine by concurrent use of St. John's wort are examples. In addition, it is common for patients to be cared for by several physicians, and duplicative, additive, counteractive, or synergistic drug combinations may therefore be administered if the physicians are not aware of the patients' drug histories. Every physician should determine what drugs a patient has been taking, for the previous month or two ideally, before prescribing any medications. Medications stopped for inefficacy or adverse effects should be documented to avoid pointless and potentially dangerous reexposure. A frequently overlooked source of additional drug exposure is topical therapy; for example, a patient complaining of bronchospasm may not mention that an ophthalmic beta blocker is being used unless specifically asked. A history of previous adverse drug effects in patients is common. Since these patients have shown a pre-

disposition to drug-induced illnesses, such a history should dictate added caution in prescribing drugs.

Laboratory studies may include demonstration of serum antibody in some persons with drug allergies involving cellular blood elements, as in agranulocytosis, hemolytic anemia, and thrombocytopenia. For example, both quinine and quinidine can produce platelet agglutination in vitro in the presence of complement and the serum from a patient who has developed thrombocytopenia following use of this drug. Biochemical abnormalities such as G6PD deficiency, serum pseudocholinesterase level, or genotyping may also be useful in diagnosis, often after an adverse effect has occurred in the patient or a family member.

Once an adverse reaction is suspected, discontinuation of the suspected drug followed by disappearance of the reaction is presumptive evidence of a drug-induced illness. Confirming evidence may be sought by cautiously reintroducing the drug and seeing if the reaction reappears. However, that should be done only if confirmation would be useful in the future management of the patient and if the attempt would not entail undue risk. With concentration-dependent adverse reactions, lowering the dosage may cause the reaction to disappear, and raising it may cause the reaction to reappear. When the reaction is thought to be allergic, however, readministration of the drug may be hazardous, since anaphylaxis may develop. Readministration is unwise under these conditions unless no alternative drugs are available and treatment is necessary.

If the patient is receiving many drugs when an adverse reaction is suspected, the drugs likeliest to be responsible can usually be identified; this should include both potential culprit agents as well as drugs that alter their elimination. All drugs may be discontinued at once or, if this is not practical, discontinued one at a time, starting with the ones most suspect, and the patient observed for signs of improvement. The time needed for a concentration-dependent adverse effect to disappear depends on the time required for the concentration to fall below the range associated with the adverse effect; that, in turn, depends on the initial blood level and on the rate of elimination or metabolism of the drug. Adverse effects of drugs with long half-lives or those not directly related to serum concentration may take a considerable time to disappear.

SUMMARY

Modern clinical pharmacology aims to replace empiricism in the use of drugs with therapy based on in-depth understanding of factors that determine an individual's response to drug treatment. Molecular pharmacology, pharmacokinetics, genetics, clinical trials, and the educated prescriber all contribute to this process. No drug response should ever be termed *idiosyncratic*; all responses have a mechanism whose understanding will help guide further therapy with that drug or successors. This rapidly expanding understanding of variability in drug actions makes the process of prescribing drugs increasingly daunting for the practitioner. However, fundamental principles should guide this process:

- The benefits of drug therapy, however defined, should always outweigh the risk.
- The smallest dosage necessary to produce the desired effect should be used.
- The number of medications and doses per day should be minimized.
- Although the literature is rapidly expanding, accessing it is becoming easier; tools such as computers and hand-held devices to search databases of literature and unbiased opinion will become increasingly commonplace.
- Genetics play a role in determining variability in drug response and may become a part of clinical practice.
- Prescribers should be particularly wary when adding or stopping specific drugs that are especially liable to provoke interactions and adverse reactions.
- Prescribers should use only a limited number of drugs, with which they are thoroughly familiar.

6 Women's Health

Andrea Dunaif

The study of biologic differences between sexes has emerged as a distinct scientific discipline. A report from the Institute of Medicine (IOM) found that sex has a broad impact on biologic and disease processes and succinctly concluded: sex matters. The National Institutes of Health established the Office of Research on Women's Health in 1990 to develop an agenda for future research in the field. In parallel, women's health has become a distinct clinical discipline with a focus on disorders that are disproportionately represented in women. The integration of women's health into internal medicine and other specialties has been accompanied by novel approaches to health care delivery, including greater attention to patient education and involvement in disease prevention and medical decision-making.

The IOM report recommended the term *sex difference* to describe biologic processes that differ between males and females and *gender difference* for features related to social influences. Disorders highlighted here are reviewed in detail in other chapters.

DISEASE RISK: REALITY AND PERCEPTION

The leading causes of death are the same in women and men: (1) heart disease, (2) cancer, and (3) cerebrovascular disease (Table 6-1; Fig.

TABLE 6-1 DEATHS AND PERCENT OF TOTAL DEATHS FOR THE 15 LEADING CAUSES OF DEATH BY SEX IN THE UNITED STATES, 2003

	Women			Men		
Cause of Death	Rank	Deaths	Total Deaths, %	Rank	Deaths	Total Deaths, %
Diseases of heart	1	348,994	28.0	1	336,095	28.0

Source: Data from Centers for Disease Control and Prevention: National Vital Statistics Reports, Vol. 54, No. 13, April 19, 2006, Table 12, *http://www.cdc.gov/nchs/data/nvsr/nvsr54/nvsr54_13.pdf.*

6-1). The leading cause of cancer death, lung cancer, is the same in both sexes, with higher mortality rates than breast, colon, and prostate cancer combined. Breast cancer is the second leading cause of cancer death in women, but it causes about 60% fewer deaths than lung cancer. Men are substantially more likely to die from suicide, homicide, and accidents than women.

Women's risk for many diseases increases at menopause, which occurs at a median age of 51.4 years. In the industrialized world, women spend one-third of their lives in the postmenopausal period. Estrogen levels fall abruptly at menopause, inducing a variety of physiologic and metabolic responses. Rates of cardiovascular disease increase and bone density begins to decrease rapidly after menopause. In the United States, women live on average about 5 years longer than men, with a life expectancy at birth in 2004 of 80.4 years, compared to 75.2 years in men. Elderly women outnumber elderly men, so that age-related conditions, such as hypertension, have a female preponderance. However, the difference in life expectancy between men and women has decreased an average of 0.1 year every year since 1980, and, if this convergence in mortality figures continues, it is projected that mortality rates will be similar by 2054.

Women's perception of disease risk is often inaccurate. Public awareness campaigns have resulted in almost 50% of U.S. women knowing that cardiovascular disease is the leading cause of death in women. Nevertheless, the condition they fear most is breast cancer, despite the fact that death rates from breast cancer have been falling since the 1990s. In any given decade of life, a woman's risk for breast cancer never exceeds 1 in 34. Although a woman's lifetime risk of developing breast cancer if she lives past 85 years is about 1 in 9, it is much more likely that she will die from cardiovascular disease than from breast cancer. In other words, many elderly women have breast cancer but die from other causes. Similarly, a minority of women are aware that lung cancer is the leading cause of cancer death in women. These misconceptions are unfortunate as they perpetuate inadequate attention to modifiable risk factors, such as dyslipidemia, hypertension, and cigarette smoking.

Physicians are also less likely to recognize women's risk for cardiovascular disease. A survey of physicians in 2004 found that women with intermediate risk for cardiovascular disease, according to Framingham risk score, were significantly more likely to be assigned to a lower risk category than men with similar risk profiles. Moreover, when presented with actors portraying patients with chest pain, physicians' estimates for probability of coronary heart disease (CHD) were significantly lower for women than for men and lower for black women than for white women. These perceptions on the part of both the patient and her physician lead to important differences in cardiac care.

SEX DIFFERENCES IN HEALTH AND DISEASE

ALZHEIMER'S DISEASE

(See also Chap. 365) Alzheimer's disease (AD) affects approximately twice as many women as men. Because the risk for AD increases with age, part of this sex difference is accounted for by the fact that women live longer than men. However, additional factors likely contribute to the increased risk for AD in women, including sex differences in brain size, structure, and functional organization. There is emerging evidence for sex-specific differences in gene expression, not only for genes on the X and Y chromosomes but also for some autosomal genes. Estrogens have pleiotropic genomic and nongenomic effects on the central nervous system, including neurotrophic actions in key areas involved in cognition and memory. Women with AD have lower endogenous estrogen levels compared to women without AD. These observations have led to the hypothesis that estrogen is neuroprotective.

Some studies have suggested that estrogen administration improves cognitive function in nondemented postmenopausal women as well as in women with AD, and several observational studies have suggested that postmenopausal hormone therapy (PHT) may decrease the risk of AD. However, recent placebo-controlled trials have found no improvement in disease progression or cognitive function after up to 15 months of PHT in women with AD. Further, the Women's Health Initiative Memory Study (WHIMS), an ancillary study in the Women's Health Initiative (WHI), found no benefit compared to placebo of estrogen alone [combined continuous equine estrogen (CEE), 0.625 mg qd] or estrogen with progestin [CEE, 0.625 mg qd, and medroxyprogesterone acetate (MPA), 2.5 mg qd] on cognitive function or the development of dementia in women 65 years and older. Indeed, there was a significantly increased risk for both dementia and mild cognitive impairment in women receiving hormone therapy. The possible explanations for the discrepant results between the observational studies and the randomized clinical trials remain unclear (Chap. 342).

CORONARY HEART DISEASE

(See also Chap. 237) There are major sex differences in CHD, the leading cause of death in men and women in developed countries. CHD death rates have been falling in men over the past 30 years, but they have been increasing in women. Since 1984, more women than men have died of cardiovascular disease. Gonadal steroids have major effects on the cardiovascular system and lipid metabolism. Estrogen increases high-density lipoprotein (HDL) and lowers low-density lipoprotein (LDL), whereas androgens have the opposite effect. Estrogen has direct vasodilatory effects on the vascular endothelium, enhances insulin sensitivity, and has antioxidant properties. There is a striking increase in CHD after both natural and surgical menopause suggesting that endogenous estrogens are cardioprotective. Women also have longer QT intervals on electrocardiograms, which increases their susceptibility to certain arrhythmias. Animal studies suggest that the sex difference in QT interval duration is caused by sex steroid effects on cardiac repolarization, in part related to their effects on cardiac voltage-gated potassium channels; there is a lower density of the

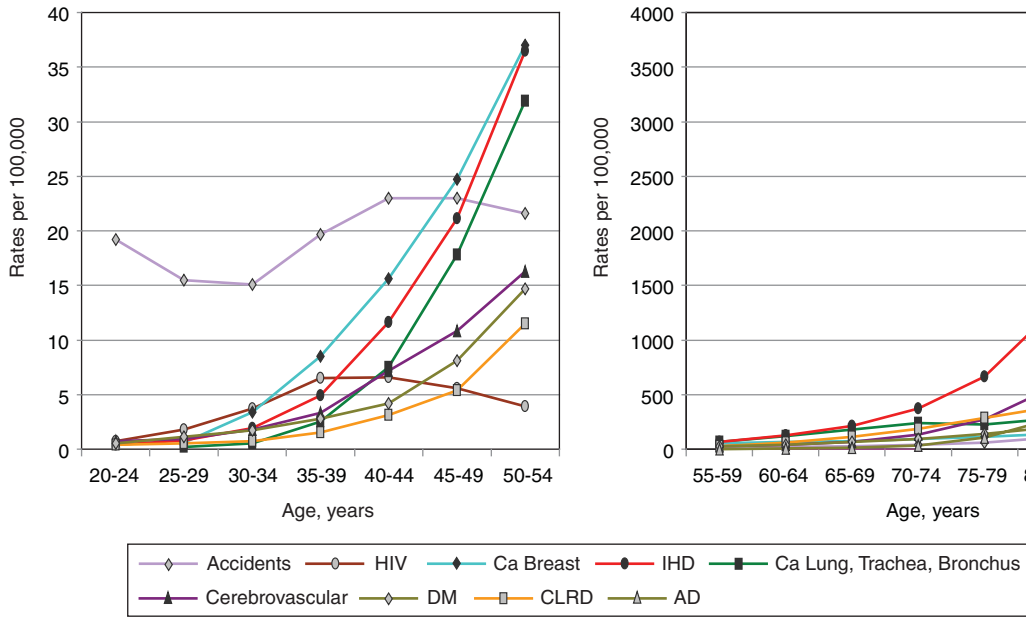

FIGURE 6-1 Death rates per 100,000 population for 2003 by 5-year age groups in U.S. women. Note that the scale of the *y*-axis is increased by tenfold in the graph on the right compared to that on the left. Accidents and HIV/AIDS are the leading causes of death in young women 20–34 years of age. Accidents, breast cancer, and ischemic heart disease (IHD) are the leading causes of death in women 35–44 years of age. Breast cancer is the leading cause of death in women 45–49 years of age, and IHD becomes the leading cause of death in women beginning at 50 years of age. In older women, IHD remains the leading cause of death, cerebrovascular disease becomes the second leading cause of death, and lung cancer is the leading cause of cancer-related deaths. AD, Alzheimer's disease; Ca, cancer; CLRD, chronic lower respiratory disease; DM, diabetes mellitus. *(Data adapted from Centers for Disease Control and Prevention, www.cdc.gov/nchs/data/statab/Mortfinal2003_worktable210r.pdf.)*

rapid component (I_{Kr}) of the delayed rectifier potassium current (I_K) in females.

CHD presents differently in women, who are usually 10–15 years older than their male counterparts and are more likely to have comorbidities such as hypertension, congestive heart failure, and diabetes mellitus (DM). In the Framingham study, angina was the most frequent initial symptom of CHD in women, whereas myocardial infarction was the most frequent initial presentation in men. Women more often have atypical symptoms, such as nausea, vomiting, indigestion, and upper back pain.

Women with myocardial infarction are more likely to present with cardiac arrest or cardiogenic shock, whereas men are more likely to present with ventricular tachycardia. Further, younger women with myocardial infarction are more likely to die than men of similar age, with women under 50 experiencing twice the mortality rate of men, even after adjustment for differences in disease severity and management. Indeed, the younger the woman, the greater the risk of death from myocardial infarction compared to men (Fig. 6-2).

Physicians are less likely to suspect heart disease in women with chest pain and less likely to perform diagnostic and therapeutic cardiac procedures in women. In addition, there are sex differences in the accuracy of certain diagnostic procedures. The exercise electrocardiogram has substantial false-positive as well as false-negative rates in women compared to men. Women are less likely to receive therapies such as angioplasty, thrombolytic therapy, coronary artery bypass grafts (CABGs), beta blockers, or aspirin. There are also sex differences in outcomes when women with CHD do receive therapeutic interventions. Women undergoing CABG surgery have more advanced disease, a higher perioperative mortality rate, less relief of angina, and less graft patency; however, 5- and 10-year survival rates are similar. Women undergoing percutaneous transluminal coronary angioplasty have lower rates of initial angiographic and clinical success than men, but they also have a lower rate of restenosis and a better long-term outcome. Women may benefit less and have more frequent serious bleeding complications from thrombolytic therapy than do men. Factors such as older age, more comorbid conditions, and more severe CHD in women at the time of events or procedures appear to account in part for the observed sex differences.

Elevated cholesterol levels, hypertension, smoking, obesity, low HDL cholesterol levels, DM, and lack of physical activity are important risk factors for CHD in both men and women. Total triglyceride levels are an independent risk factor for CHD in women but not in men. Low HDL cholesterol and DM are more important risk factors for CHD in women than in men. Smoking is an important risk factor for CHD in women—it accelerates atherosclerosis, exerts direct negative effects on cardiac function, and is associated with an earlier age of menopause. Cholesterol-lowering drugs are equally effective in men and women for primary and secondary prevention of CHD. However, because of perceptions that women are at lower risk for CHD, they receive fewer interventions for modifiable risk factors than do men. In contrast to men, randomized

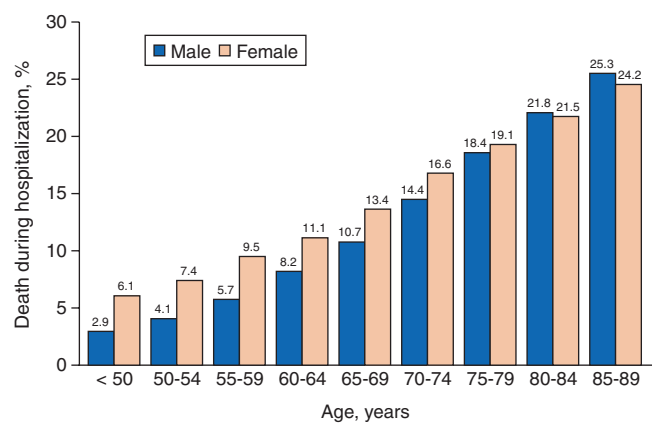

FIGURE 6-2 Rates of death during hospitalization for myocardial infarction among women and men according to age. The overall mortality rate during hospitalization was 16.7% among women and 11.5% among men but was twice the rate in women <50 years compared to men in the same age range. The interaction between sex and age was significant (p <.001). *(From V Vaccarino et al: N Engl J Med 341:217, 1999; with permission.)*

trials have shown that aspirin was not effective in the primary prevention of CHD in women; it did significantly reduce the risk of ischemic stroke. Secondary prevention in women with known CHD is also suboptimal. At baseline, only about 30% of women enrolled in the Heart and Estrogen/progestin Replacement Study (HERS), a secondary prevention trial in women with established CHD, were taking beta blockers, and only 45% received lipid-lowering medications.

The sex differences in CHD prevalence, beneficial biologic effects of estradiol on the cardiovascular system, and reduced risk for CHD in observational studies of women receiving PHT led to the widespread use of PHT for the prevention of CHD. However, the WHI, which studied more than 16,000 women on CEE plus MPA or placebo and more than 10,000 women with hysterectomy on CEE alone or placebo, did not demonstrate a benefit of PHT for the primary or secondary prevention of CHD. In addition, CEE plus MPA was associated with an increased risk for CHD, particularly in the first year of therapy, whereas CEE alone neither increased nor decreased CHD risk. There was no evidence for cardioprotective effects of estrogens in smaller randomized trials that used either oral or transdermal estradiol, arguing against the hypothesis that the type of estrogen or its route of administration accounted for the lack of CHD risk reduction. In the WHI, there was a suggestion of a reduction in CHD risk in women ages 50–59 at baseline who received CEE alone. This finding suggests that the time at which PHT is initiated is critical for cardioprotection and is consistent with the "timing hypothesis." According to this hypothesis, PHT has differential effects depending on the stage of atherosclerosis; adverse effects are seen with advanced, unstable lesions. This hypothesis is currently under investigation in randomized clinical trials. **PHT is discussed further in Chap. 342.**

DIABETES MELLITUS

(See also Chap. 338) Women are more sensitive to insulin than men. Despite this, the prevalence of type 2 DM is similar in men and women. There is a sex difference in the relationship between endogenous androgen levels and DM risk: higher bioavailable testosterone levels are associated with increased risk in women, whereas lower bioavailable testosterone levels are associated with increased risk in men. Polycystic ovary syndrome and gestational DM—common conditions in premenopausal women—are associated with a significantly increased risk for type 2 DM. Premenopausal women with DM lose the cardioprotective effect of female sex and have identical rates of CHD to those in males. These women have impaired endothelial function and reduced coronary vasodilatory responses, which may predispose to cardiovascular complications. In individuals with DM, women have a greater risk for myocardial infarction than men. Women with DM are more likely to have left ventricular hypertrophy. In the WHI, CEE plus MPA significantly reduced the incidence of DM, whereas with CEE alone there was a trend only toward decreased DM incidence.

HYPERTENSION

(See also Chap. 241) After age 60, hypertension is more common in U.S. women than in men, largely because of the high prevalence of hypertension in older age groups and the longer survival of women. Isolated systolic hypertension is present in 30% of women >60 years. Sex hormones affect blood pressure. Both normotensive and hypertensive women have higher blood pressure levels during the follicular phase than during the luteal phase. In the Nurses Health Study, the relative risk of hypertension was 1.8 in current users of oral contraceptives, but this risk is lower with the newer low-dose contraceptive preparations. PHT is not associated with hypertension. Among secondary causes of hypertension, there is a female preponderance of renal artery fibromuscular dysplasia.

The benefits of treatment for hypertension have been dramatic in both women and men. In a meta-analysis of the effects of hypertension treatment, the Individual Data Analysis of Antihypertensive Intervention Trial found a reduction of risk for stroke and for major cardiovascular events in women. The effectiveness of various antihypertensive drugs appears to be comparable in women and men; however, women may experience more side effects. For example, women are more likely to develop cough with angiotensin-converting enzyme inhibitors.

AUTOIMMUNE DISORDERS

(See also Chap. 312) Most autoimmune disorders occur more commonly in women than in men; these include autoimmune thyroid and liver diseases, lupus, rheumatoid arthritis (RA), scleroderma, multiple sclerosis (MS), and idiopathic thrombocytopenic purpura. However, there is no sex difference in the incidence of type 1 DM, and ankylosing spondylitis occurs more commonly in men. There are relatively few differences in bacterial disease infection rates in men and women. In general, sex differences in viral diseases can be accounted for by differences in behaviors, such as exposures or rates of immunization. Sex differences in both immune responses and adverse reactions to vaccines have been reported. For example, there is a female preponderance of postvaccination arthritis.

The mechanisms for these sex differences remain obscure. Adaptive immune responses are more robust in women than in men, which may be explained by the stimulatory actions of estrogens and the inhibitory actions of androgens on the cellular mediators of immunity. Consistent with an important role for gonadal hormones, there is variation in immune responses during the menstrual cycle, and the activity of certain autoimmune disorders is altered by castration or pregnancy (e.g., RA and MS may remit during pregnancy). Nevertheless, the majority of studies show that exogenous estrogens and progestins in the form of PHT or oral contraceptives do not alter autoimmune disease incidence or activity. Exposure to fetal antigens, including circulating fetal cells that persist in certain tissues, has been speculated to increase the risk of autoimmune responses. There is clearly an important genetic component to autoimmunity, as indicated by the familial clustering and HLA association of many such disorders. However, HLA types are not sexually dimorphic.

HIV INFECTION

(See also Chap. 182) Women account for almost 50% of the 40 million persons infected with HIV-1 worldwide. AIDS is an important cause of death in younger women (Fig. 6-1). Heterosexual contact with an at-risk partner is the fastest-growing transmission category, and women are more susceptible to HIV infection than men. This increased susceptibility is in part accounted for by an increased prevalence of sexually transmitted diseases in women. Some studies have suggested that hormonal contraceptives may increase the risk of HIV transmission. Progesterone has been shown to increase susceptibility to infection in nonhuman primate models of HIV. Women are also more likely to be infected by multiple variants of the virus than men. Women with HIV have more rapid decreases in their CD4 cell counts than men. Compared with men, HIV-infected women more frequently develop candidiasis, but Kaposi's sarcoma is less common than in men.

Other sexually transmitted diseases, such as chlamydial infection and gonorrhea, are important causes of infertility in women, and papilloma virus infection predisposes to cervical cancer.

OBESITY

(See also Chap. 75) The prevalence of obesity is higher in women than in men. However, according to a recent study by the Agency for Healthcare Research and Quality, >80% of patients undergoing bariatric surgery are women. Pregnancy and menopause are risk factors for obesity. There are major sex differences in body fat distribution. Women characteristically have gluteal and femoral or gynoid pattern of fat distribution, whereas men typically have a central or android pattern. Gonadal steroids appear to be the major regulators of fat distribution through a number of direct effects on adipose tissue. Studies in humans also suggest that gonadal steroids play a role in modulating food intake and energy expenditure.

In men and women, upper-body obesity characterized by increased visceral fat is associated with an increased risk for cardiovascular disease and DM. In women, endogenous androgen levels are positively associated with upper-body obesity, and androgen administration increases visceral fat. In contrast, there is an inverse relationship between endogenous

androgen levels and central obesity in men. Further, androgen administration decreases visceral fat in centrally obese men. The reasons for these sex differences in the relationship between visceral fat and androgens are unknown. Obesity increases a woman's risk for certain cancers, in particular postmenopausal breast and endometrial cancer, in part because adipose tissue provides an extragonadal source of estrogen through aromatization of circulating adrenal and ovarian androgens, especially the conversion of androstenedione to estrone. Obesity increases the risk of infertility, miscarriage, and complications of pregnancy.

OSTEOPOROSIS

(See also Chap. 348) Osteoporosis is about five times more common in postmenopausal women than in age-matched men, and osteoporotic hip fractures are a major cause of morbidity in elderly women. Men accumulate more bone mass and lose bone more slowly than women. Sex differences in bone mass are found as early as infancy. Calcium intake, vitamin D, and estrogen all play important roles in bone formation and bone loss. Particularly during adolescence, calcium intake is an important determinant of peak bone mass. Vitamin D deficiency is surprisingly common in elderly women, occurring in >40% of women living in northern latitudes. Receptors for estrogens and androgens have been identified in bone. Estrogen deficiency is associated with increased osteoclast activity and a decreased number of bone-forming units, leading to net bone loss. The aromatase enzyme, which converts androgens to estrogens, is also present in bone. Recent studies show that estrogen is an important determinant of bone mass in men (derived from the aromatization of androgens) as well as in women.

PHARMACOLOGY

On average, women have lower body weights, smaller organs, higher percent body fat, and lower total-body water than men. There are also important sex differences in drug action and metabolism that are not accounted for by these differences in body size and composition. Gonadal steroids alter the binding and metabolism of a number of drugs. Further, menstrual cycle phase and pregnancy can alter drug action. Two-thirds of cases of drug-induced torsades des pointes, a rare, life-threatening ventricular arrhythmia, occur in women because they have a longer, more vulnerable QT interval. These drugs, which include certain antihistamines, antibiotics, antiarrhythmics, and antipsychotics, can prolong cardiac repolarization by blocking cardiac voltage-gated potassium channels, particularly I_{Kr}. Women require lower doses of neuroleptics to control schizophrenia. Women awaken from anesthesia faster than men given the same doses of anesthetics. Women also take more medications than men, including over-the-counter formulations and supplements. The greater use of medications combined with these biologic differences may account for the reported higher frequency of adverse drug reactions in women than in men.

PSYCHOLOGICAL DISORDERS

(See also Chap. 386) Depression, anxiety, and affective and eating disorders (bulimia and anorexia nervosa) are more common in women than in men. Epidemiologic studies from both developed and developing nations consistently find major depression to be twice as common in women as in men, with the sex difference becoming evident in early adolescence. Depression occurs in 10% of women during pregnancy and in 10–15% of women during the postpartum period. There is a high likelihood of recurrence of postpartum depression with subsequent pregnancies. The incidence of major depression diminishes after age 45 years and does not increase with the onset of menopause. Depression in women appears to have a worse prognosis than in men; episodes last longer, and there is a lower rate of spontaneous remission. Schizophrenia and bipolar disorders occur at equal rates in men and women, although there may be sex differences in symptoms.

Both biologic and social factors account for the greater prevalence of depressive disorders in women. Men have higher levels of the neurotransmitter serotonin. Gonadal steroids also affect mood, and fluctuations during the menstrual cycle have been linked to symptoms of premenstrual syndrome. Sex hormones differentially affect the hypothalamic-pituitary-adrenal responses to stress. Testosterone appears to blunt cortisol responses to corticotropin-releasing hormone. Both low and high levels of estrogen can activate the hypothalamic-pituitary-adrenal axis.

SLEEP DISORDERS

(See also Chap. 28) There are striking sex differences in sleep and its disorders. During sleep, women have an increased amount of slow-wave activity, differences in timing of delta activity, and an increase in the number of sleep spindles. Testosterone modulates neural control of breathing and upper airway mechanics. Men have a higher prevalence of sleep apnea. Testosterone administration to hypogonadal men as well as to women increases apneic episodes during sleep. Women with the hyperandrogenic disorder polycystic ovary syndrome have an increased prevalence of obstructive sleep apnea, and apneic episodes are positively correlated with their circulating testosterone levels. In contrast, progesterone accelerates breathing, and, in the past, progestins were used for treatment of sleep apnea.

SUBSTANCE ABUSE AND TOBACCO

(See also Chaps. 387 and 390) Substance abuse is more common in men than in women. However, one-third of Americans who suffer from alcoholism are women. Women alcoholics are less likely to be diagnosed than men. A greater proportion of men than women seek help for alcohol and drug abuse. Men are more likely to go to an alcohol or drug treatment facility, while women tend to approach a primary care physician or mental health professional for help under the guise of a psychosocial problem. Late-life alcoholism is more common in women than men. On average, alcoholic women drink less than alcoholic men but exhibit the same degree of impairment. Blood alcohol levels are higher in women than in men after drinking equivalent amounts of alcohol, adjusted for body weight. This greater bioavailability of alcohol in women is due to both the smaller volume of distribution and the slower gastric metabolism of alcohol secondary to lower activity of gastric alcohol dehydrogenase than is the case in men. In addition, alcoholic women are more likely to abuse tranquilizers, sedatives, and amphetamines. Women alcoholics have a higher mortality rate than do nonalcoholic women and alcoholic men. Women also appear to develop alcoholic liver disease and other alcohol-related diseases with shorter drinking histories and lower levels of alcohol consumption. Alcohol abuse also poses special risks to a woman, adversely affecting fertility and the health of the baby (fetal alcohol syndrome). Even moderate alcohol use increases the risk of breast cancer, hypertension, and stroke in women.

More men than women smoke tobacco, but the prevalence of smoking is declining faster in men than in women. Smoking markedly increases the risk of cardiovascular disease in premenopausal women and is also associated with a decrease in the age of menopause. Women who smoke are more likely to develop chronic obstructive pulmonary disease and lung cancer than men and at lower levels of tobacco exposure.

VIOLENCE AGAINST WOMEN

Domestic violence is the most common cause of physical injury in women, exceeding the combined incidence of all other types of injury (such as from rape, mugging, and auto accidents). Sexual assault is one of the most common crimes against women. One in five adult women in the United States reports having experienced sexual assault during her lifetime. Adult women are much more likely to be raped by a spouse, ex-spouse, or acquaintance than by a stranger. Domestic violence may be an unrecognized feature of certain clinical presentations such as chronic abdominal pain, headaches, substance abuse, and eating disorders, in addition to more obvious manifestations such as trauma.

SUMMARY

Women's health is now a mature discipline, and the importance of sex differences in biologic processes is well-recognized. It is clear that understanding the mechanisms of these differences will have an impact on both women's and men's health. For example, estrogen is now recognized

as an important regulator of bone density in men as well as in women. Elucidating the biology of sex hormone action has resulted in the design of drugs with tissue-specific hormone agonist and antagonist effects. These discoveries will make it feasible to selectively modulate the actions of sex hormones in both women and men to prevent and treat disease.

7 Medical Disorders during Pregnancy

Robert L. Barbieri, John T. Repke

Approximately 4 million births occur in the United States each year. A significant proportion of these are complicated by one or more medical disorders. Three decades ago, many medical disorders were contraindications to pregnancy. Advances in obstetrics, neonatology, obstetric anesthesiology, and medicine have increased the expectation that pregnancy will result in an excellent outcome for both mother and fetus despite most of these conditions. Successful pregnancy requires important physiologic adaptations, such as a marked increase in cardiac output. Medical problems that interfere with the physiologic adaptations of pregnancy increase the risk for poor pregnancy outcome; conversely, in some instances pregnancy may adversely impact an underlying medical disorder.

HYPERTENSION (See also Chap. 241)

In pregnancy, cardiac output increases by 40%, most of which is due to an increase in stroke volume. Heart rate increases by ~10 beats/min during the third trimester. In the second trimester of pregnancy, systemic vascular resistance decreases and this is associated with a fall in blood pressure. During pregnancy, a blood pressure of 140/90 mmHg is considered to be abnormally elevated and is associated with an increase in perinatal morbidity and mortality. In all pregnant women, the measurement of blood pressure should be performed in the sitting position, because for many the lateral recumbent position is associated with a blood pressure lower than that recorded in the sitting position. The diagnosis of hypertension requires the measurement of two elevated blood pressures, at least 6 h apart. Hypertension during pregnancy is usually caused by preeclampsia, chronic hypertension, gestational hypertension, or renal disease.

PREECLAMPSIA

Approximately 5–7% of all pregnant women develop *preeclampsia*, the new onset of hypertension (blood pressure >140/90 mmHg) and proteinuria (>300 mg/24 h) after 20 weeks of gestation. Although the precise placental factors that cause preeclampsia are unknown, the end result is vasospasm and endothelial injury in multiple organs. Excessive placental secretion of a soluble fms-like tyrosine kinase 1, a naturally occurring vascular endothelial growth factor antagonist, and decreased secretion of placental growth factor may contribute to the endothelial dysfunction, hypertension, and proteinuria observed in preeclampsia. Glomerular endothelial cells demonstrate swelling and encroach on the vascular lumen. Preeclampsia is associated with abnormalities of cerebral circulatory autoregulation, which increase the risk of stroke at near-normal blood pressures. Risk factors for the development of preeclampsia include nulliparity, diabetes mellitus, a history of renal disease or chronic hypertension, a prior history of preeclampsia, extremes of maternal age (>35 years or <15 years), obesity, factor V Leiden mutation, angiotensinogen gene T235, G20210A prothrombin gene mutation, antiphospholipid antibody syndrome, and multiple gestation.

Severe preeclampsia is the presence of new-onset hypertension and proteinuria accompanied by central nervous system (CNS) dysfunction (headaches, blurred vision, seizures, coma), marked elevations of blood pressure (>160/110 mmHg), severe proteinuria (>5 g/24 h), oliguria or renal failure, pulmonary edema, hepatocellular injury (ALT > 2 × the upper limits of normal), thrombocytopenia (platelet count < 100,000/L), or disseminated intravascular coagulation. Women with *mild preeclampsia* are those with the diagnosis of new-onset hypertension, proteinuria, and edema without evidence of severe preeclampsia. The HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) syndrome is a special subgroup of severe preeclampsia and is a major cause of morbidity and mortality in this disease. The presence of platelet dysfunction and coagulation disorders further increases the risk of stroke.

Rx PREECLAMPSIA

Preeclampsia resolves within a few weeks after delivery. For pregnant women with preeclampsia prior to 37 weeks' gestation, delivery reduces the mother's morbidity but exposes the fetus to the risk of premature delivery. The management of preeclampsia is challenging because it requires the clinician to balance the health of both mother and fetus simultaneously and to make management decisions that afford both the best opportunities for infant survival. In general, prior to term, women with *mild* preeclampsia can be managed conservatively with bed rest, close monitoring of blood pressure and renal function, and careful fetal surveillance. For women with *severe* preeclampsia, delivery is recommended unless the patient is eligible for expectant management in a tertiary hospital setting. Expectant management of severe preeclampsia remote from term affords some benefits for the fetus with significant risks for the mother.

The definitive treatment of preeclampsia is delivery of the fetus and placenta. For women with severe preeclampsia, aggressive management of blood pressures > 160/110 mmHg reduces the risk of cerebrovascular accidents. Intravenous labetalol or hydralazine are the drugs most commonly used to manage preeclampsia. Intravenous hydralazine may be associated with more episodes of maternal hypotension than labetalol. Alternative agents such as calcium channel blockers may be used. Elevated arterial pressure should be reduced slowly to avoid hypotension and a decrease in blood flow to the fetus. *Angiotensin-converting enzyme (ACE) inhibitors as well as angiotensin-receptor blockers should be avoided in the second and third trimesters of pregnancy because of their adverse effects on fetal development.* Pregnant women treated with ACE inhibitors often develop oligohydramnios, which may be caused by decreased fetal renal function.

Magnesium sulfate is the treatment of choice for the prevention and treatment of eclamptic seizures. Two large randomized clinical trials have demonstrated the superiority of magnesium sulfate over phenytoin and diazepam, and a recent large randomized clinical trial has demonstrated the efficacy of magnesium sulfate in reducing the risk of seizure and possibly reducing the risk of maternal death. Magnesium may prevent seizures by interacting with *N*-methyl-D-aspartate (NMDA) receptors in the CNS. Given the difficulty of predicting eclamptic seizures on the basis of disease severity, it is recommended that once the decision to proceed with deliv-

ery is made, all patients carrying a diagnosis of preeclampsia be treated with magnesium sulfate (see **Regimens**, below).

REGIMENS FOR THE ADMINISTRATION OF MAGNESIUM SULFATE FOR SEIZURE PROPHYLAXIS IN WOMEN IN LABOR WITH PREECLAMPSIA

Intramuscular	Intravenous
10 g (5 g IM deep in each buttock)[a] 5 g IM deep q4h, alternating sides	6-g bolus over 15 min 1–3 g/h by continuous infusion pump May be mixed in 100 mL crystalloid; if given by intravenous push, make up as 20% solution; push at maximum rate of 1 g/min 40-g $MgSO_4 \cdot 7H_2O$ in 1000 mL Ringers lactate; run at 25–75 mL/h (1–3 g/h)[a]

[a]Made up as 50% solution

CHRONIC ESSENTIAL HYPERTENSION

Pregnancy complicated by chronic essential hypertension is associated with intrauterine growth restriction and increased perinatal mortality. Pregnant women with chronic hypertension are at increased risk for superimposed preeclampsia and abruptio placenta. Women with chronic hypertension should have a thorough prepregnancy evaluation, both to identify remediable causes of hypertension and to ensure that the prescribed antihypertensive agents are not associated with an adverse outcome of pregnancy (e.g., ACE inhibitors, angiotensin-receptor blockers). α-Methyldopa, labetalol, and nifedipine are the most commonly used medications for the treatment of chronic hypertension in pregnancy. Baseline evaluation of renal function is necessary to help differentiate the effects of chronic hypertension versus superimposed preeclampsia should the hypertension worsen during pregnancy. There are no convincing data that demonstrate that treatment of mild chronic hypertension improves perinatal outcome.

GESTATIONAL HYPERTENSION

This is the development of elevated blood pressure during pregnancy or in the first 24 h post partum in the absence of preexisting chronic hypertension and other signs of preeclampsia. Uncomplicated gestational hypertension that does not progress to preeclampsia has not been associated with adverse pregnancy outcome or adverse long-term prognosis.

RENAL DISEASE (See also Chaps. 272 and 280)

Normal pregnancy is characterized by an increase in glomerular filtration rate and creatinine clearance. This occurs secondary to a rise in renal plasma flow and increased glomerular filtration pressures. Patients with underlying renal disease and hypertension may expect a worsening of hypertension during pregnancy. If superimposed preeclampsia develops, the additional endothelial injury results in a capillary leak syndrome that may make the management of these patients challenging. In general, patients with underlying renal disease and hypertension benefit from aggressive management of blood pressure. Preconception counseling is also essential for these patients so that accurate risk assessment can occur prior to the establishment of pregnancy and important medication changes and adjustments can be made. In general, a prepregnancy serum creatinine level <133 μmol/L (<1.5 mg/dL) is associated with a favorable prognosis. When renal disease worsens during pregnancy, close collaboration between the nephrologist and the maternal-fetal medicine specialist is essential so that decisions regarding delivery can be weighed in the context of sequelae of prematurity for the neonate versus long-term sequelae for the mother with respect to future renal function.

CARDIAC DISEASE

VALVULAR HEART DISEASE

(See also Chap. 230) This is the most common cardiac problem complicating pregnancy.

Mitral Stenosis This is the valvular disease most likely to cause death during pregnancy. The pregnancy-induced increase in blood volume, cardiac output, and tachycardia can increase the transmitral pressure gradient and cause pulmonary edema in women with mitral stenosis. Pregnancy associated with long-standing mitral stenosis may result in pulmonary hypertension. Sudden death has been reported when hypovolemia has been allowed to occur in this condition. Careful control of heart rate, especially during labor and delivery, minimizes the impact of tachycardia and reduced ventricular filling times on cardiac function. Pregnant women with mitral stenosis are at increased risk for the development of atrial fibrillation and other tachyarrhythmias. Medical management of severe mitral stenosis and atrial fibrillation with digoxin and beta blockers is recommended. Balloon valvulotomy can be carried out during pregnancy.

Mitral Regurgitation and Aortic Regurgitation and Stenosis These are generally well tolerated during pregnancy. The pregnancy-induced decrease in systemic vascular resistance reduces the risk of cardiac failure with these conditions. As a rule, mitral valve prolapse does not present problems for the pregnant patient, and aortic stenosis, unless very severe, is well tolerated. In the most severe cases of aortic stenosis, limitation of activity or balloon valvuloplasty may be indicated.

CONGENITAL HEART DISEASE

(See also Chap. 229) The presence of a congenital cardiac lesion in the mother increases the risk of congenital cardiac disease in the newborn. Prenatal screening of the fetus for congenital cardiac disease with ultrasound is recommended. Atrial or ventricular septal defect is usually well tolerated during pregnancy in the absence of pulmonary hypertension, provided that the woman's prepregnancy cardiac status is favorable. Use of air filters on IV sets during labor and delivery in patients with intracardiac shunts is generally recommended.

OTHER CARDIAC DISORDERS

Supraventricular tachycardia (Chap. 226) is a common cardiac complication of pregnancy. Treatment is the same as in the nonpregnant patient, and fetal tolerance of medications such as adenosine and calcium channel blockers is acceptable. When necessary, electrocardioversion may be performed and is generally well tolerated by mother and fetus.

Peripartum cardiomyopathy (Chap. 231) is an uncommon disorder of pregnancy associated with myocarditis, and its etiology remains unknown. Treatment is directed toward symptomatic relief and improvement of cardiac function. Many patients recover completely; others are left with a progressive dilated cardiomyopathy. Recurrence in a subsequent pregnancy has been reported, and women should be counseled to avoid pregnancy after a diagnosis of peripartum cardiomyopathy.

SPECIFIC HIGH-RISK CARDIAC LESIONS

Marfan Syndrome (See also Chap. 357) This is an autosomal dominant disease, associated with a high risk of maternal morbidity. Approximately 15% of pregnant women with Marfan syndrome develop a major cardiovascular manifestation during pregnancy, with almost all women surviving. An aortic root diameter <40 mm is considered to be associated with a favorable outcome of pregnancy. Prophylactic therapy with beta blockers has been advocated, although large-scale clinical trials in pregnancy have not been performed.

Pulmonary Hypertension (See also Chap. 244) Maternal mortality in the setting of severe pulmonary hypertension is high, and primary pulmonary hypertension is a contraindication to pregnancy. Termination of pregnancy may be advisable in these circumstances to preserve the life of the mother. In the Eisenmenger syndrome, i.e., the combination of pulmonary hypertension with right-to-left shunting due to congenital abnormalities (Chap. 229), maternal and fetal death occur frequently. Systemic hypotension may occur after blood loss, prolonged Valsalva maneuver, or regional anesthesia; sudden death secondary to hypotension is a dreaded complication. Management of

these patients is challenging, and invasive hemodynamic monitoring during labor and delivery is generally recommended.

In patients with pulmonary hypertension, vaginal delivery is less stressful hemodynamically than cesarean section, which should be reserved for accepted obstetric indications.

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM (See also Chap. 256)

A hypercoagulable state is characteristic of pregnancy, and deep venous thrombosis (DVT) occurs in about 1 in 2000 pregnancies. Pulmonary embolism is one of the most common causes of maternal death in the United States. In pregnant women, DVT occurs much more commonly in the left leg than in the right leg, due to the compression of the left iliac vein by the iliac artery and the uterus. Activated protein C resistance caused by the factor V Leiden mutation increases the risk for DVT and pulmonary embolism during pregnancy. Approximately 25% of women with DVT during pregnancy carry the factor V Leiden allele. The presence of the factor V Leiden mutation also increases the risk for severe preeclampsia. Additional genetic mutations associated with DVT during pregnancy include the prothrombin G20210A mutation (heterozygotes and homozygotes) and the methylenetetrahydrofolate reductase C677T mutation (homozygotes).

Rx DEEP VENOUS THROMBOSIS

Aggressive diagnosis and management of DVT and suspected pulmonary embolism optimize the outcome for mother and fetus. In general, all diagnostic and therapeutic modalities afforded the nonpregnant patient should be utilized in pregnancy. Anticoagulant therapy with low-molecular-weight heparin (LMWH) or unfractionated heparin is indicated in pregnant women with DVT. LMWH may be associated with an increased risk of epidural hematoma in women receiving an epidural anesthetic in labor. One approach to this problem is to switch from LMWH to unfractionated heparin before the anticipated delivery date. Warfarin therapy is contraindicated in the first trimester due to its association with fetal chondrodysplasia punctata. In the second and third trimesters, warfarin may cause fetal optic atrophy and mental retardation. When DVT occurs in the postpartum period, LMWH therapy for 7–10 days may be followed by warfarin therapy for 3–6 months. Warfarin is not contraindicated in breast-feeding women.

ENDOCRINE DISORDERS

DIABETES MELLITUS

(See also Chap. 338) In pregnancy, the fetoplacental unit induces major metabolic changes, the purpose of which is to shunt glucose and amino acids to the fetus while the mother uses ketones and triglycerides to fuel her metabolic needs. These metabolic changes are accompanied by maternal insulin resistance, caused in part by placental production of steroids, a growth hormone variant, and placental lactogen. Although pregnancy has been referred to as a state of "accelerated starvation," it is better characterized as "accelerated ketosis." In pregnancy, after an overnight fast, plasma glucose is lower by 0.8–1.1 mmol/L (15–20 mg/dL) than in the nonpregnant state. This is due to the use of glucose by the fetus. In early pregnancy, fasting may result in circulating glucose concentrations in the range of 2.2 mmol/L (40 mg/dL) and may be associated with symptoms of hypoglycemia. In contrast to the decrease in maternal glucose concentration, plasma hydroxybutyrate and acetoacetate levels rise to two to four times normal after a fast.

Rx DIABETES MELLITUS IN PREGNANCY

Pregnancy complicated by diabetes mellitus is associated with higher maternal and perinatal morbidity and mortality rates. Preconception counseling and treatment are important for the diabetic patient contemplating pregnancy and can reduce the risk of congenital malformations and improve pregnancy outcome. Folate supplementation reduces the incidence of fetal neural tube defects, which occur with greater frequency in fetuses of diabetic mothers. In addition, optimizing glucose control during key periods of organogenesis reduces other congenital anomalies including sacral agenesis, caudal dysplasia, renal agenesis, and ventricular septal defect.

Once pregnancy is established, glucose control should be managed more aggressively than in the nonpregnant state. In addition to dietary changes, this requires more frequent blood glucose monitoring and often involves additional injections of insulin or conversion to an insulin pump. Fasting blood glucose levels should be maintained at <5.8 mmol/L (<105 mg/dL) with no values >7.8 mmol/L (140 mg/dL). Commencing in the third trimester, regular surveillance of maternal glucose control as well as assessment of fetal growth (obstetric sonography) and fetoplacental oxygenation (fetal heart rate monitoring or biophysical profile) optimizes pregnancy outcome. Pregnant diabetic patients without vascular disease are at greater risk for delivering a macrosomic fetus, and attention to fetal growth via clinical and ultrasound examinations is important. Fetal macrosomia is associated with an increased risk of maternal and fetal birth trauma. Pregnant women with diabetes have an increased risk of developing preeclampsia, and those with vascular disease are at greater risk for developing intrauterine growth restriction, which is associated with an increased risk of fetal and neonatal death. Excellent pregnancy outcomes in patients with diabetic nephropathy and proliferative retinopathy have been reported with aggressive glucose control and intensive maternal and fetal surveillance.

Glycemic control may become more difficult to achieve as pregnancy progresses due to an increase in insulin resistance. Because of delayed pulmonary maturation of the fetuses of diabetic mothers, early delivery should be avoided unless there is biochemical evidence of fetal lung maturity. In general, efforts to control glucose and maintain the pregnancy until the estimated date of delivery result in the best overall outcome for both mother and newborn.

GESTATIONAL DIABETES

All pregnant women should be screened for gestational diabetes unless they are in a low-risk group. Women at low risk for gestational diabetes are those <25 years of age; those with a body mass index < 25 kg/m^2, no maternal history of macrosomia or gestational diabetes, and no diabetes in a first-degree relative; and those not members of a high-risk ethnic group (African American, Hispanic, Native American). A typical two-step strategy for establishing the diagnosis of gestational diabetes involves administration of a 50-g oral glucose challenge with a single serum glucose measurement at 60 min. If the plasma glucose is <7.8 mmol/L (<140 mg/dL), the test is considered normal. Serum glucose > 7.8 mmol/L (>140 mg/dL) warrants administration of a 100-g oral glucose challenge with serum glucose measurements obtained in the fasting state, and at 1, 2, and 3 h. Normal values are plasma glucose concentrations <5.8 mmol/L (<105 mg/dL), 10.5 mmol/L (190 mg/dL), 9.1 mmol/L (165 mg/dL), and 8.0 mmol/L (145 mg/dL), respectively. Some centers have adopted more conservative criteria, using <7.5 mmol/L (<135 mg/dL) as the screening threshold, and values of <5.3 mmol/L (<95 mg/dL), <10 mmol/L (<180 mg/dL), <8.6 mmol/L (<155 mg/dL), and <7.8 mmol/L (<140 mg/dL) as the upper norms for a 3-h glucose tolerance test.

Pregnant women with gestational diabetes are at increased risk of preeclampsia, delivering infants who are large for their gestational age, and birth lacerations. Their fetuses are at risk of hypoglycemia and birth trauma (brachial plexus) injury.

Rx GESTATIONAL DIABETES

Treatment of gestational diabetes with a two-step strategy of dietary intervention followed by insulin injections if diet alone does not adequately control blood sugar [fasting glucose < 5.6 mmol/L (<100 mg/dL) and 2-h post-prandial <7.0 mmol/L (<126 mg/dL)] is associated with a decreased risk of birth trauma for the fetus. More recently the use of the oral hypoglycemic agent glyburide has become popular for managing gestational diabetes refractory to nutritional management. More data on the safety and efficacy of glyburide for the management of gestational diabetes are needed before it supplants insulin as the treatment agent of choice. For women with gestational diabetes, within the 10 years after the index pregnancy there is a 40% risk of being diagnosed with diabetes. All women

with a history of gestational diabetes should be counseled about prevention strategies and evaluated regularly for diabetes.

THYROID DISEASE

(See also Chap. 335) In pregnancy, the estrogen-induced increase in thyroxine-binding globulin causes an increase in circulating levels of total T_3 and total T_4. The normal range of circulating levels of free T_4, free T_3, and thyroid-stimulating hormone (TSH) remain unaltered by pregnancy.

The thyroid gland normally enlarges during pregnancy. Maternal hyperthyroidism occurs at a rate of ~2 per 1000 pregnancies and is generally well tolerated by pregnant women. Clinical signs and symptoms should alert the physician to the occurrence of this disease. Many of the physiologic adaptations to pregnancy may mimic subtle signs of hyperthyroidism. Although pregnant women are able to tolerate mild hyperthyroidism without adverse sequelae, more severe hyperthyroidism can cause spontaneous abortion or premature labor, and thyroid storm is associated with a significant risk of maternal mortality.

℞ HYPERTHYROIDISM IN PREGNANCY

Hyperthyroidism in pregnancy should be aggressively evaluated and treated. The treatment of choice is propylthiouracil. Because it crosses the placenta, the minimum effective dose should be used to maintain free T_4 in the upper normal range. Methimazole crosses the placenta to a greater degree than propylthiouracil and has been associated with fetal aplasia cutis. Radioiodine should not be used during pregnancy, either for scanning or treatment, because of effects on the fetal thyroid. In emergent circumstances, additional treatment with beta blockers and a saturated solution of potassium iodide may be necessary. Hyperthyroidism is most difficult to control in the first trimester of pregnancy and easiest to control in the third trimester.

The goal of therapy for *hypothyroidism* is to maintain the serum TSH in the normal range, and thyroxine is the drug of choice. Children born to women with an elevated serum TSH (and a normal total thyroxine) during pregnancy have impaired performance on neuropsychologic tests. During pregnancy, the dose of thyroxine required to keep the TSH in the normal range rises. In one study, the mean replacement dose of thyroxine required to maintain the TSH in the normal range was 0.1 mg daily before pregnancy, and it increased to 0.15 mg daily during pregnancy. Since the increased thyroxine requirement occurs as early as the fifth week of pregnancy, one approach is to increase the thyroxine dose by 30% as soon as pregnancy is diagnosed and then adjust the dose by serial measurement of TSH.

HEMATOLOGIC DISORDERS

Pregnancy has been described as a state of physiologic anemia. Part of the reduction in hemoglobin concentration is dilutional, but iron and folate deficiencies are the major causes of correctable anemia during pregnancy.

In populations at high risk for hemoglobinopathies (Chap. 99), hemoglobin electrophoresis should be performed as part of the prenatal screen. Hemoglobinopathies can be associated with increased maternal and fetal morbidity and mortality. Management is tailored to the specific hemoglobinopathy and is generally the same for both pregnant and nonpregnant women. Prenatal diagnosis of hemoglobinopathies in the fetus is readily available and should be discussed with prospective parents either prior to or early in pregnancy.

Thrombocytopenia occurs commonly during pregnancy. The majority of cases are benign gestational thrombocytopenias, but the differential diagnosis should include immune thrombocytopenia (Chap. 109) and preeclampsia. Maternal thrombocytopenia may also be caused by catastrophic obstetric events such as retention of a dead fetus, sepsis, abruptio placenta, and amniotic fluid embolism.

NEUROLOGIC DISORDERS

Headache appearing during pregnancy is usually due to migraine (Chap. 15), a condition that may worsen, improve, or be unaffected by pregnancy. A new or worsening headache, particularly if associated with visual blurring, may signal eclampsia (above) or pseudotumor cerebri (benign intracranial hypertension; Chap. 29); diplopia due to a sixth nerve palsy suggests pseudotumor cerebri. The risk of seizures in patients with epilepsy increases in the postpartum period but not consistently during pregnancy; management is discussed in Chap. 363. The risk of stroke is generally thought to increase during pregnancy because of a hypercoagulable state; however, studies suggest that the period of risk occurs primarily in the postpartum period and that both ischemic and hemorrhagic strokes may occur at this time. Guidelines for use of heparin therapy are summarized above (see "Deep Venous Thrombosis and Pulmonary Embolism"); warfarin is teratogenic and should be avoided.

The onset of a new movement disorder during pregnancy suggests chorea gravidarum, a variant of Sydenham's chorea associated with rheumatic fever and streptococcal infection (Chap. 315); the chorea may recur with subsequent pregnancies. Patients with preexisting multiple sclerosis (Chap. 375) experience a gradual decrease in the risk of relapses as pregnancy progresses and, conversely, an increase in attack risk during the postpartum period. Beta interferons should *not* be administered to pregnant MS patients, but moderate or severe relapses can be safely treated with pulse glucocorticoid therapy. Finally, certain tumors, particularly pituitary adenoma and meningioma (Chap. 374), may manifest during pregnancy because of accelerated growth, possibly driven by hormonal factors.

Peripheral nerve disorders associated with pregnancy include Bell's palsy (idiopathic facial paralysis, Chap. 379), which is approximately threefold more likely to occur during the third trimester and immediate postpartum period than in the general population. Therapy with glucocorticoids should follow the guidelines established for nonpregnant patients. Entrapment neuropathies are common in the later stages of pregnancy, presumably as a result of fluid retention. Carpal tunnel syndrome (median nerve) presents as pain and paresthesia in the hand, often worse at night, and later with weakness in the thenar muscles. Treatment is generally conservative; wrist splints may be helpful, and glucocorticoid injections or surgical section of the carpal tunnel can usually be postponed. Meralgia paresthetica (lateral femoral cutaneous nerve) consists of pain and numbness in the lateral aspect of the thigh without weakness. Patients are usually reassured to learn that these symptoms are benign and can be expected to remit spontaneously after the pregnancy has been completed.

Judicious use of neuroimaging procedures is reasonable during pregnancy. Some centers require that formal consent be obtained from pregnant patients before MRI scans are administered. Experimental data indicate that high-field-strength MRI may be teratogenic to rodents; however, studies in pregnant MRI technicians have failed to show any risk to the fetus, even with chronic exposure. The paramagnetic MRI contrast agent gadolinium is usually not administered, particularly during the first trimester, because it crosses the blood-brain barrier. CT scanning of the brain is also considered safe, particularly as the procedure is fast, little radioactive scatter is produced, and pelvic contents are easily shielded; iodinated contrast media should be avoided whenever possible.

GASTROINTESTINAL AND LIVER DISEASE

Up to 90% of pregnant women experience nausea and vomiting during the first trimester of pregnancy. Occasionally, hyperemesis gravidarum requires hospitalization to prevent dehydration, and sometimes parenteral nutrition is required.

Crohn's disease may be associated with exacerbations in the second and third trimesters. Ulcerative colitis is associated with disease exacerbations in the first trimester and during the early postpartum period. Medical management of these diseases during pregnancy is identical to the management in the nonpregnant state (Chap. 289).

Exacerbation of gall bladder disease is commonly observed during pregnancy. In part this may be due to pregnancy-induced alteration in the metabolism of bile and fatty acids. Intrahepatic cholestasis of preg-

nancy is generally a third-trimester event. Profound pruritus may accompany this condition, and it may be associated with increased fetal mortality. It has been suggested that placental bile salt deposition may contribute to progressive uteroplacental insufficiency. Therefore, regular fetal surveillance should be undertaken once the diagnosis of intrahepatic cholestasis is made. Favorable results with ursodiol have been reported.

Acute fatty liver is a rare complication of pregnancy. Frequently confused with the HELLP syndrome (see "Preeclampsia," above) and severe preeclampsia, the diagnosis of acute fatty liver of pregnancy may be facilitated by imaging studies and laboratory evaluation. Acute fatty liver of pregnancy is generally characterized by markedly increased levels of bilirubin and ammonia and by hypoglycemia. Management of acute fatty liver of pregnancy is supportive; recurrence in subsequent pregnancies has been reported.

All pregnant women should be screened for hepatitis B. This information is important for pediatricians after delivery of the infant. All infants receive hepatitis B vaccine. Infants born to mothers who are carriers of hepatitis B surface antigen should also receive hepatitis B immune globulin as soon after birth as possible and preferably within the first 72 h. Screening for hepatitis C is recommended for individuals at high risk for exposure.

INFECTIONS

BACTERIAL INFECTIONS

Other than bacterial vaginosis, the most common bacterial infections during pregnancy involve the urinary tract (Chap. 282). Many pregnant women have asymptomatic bacteriuria, most likely due to stasis caused by progestational effects on ureteral and bladder smooth muscle and later in pregnancy due to compression effects of the enlarging uterus. In itself, this condition is not associated with an adverse outcome of pregnancy. However, if asymptomatic bacteriuria is left untreated, symptomatic pyelonephritis may occur. Indeed, ~75% of cases of pregnancy-associated pyelonephritis are the result of untreated asymptomatic bacteriuria. All pregnant women should be screened with a urine culture for asymptomatic bacteriuria at the first prenatal visit. Subsequent screening with nitrite/leukocyte esterase strips is indicated for high-risk women, such as those with sickle cell trait or a history of urinary tract infections. All women with positive screens should be treated.

Abdominal pain and fever during pregnancy create a clinical dilemma. The diagnosis of greatest concern is intrauterine amniotic infection. While amniotic infection most commonly follows rupture of the membranes, this is not always the case. In general, antibiotic therapy is not recommended as a temporizing measure in these circumstances. If intrauterine infection is suspected, induced delivery with concomitant antibiotic therapy is generally indicated. Intrauterine amniotic infection is most often caused by pathogens such as *Escherichia coli* and group B streptococcus. In high-risk patients at term or in preterm patients, routine intrapartum prophylaxis of group B streptococcal (GBS) disease is recommended. Penicillin G and ampicillin are the drugs of choice. In penicillin-allergic patients, clindamycin is recommended. For the reduction of neonatal morbidity due to GBS, universal screening of pregnant women for GBS between 35 and 37 weeks gestation with intrapartum antibiotic treatment of infected women is recommended.

Postpartum infection is a significant cause of maternal morbidity and mortality. While rare after vaginal delivery, postpartum endomyometritis develops in 5% of patients having elective repeat cesarean section and in 25% of patients after emergency cesarean section following prolonged labor. Prophylactic antibiotics should be given to all patients undergoing cesarean section. As most cases of postpartum endomyometritis are polymicrobial, broad-spectrum antibiotic coverage with a penicillin, aminoglycoside, and metronidazole is recommended (Chap. 157). Most cases resolve within 72 h. Women who do not respond to antibiotic treatment for postpartum endomyometritis should be evaluated for septic pelvic thrombophlebitis. Imaging studies may be helpful in establishing the diagnosis, which is primarily a clinical diagnosis of exclusion. Patients with septic pelvic thrombophlebitis generally have tachycardia out of proportion to their fever and respond rapidly to intravenous administration of heparin.

All patients are screened prenatally for gonorrhea and chlamydial infections, and the detection of either should result in prompt treatment. Ceftriaxone and azithromycin are the agents of choice (Chaps. 137 and 169).

VIRAL INFECTIONS

Cytomegalovirus Infection Viral infection in pregnancy presents a significant challenge. The most common cause of congenital viral infection in the United States is cytomegalovirus (CMV) (Chap. 175). As many as 50–90% of women of childbearing age have antibodies to CMV, but only rarely does CMV reactivation result in neonatal infection. More commonly, primary CMV infection during pregnancy creates a risk of congenital CMV. No currently accepted treatment of CMV during pregnancy has been demonstrated to protect the fetus effectively. Moreover, it is impossible to predict which fetus will sustain life-threatening CMV infection. Severe CMV disease in the newborn is characterized most often by petechiae, hepatosplenomegaly, and jaundice. Chorioretinitis, microcephaly, intracranial calcifications, hepatitis, hemolytic anemia, and purpura may also develop. CNS involvement, resulting in the development of psychomotor, ocular, auditory, and dental abnormalities over time, has been described.

Rubella (See also Chap. 186) Rubella virus is a known teratogen; first-trimester rubella carries a high risk of fetal anomalies, though the risk decreases significantly later in pregnancy. Congenital rubella may be diagnosed by percutaneous umbilical blood sampling with the detection of IgM antibodies in fetal blood. All pregnant women should be screened for their immune status to rubella. Indeed, all women of childbearing age, regardless of pregnancy status, should have their immune status for rubella verified and be immunized if necessary. The incidence of congenital rubella in the United States is extremely low.

Herpesvirus (See also Chap. 172) The acquisition of genital herpes during pregnancy is associated with spontaneous abortion, prematurity, and congenital and neonatal herpes. A recent cohort study of pregnant women without evidence of previous herpes infection demonstrated that ~2% of the women acquired a new herpes infection during the pregnancy. Approximately 60% of the newly infected women had no clinical symptoms. Infection occurred equally in all three trimesters. If herpes seroconversion occurred early in pregnancy, the risk of transmission to the newborn was very low. In women who acquired genital herpes shortly before delivery, the risk of transmission was high. The risk of active genital herpes lesions at term can be reduced by prescribing acyclovir for the last 4 weeks of pregnancy to women who have had their first episode of genital herpes during the pregnancy.

Herpesvirus infection in the newborn can be devastating. Disseminated neonatal herpes carries with it high mortality and morbidity rates from CNS involvement. It is recommended that pregnant women with active genital herpes lesions at the time of presentation in labor be delivered by cesarean section.

Parvovirus (See also Chap. 177) Parvovirus infection (human parvovirus B19) may occur during pregnancy. It rarely causes sequelae, but susceptible women infected during pregnancy may be at risk for fetal hydrops secondary to erythroid aplasia and profound anemia.

HIV Infection (See also Chap. 182) The predominant cause of HIV infection in children is transmission of the virus from the mother to the newborn during the perinatal period. Exposures, which increase the risk of mother-to-child transmission, include vaginal delivery, preterm delivery, trauma to the fetal skin, and maternal bleeding. Additionally, recent infection with high maternal viral load, low maternal CD4+ T cell count, prolonged labor, prolonged length of membrane rupture, and the presence of other genital tract infections, such as

syphilis or herpes, increase the risk of transmission. Breast-feeding may also transmit HIV to the newborn and is therefore contraindicated in most developed countries for HIV-infected mothers. There is no clear evidence to suggest that the course of HIV disease is altered by pregnancy. There is also no clear evidence to suggest that uncomplicated HIV disease adversely impacts pregnancy other than by its inherent infection risk.

℞ HIV INFECTION IN PREGNANCY

The majority of cases of mother-to-child (vertical) transmission of HIV-1 occur during the intrapartum period. Mechanisms of vertical transmission include infection after rupture of the membranes and direct contact of the fetus with infected secretions or blood from the maternal genital tract. Zidovudine (ZDV) administered during pregnancy and labor and to the newborn reduces the risk of vertical transmission by 70%. Cesarean section is associated with additional risk reduction compared to vaginal delivery, especially in women with a viral load >1000 copies/mL. Regardless of the mode of delivery, intrapartum ZDV should be provided.

SUMMARY

Maternal mortality has decreased steadily during the past 70 years. The maternal death rate has decreased from nearly 600/100,000 live births in 1935 to 8/100,00 live births in 2002. The most common causes of maternal death in the United States today are, in decreasing order of frequency, pulmonary embolism, obstetric hemorrhage, hypertension, sepsis, cardiovascular conditions including peripartum cardiomyopathy, and ectopic pregnancy. With improved diagnostic and therapeutic modalities as well as with advances in the treatment of infertility, more patients with medical complications will be seeking, and be in need of, complex obstetric care. Improving outcome of pregnancy in these women will be best obtained by assembling a team of internists, specialists in maternal-fetal medicine (high-risk obstetrics), and anesthesiologists to counsel these patients about the risks of pregnancy and to plan their treatment prior to conception. The importance of preconception counseling cannot be overstated. It is the responsibility of all physicians caring for women in the reproductive age group to assess their patient's reproductive plans as part of their overall health evaluation.

8 Medical Evaluation of the Surgical Patient

Wei C. Lau, Kim A. Eagle

Over 40 million persons undergo noncardiac surgical procedures in the United States annually. Cardiovascular and pulmonary complications continue to account for major morbidity and mortality in such patients. Emerging evidence-based practices dictate that the internist should perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment and stratification in order to guide optimum perioperative risk-reduction strategies. This chapter reviews cardiovascular and pulmonary preoperative risk assessment, targeting intermediate- and high-risk patients to strategically guide perioperative therapies in order to improve outcome. It also reviews perioperative management and prophylaxis of diabetes mellitus, endocarditis, and venous thromboembolism.

ANESTHETICS

Mortality is extremely low with safe delivery of modern anesthesia, especially in low-risk patients undergoing low-risk surgery (Table 8-1). Inhaled anesthetics have predictable circulatory and respiratory effects; all decrease arterial pressure in a dose-dependent manner by reducing sympathetic tone, causing systemic vasodilation, myocardial depression, and decreased cardiac output. Inhaled anesthetics also cause respiratory depression with diminished responses to both hypercapnia and hypoxemia in a dose-dependent manner, and they have a variable effect on heart rate. In combination with neuromuscular blockade, inhaled anesthetic agents also cause reduction in functional residual lung capacity due to loss of diaphragmatic and intercostal muscle function. This decreases lung volume, which may lead to atelectasis in the dependent lung regions and, in turn, may result in arterial hypoxemia from ventilation-perfusion mismatch as well as an increased risk of postoperative pulmonary complications.

Several meta-analyses have examined the safety of general (inhaled) and neuroaxial (epidural or spinal) anesthesia and found that overall mortality was lower in patients receiving neuroaxial anesthesia. Lower rates of venous thrombosis, pulmonary embolism, pneumonia, and respiratory depression were also observed in patients who were provided neuroaxial anesthesia. However, there were no significant differences in cardiac events between the two approaches. A combination of neuroaxial blockade and general anesthesia is useful when it is desired to reduce general anesthesia requirements. Evidence from a meta-analysis of randomized controlled trials also supports postoperative epidural analgesia for the purpose of pain relief for more than 24 h.

EVALUATION OF INTERMEDIATE- TO HIGH-RISK PATIENTS

Simple, standardized preoperative screening questionnaires, such as the one shown in Table 8-2, have been developed for the purpose of identifying patients at intermediate or high risk who would benefit from a more detailed clinical evaluation. Evaluation of such patients for operation should always begin with a thorough history and physical examination and with a 12-lead resting ECG, in accordance with the American College of Cardiology/American Heart Association (ACC/AHA) guideline recommendations. The history should focus on symptoms of occult cardiac or pulmonary disease. The urgency of the surgery should be determined, as true emergent procedures are associ-

TABLE 8-1 SURGERY: GRADATION OF RISK OF COMMON NONCARDIAC SURGICAL PROCEDURES

Higher	• Emergent major operations, especially elderly • Aortic and other noncarotid major vascular surgery (endovascular and nonendovascular) • Prolonged surgery associated with large fluid shift and/or blood loss
Intermediate	• Major thoracic surgery • Major abdominal surgery • Carotid endarterectomy surgery • Head/neck surgery • Orthopedic surgery • Prostate surgery
Lower	• Eye, skin, and superficial surgery • Endoscopic procedures

ated with an unavoidably higher morbidity and mortality. Preoperative laboratory testing should be carried out only for specific clinical conditions based on the clinical examination. Thus, healthy patients of any age undergoing elective surgical procedures without coexisting medical conditions should not require any testing unless the degree of surgical stress may result in unusual changes from the baseline state.

PREOPERATIVE CARDIAC RISK ASSESSMENT

Assessment of exercise tolerance in the prediction of in-hospital perioperative risk is most helpful in patients who self-report worsening exercise-induced cardiopulmonary symptoms, those who may benefit from noninvasive or invasive cardiac testing regardless of scheduled surgical procedure, and those with known coronary artery disease (CAD) or with multiple risk factors who are able to exercise. For predicting perioperative events, poor exercise tolerance has been defined as the inability to walk four blocks or climb two flights of stairs at a normal pace or to meet a metabolic equivalent (MET) level of four (e.g., carrying objects of 15–20 lb, playing golf or doubles tennis) because of the development of dyspnea, angina, or excessive fatigue (Table 8-3).

TABLE 8-2 STANDARDIZED PREOPERATIVE QUESTIONNAIRES[a]

1. Age, weight, height
2. Are you:
   Female and 55 years of age or older or male and 45 years of age of older?
   If yes, are you also 70 years of age or older?
3. Do you take anticoagulant ("blood thinners") medications?
4. Do you have or have you had any of the following heart related conditions?
   Heart disease
   Heart attack within the last 6 months
   Angina (chest pain)
   Irregular heartbeat
   Heart failure
5. Do you have or have you ever had any of the following?
   Rheumatoid arthritis
   Kidney disease
   Liver disease
   Diabetes
6. Do you get short of breath when you lie flat?
7. Are you currently on oxygen treatment?
8. Do you have a chronic cough that produces any discharge or fluid?
9. Do you have lung problems or diseases?
10. Have you or any blood member of your family ever had a problem with any anesthesia other than nausea?
    If yes, describe:
11. If female, is it possible that you could be pregnant?
    Pregnancy test:
    Please list date of last menstrual period:

[a]University of Michigan Health System patient information report. Patients who answer yes to any of questions 2–9 should receive a more detailed clinical evaluation.

Previous studies have prospectively compared several cardiac risk indices. Given its accuracy and simplicity, the revised cardiac risk index (RCRI) (Table 8-4) is favored. The RCRI relies on the presence or absence of six identifiable predictive factors, which include high-risk surgery, ischemic heart disease, congestive heart failure, cerebrovascular disease, diabetes mellitus, and renal dysfunction. Each of these predictors is assigned one point. The risk of major cardiac events—defined as myocardial infarction, pulmonary edema, ventricular fibrillation or primary cardiac arrest, and complete heart block—can then be predicted. Based on the presence of none, one, two, three, or more of these clinical predictors, the rate of development of one of these major cardiac events is estimated to be 0.5, 1, 5, and 10%, respectively (Fig. 8-1). RCRI 0 has 0.4–0.5% risk of cardiac events; RCRI 1 has 0.9–1.3%; RCRI 2 has 4–6.6%; and RCRI ≥3 has 9–11% risk of cardiac events. The clinical utility of the RCRI is to identify patients with three or more predictors who are at higher risk (≥10%) for cardiac complications, and who may benefit from further risk stratification with noninvasive cardiac testing or initiation of preoperative preventive medical management.

PREOPERATIVE NONINVASIVE CARDIAC TESTING FOR RISK STRATIFICATION

There is little evidence to support widespread application of preoperative noninvasive cardiac testing for all patients undergoing major surgery. Rather, a selective approach based on clinical risk categorization appears to be both useful clinically and cost-effective. There is potential benefit in identifying asymptomatic but high-risk patients, such as those with left main or left main–equivalent CAD, or those with three-vessel CAD with poor left ventricular function who may benefit from coronary revascularization (Chap. 237). However, evidence does not support aggressive attempts to identify patients at intermediate risk with asymp-

TABLE 8-4 REVISED CARDIAC RISK INDEX CLINICAL MARKERS

High-risk surgical procedures
- Vascular surgery
- Major intraperitoneal or intrathoracic procedures

Ischemic heart disease
- History of myocardial infarction
- Current angina considered to be ischemic
- Requiring sublingual nitroglycerin
- Positive exercise test
- Pathological Q-waves on ECG
- History of PTCA and/or CABG with current angina considered to be ischemic

Congestive heart failure
- Left ventricular failure by physical examination
- History of paroxysmal nocturnal dyspnea
- History of pulmonary edema
- S3 gallop on cardiac auscultation
- Bilateral rales on pulmonary auscultation
- Pulmonary edema on chest x-ray

Cerebrovascular disease
- History of transient ischemic attack
- History of cerebrovascular accident

Diabetes mellitus
- Treatment with insulin

Chronic renal insufficiency
- Serum creatinine >2 mg/dL

Note: ECG, electrocardiogram; PTCA, percutaneous transluminal coronary angioplasty; CABG, coronary artery bypass grafting.

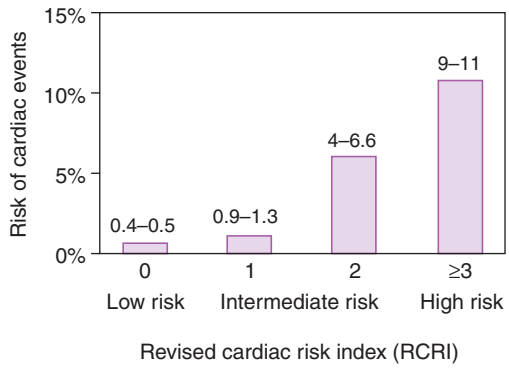

FIGURE 8-1 Risk stratification based on the Revised Cardiac Risk Index. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. Cardiac events include myocardial infarction, pulmonary edema, ventricular fibrillation, cardiac asystole, and complete heart block. *(Adapted from TH Lee et al, with permission.)*

tomatic but advanced coronary artery disease, since coronary revascularization appears to offer little advantage over medical therapy.

An RCRI score ≥3 in patients with severe myocardial ischemia on stress testing should lead to consideration of coronary revascularization prior to noncardiac surgery. Noninvasive cardiac testing is most appropriate if it is anticipated that in the event of a strongly positive test a patient will meet guidelines for coronary angiography and coronary revascularization. Pharmacologic stress tests are more useful than exercise testing in patients with functional limitations. Dobutamine echocardiography and persantine, adenosine or dobutamine nuclear perfusion testing (Chap. 222) have excellent negative predictive values (near 100%) but poor positive predictive values (< 20%) for identification of patients at risk for perioperative myocardial infarction or death. Thus, a negative study is reassuring, but a positive study is a relatively weak predictor of a "hard" perioperative cardiac event. A stepwise approach is illustrated in Fig. 8-2.

RISK MODIFICATION USING PREVENTIVE STRATEGIES TO REDUCE CARDIAC RISK

Perioperative Coronary Revascularization Currently, potential options for reducing perioperative cardiovascular risk include coronary artery revascularization and/or perioperative medical preventive therapies

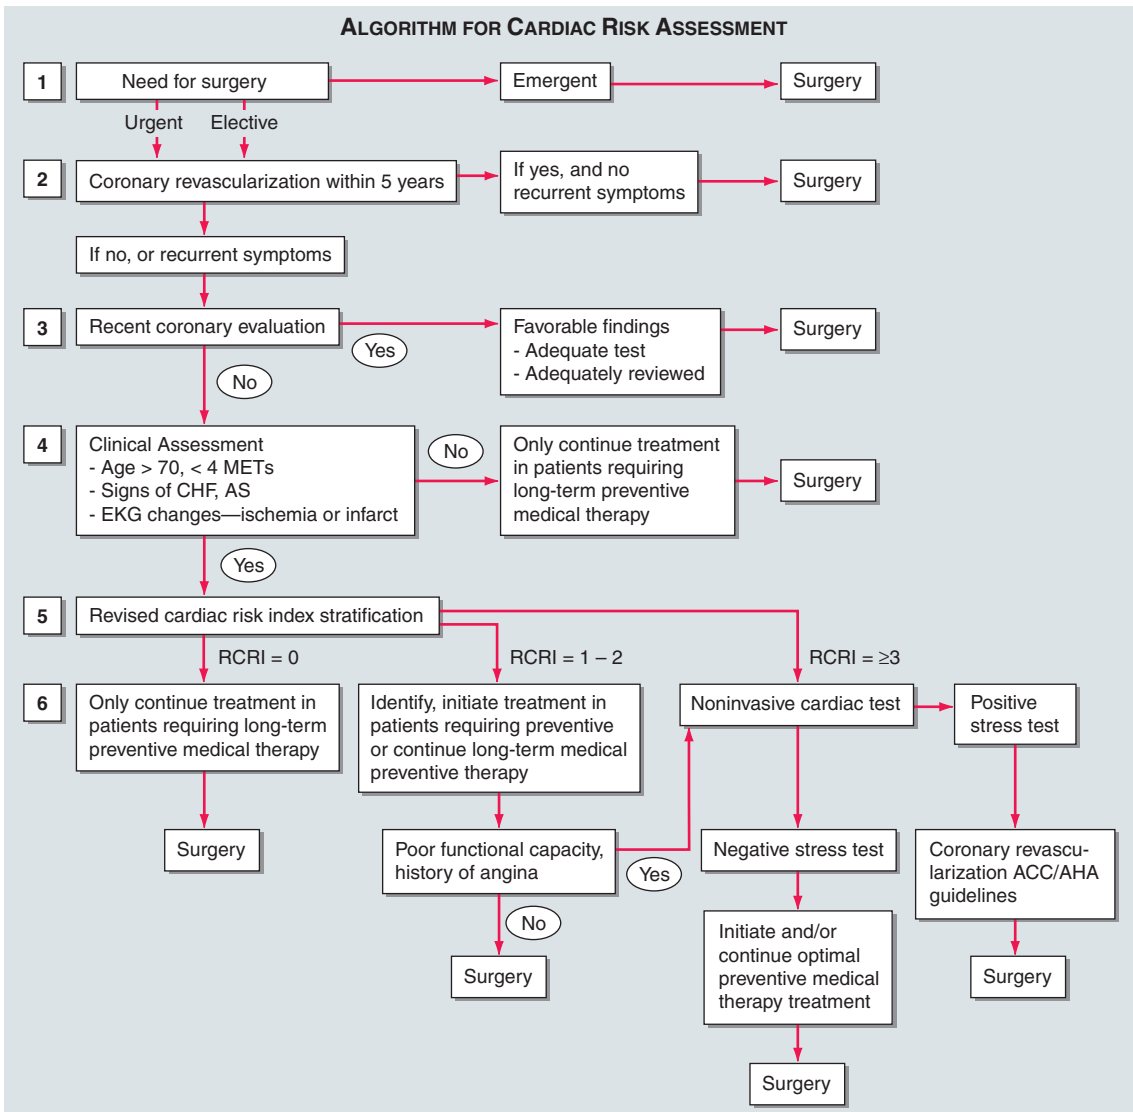

FIGURE 8-2 Composite algorithm for cardiac risk assessment and stratification in patients undergoing noncardiac surgery. Stepwise clinical evaluation: [1] Emergency surgery; [2] Prior coronary revascularization; [3] Prior coronary evaluation; [4] Clinical assessment; [5] Revised cardiac risk index; [6] Risk modification strategies. Preventative medical therapy = beta blocker and statin therapy. RCRI, revised cardiac risk index. *(Adapted from KA Eagle et al and TH Lee et al.)*

(Chap. 237). *Prophylactic* coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) provides no short- or midterm survival benefit for patients *without* left main CAD or three-vessel CAD in the presence of poor left ventricular systolic function. Although PCI is associated with lower procedural risk than is CABG in the perioperative setting, the placement of a coronary artery stent in a short period of time prior to noncardiac surgery may increase the risk of bleeding during surgery if dual antiplatelet therapy (aspirin and clopidogrel) is administered, or it increases the perioperative risk of myocardial infarction and cardiac death due to stent thrombosis if such therapy is withdrawn prematurely (Chap. 240). It is recommended that, if possible, noncardiac surgery be delayed 4–6 weeks after placement of a bare metal coronary stent and 3–6 months after a drug-eluting stent. For patients who *must* undergo noncardiac surgery early (first few days to 4 weeks) after PCI, simple balloon angioplasty without stent placement appears to be a reasonable alternative, since dual antiplatelet therapy is not necessary in such patients.

PERIOPERATIVE MEDICAL PREVENTIVE THERAPIES Perioperative preventive medical therapy with β-adrenergic antagonists, HMG-CoA reductase inhibitors (statins), and aspirin has the goal of reducing perioperative adrenergic stimulation, ischemia, and inflammation, which are triggered during the perioperative period.

β-ADRENERGIC ANTAGONISTS A recent expedited update of the ACC/AHA guideline focusing on recommendations for perioperative beta blocker therapy recommended the following: (1) Beta blockers *should be continued* in high-risk patients previously receiving these drugs who undergo vascular surgery, and they *should be administered* to high-risk patients identified by myocardial ischemia on preoperative assessment who are scheduled to undergo vascular surgery (Class I indications). (2) Beta blockers are *probably recommended* (Class IIa indication) for high-risk patients defined by multiple clinical predictors who undergo intermediate- or high-risk procedures. They *may be considered* (Class IIb indication) for intermediate-risk patients who undergo intermediate- or high-risk procedures and for low-risk patients who undergo vascular surgery.

HMG-COA REDUCTASE INHIBITORS (STATINS) A number of prospective and retrospective studies support the perioperative prophylactic use of statins for reduction of cardiac complications in patients with established atherosclerosis. Although the future role of statin prophylaxis in the reduction of perioperative cardiac risk awaits definitive clarification by an ongoing trial, perioperative statin therapy to reduce perioperative cardiac risk may now be considered in intermediate- or high-risk patients with atherosclerotic cardiovascular disease undergoing major noncardiac surgery.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS Evidence supports the discontinuation of ACE inhibitors and angiotensin receptor blockers for 24 hours prior to noncardiac surgery due to adverse circulatory effects after induction of anesthesia.

ORAL ANTIPLATELET AGENTS Evidence-based recommendations regarding perioperative use of aspirin and/or clopidogrel to reduce cardiac risk currently lack clarity. A substantial increase in perioperative bleeding and transfusion requirement in patients receiving dual antiplatelet therapy has been observed. The discontinuation of clopidogrel and aspirin for 5–7 days prior to major surgery to minimize the risk of perioperative bleeding and transfusion must be balanced with the potential increased risk of an acute coronary syndrome and of subacute stent thrombosis in patients with recent coronary stent implantation. If clinicians elect to withhold antiplatelet agents prior to surgery, they should be restarted as soon as possible postoperatively.

CALCIUM CHANNEL BLOCKERS Evidence is lacking to support the use of calcium channel blockers as a prophylactic strategy to decrease perioperative risk in major noncardiac surgery.

TABLE 8-5 PREDISPOSING RISK FACTORS FOR PULMONARY COMPLICATIONS

1. Upper respiratory tract infection: cough, dyspnea
2. Age >60 years

PREOPERATIVE PULMONARY ASSESSMENT

Perioperative pulmonary complications occur frequently and lead to significant morbidity and mortality. The guidelines from the American College of Physicians recommend the following:

(1) All patients undergoing noncardiac surgery should be assessed for risk of pulmonary complications (Table 8-5).

(2) Patients undergoing emergency or prolonged (>3 h) surgery; aortic aneurysm repair; vascular surgery; major abdominal, thoracic, neuro, head, and neck surgery; and general anesthesia should be considered to be at higher risk for postoperative pulmonary complications.

(3) Patients at higher risk of pulmonary complications should receive deep breathing exercises and/or incentive spirometry, as well as selective use of a nasogastric tube for postoperative nausea, vomiting, or symptomatic abdominal distention to reduce postoperative risk (Table 8-6).

(4) Routine preoperative spirometry and chest radiography are less helpful for predicting risk of postoperative pulmonary complications, but may be appropriate for patients with chronic obstructive pulmonary disease (COPD) or asthma.

(5) Pulmonary artery catheterization, total parenteral nutrition, and total enteral nutrition are not encouraged for postoperative pulmonary risk reduction.

Other Preoperative Pulmonary Risk-Modification Strategies Risk-modification strategies to reduce postoperative pulmonary complications should be implemented, particularly in higher-risk patients. Patients with cough or dyspnea preoperatively should be evaluated to

TABLE 8-6 RISK MODIFICATION TO REDUCE PERIOPERATIVE PULMONARY COMPLICATIONS

Preoperatively
- Cessation of smoking
- Training in proper breathing (incentive spirometry)
- Inhalation bronchodilator therapy
- Control of infection and secretion, when indicated
- Weight reduction, when appropriate

Intraoperatively
- Limited duration of anesthesia
- Select shorter acting neuromuscular blocking drugs when indicated
- Prevention of aspiration
- Maintenance of optimal bronchodilation

Postoperatively
- Continuation of preoperative measures, with particular attention to
  - inspiratory capacity maneuvers
  - mobilization of secretions
  - early ambulation
  - encouragement of coughing
  - selective use of a nasogastric tube
  - adequate pain control without excessive narcotics

Source: From VA Lawrence et al and from WF Dunn, PD Scanlon, Mayo Clin Proc 68:371, 1993, with permission.

determine the underlying cause of these symptoms. Patients who smoke should be counseled to quit for at least 8 weeks prior to elective surgery. Patients with asthma or COPD can be given steroids and bronchodilators pre- and postoperatively to optimize pulmonary function. Bacterial pulmonary infection should be treated preoperatively.

DIABETES MELLITUS

(See also Chap. 338) Many patients with diabetes mellitus have significant symptomatic or asymptomatic CAD and may have silent myocardial ischemia due to autonomic dysfunction. Evidence supports intensive perioperative glycemic control to achieve near-normal glucose levels (90–110 mg/dL) versus moderate glycemic control (120–200 mg/dL), using insulin infusion. This practice must be balanced against the risk of hypoglycemic complications. Oral hypoglycemic agonists should be held on the morning of operation. Perioperative hyperglycemia should be treated with intravenous infusion of short-acting insulin or subcutaneous sliding-scale insulin. Patients who are diet-controlled may proceed to surgery with close postoperative monitoring.

PROPHYLAXIS FOR INFECTIVE ENDOCARDITIS

(See also Chap. 118) Perioperative prophylactic antibiotics should be administered to patients with congenital or valvular heart disease, prosthetic valves, mitral valve prolapse, or other cardiac abnormalities in accordance with ACC/AHA practice guidelines.

PROPHYLAXIS OF VENOUS THROMBOEMBOLISM

(See also Chap. 256) Perioperative prophylaxis of venous thromboembolism should follow established guidelines of the American College of Chest Physicians. Aspirin is not supported as a single agent for thromboprophylaxis. Low-dose unfractionated heparin (≤5000 units subcutaneous bid), low-molecular-weight heparin (e.g., enoxaparin 30 mg bid or 40 mg od) or a pentasaccharide (fondaparinux 2.5 mg od) for patients at moderate risk, and unfractionated heparin (5000 units subcutaneous tid) for patients at high risk. Graduated compression stockings and pneumatic compression devices are useful supplements to anticoagulant therapy.

AGING

Aging is the progressive, universal decline first in functional reserve and then in function that occurs in organisms over time. Aging is heterogeneous. It varies widely in different individuals and in different organs within a particular individual. Aging is not a disease; however, the risk of developing disease is increased, often dramatically, as a function of age. The biochemical composition of tissues changes with age; physiologic capacity decreases, the ability to maintain homeostasis in adapting to stressors declines, and vulnerability to disease processes increases with age. After maturation, mortality rate increases exponentially with age.

DEMOGRAPHY OF AGING

Populations worldwide are aging. Improvements in environmental (e.g., clean water and improved sanitation) and behavioral (nutrition, reduced risk exposures) factors and the treatment and prevention of infectious diseases are largely responsible for the 30-year increase in life expectancy since 1900. In the United States, by 2030, 1 person in 5 will be >65 years. Old people are not evenly distributed geographically. Half of older people in the United States live in nine states, led by California, Florida, New York, and Texas.

GLOBAL AGING

Between 2000 and 2030, the number of older adults worldwide is expected to increase from 420 to 974 million. At present 59% of older adults live in the developing countries of Africa, Asia, Latin America, the Caribbean, and Oceania. The developing world has the largest absolute number of older adults and is experiencing the largest percentage increase.

Only 13% of those ≥80 years live in the United States; over 40% of those ≥80 years live in Asia. Embedded within these figures are additional critically important factors. Women outlive men; only 15% of centenarians are men. Men also remarry more frequently than do women; consequently, older women are frequently single and live alone. Women are more likely to have inadequate financial resources. Women also spend a greater portion of their surviving years being disabled than do men. In the United States, rates of disability decreased during the 1980s and 1990s, but the epidemics of obesity and physical inactivity may reverse these trends. A further concern for countries that already have high proportions of older adults (e.g., Japan, Sweden, Greece, and Italy, whose citizens >65 are 17–18% of their population) is the ratio of the >65 age group to the 15- to 64-year age group—the so-called dependency ratio. This ratio currently ranges from 22% in Europe to 6% in Africa but is expected to rise to >50% in Europe by 2050, with all other areas of the world exceeding 25% by 2050, except Africa.

LIFE EXPECTANCY

Often life-extending therapies are not offered to older patients because of an underestimate of life expectancy. Figure 9-1 shows average life expectancy as a function of age together with values for the lowest and highest quartiles of the population. White women currently have the highest life expectancy. Black women and white men have nearly identical life expectancies, and black men have the poorest life expectancy. At age 85 years, racial differences in life expectancy largely disappear. The average 75-year-

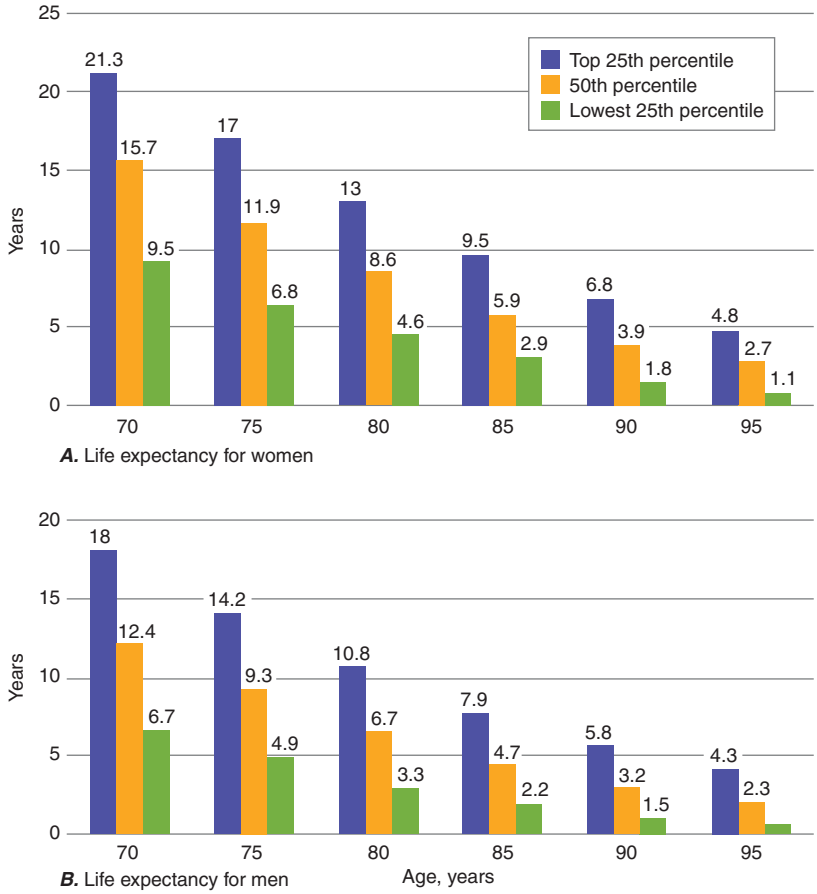

FIGURE 9-1 Upper, middle, and lower quartiles of life expectancy for women and men at selected ages. *(From LC Walter, KE Covinsky, JAMA 285:2751, 2001.)*

old is expected to live to age 86 and the average 85-year-old to age 91. Furthermore, where the issue has been examined, age is not a factor in determining the efficacy of a particular intervention. Thus, age alone generally should not be used to withhold life-extending interventions.

BIOLOGY OF AGING

As we age, we become increasingly unlike one another. For any variable one can measure, the variation in the distribution of values in a population increases with age. While the mean value may trend up or down, the age-related increase in the range of values is striking testimony to the diverse manifestations of the aging process. In addition, homeostatic mechanisms are slower to respond to stressors and take longer to restore normal function as we age. The ability to maintain stable function in the face of a change in the environment is called *allostasis* and it declines with age.

One problem as we age is nosologic; when is a particular change considered a normal age-related alteration and when does it become a disease? Ideas about the range of normal for a particular age continue to evolve. At one time, a 75-year-old with a blood pressure of 170/90 mmHg might have been considered to have an age-related increase in systolic blood pressure that did not require intervention. However, we now know that such a reading is a reflection of increased vascular stiffness, one of the most important risk factors for cardiovascular morbidity and mortality. Similarly, follow-up of individuals with fasting serum glucose levels of 6.1–6.7 mmol/L (110–120 mg/dL) have shown them to be at increased risk of diabetes complications. Accordingly impaired glucose metabolism is now defined as a fasting glucose level > 6.1 mmol/L (>110 mg/dL). Thus, the indications for interventions to alter natural history have changed and will continue to change as we learn more about aging.

Whether age-related changes that produce an aging phenotype have a common origin in a global process that alters cell or organ function or have heterogeneous contributions in different systems or different individuals is unclear. Studies of aging (*gerontology*) are aimed at understanding the cellular and molecular basis of age-related changes and have two ultimate therapeutic goals: preserving function as long as possible and extending life span. These two goals may not be linked.

The lack of model systems for studying aging has hampered progress. For many years, researchers have studied replicative senescence of normal cells in culture. Why do normal cells have a finite replicative potential in vitro and why do cells from older individuals undergo fewer divisions than cells from younger individuals? Many have hoped that insights from such studies would reveal information about the aging process. However, the link between the failure of cells to divide in a synthetic culture medium and the aging phenotype of a whole organism is tenuous, at best. The body tissues with the greatest replicative potential should identify the organs most susceptible to age-related defective replication. In humans, these organs are the lining of the small intestine and the hematopoietic system. In the absence of disease, no age-related problem is caused by the inability of cells to replicate. Old people do not run out of absorptive surface in the small intestine or fail to make blood cells. Better in vitro models of aging are needed.

Experimental aging studies rely heavily on manipulation of life span in intact organisms such as worms, flies, and rodents. Such studies have revealed important insights. Alteration of genes involved in DNA repair often leads to premature aging. Alteration of genes involved in insulin signaling often leads to life extension. In the worm, life extension can be accomplished by alteration of gene expression in a single tissue, neurons. Calorie restriction (at least 30% lower than an ad lib diet) increases both average and maximal life span in a wide range of species. In several species, interventions associated with increased life span activate the expression of one or more of a family of genes, called *sirtuins*, that function by silencing the expression of certain other genes. However, these and other important observations have not yet led to a complete picture of the molecular basis of aging. Some ideas are summarized in Table 9-1.

Additional insights about aging may be derived by understanding the clinical syndromes that produce a premature aging phenotype, the so-called segmental progerias. These syndromes are rare inherited disorders that mimic normal aging imperfectly. They include Werner

TABLE 9-1 SOME THEORIES OF AGING

Hypothesis	How It May Work
Genetic	Aging is a genetic program activated in post-reproductive life when an individual's evolutionary mission is accomplished
Oxidative stress	Accumulation of oxidative damage to DNA, proteins, and lipids interferes with normal function and produces a decrease in stress responses
Mitochondrial dysfunction	A common deletion in mitochondrial DNA with age compromises function and alters cell metabolic processes and adaptability to environmental change
Hormonal changes	The decline and loss of circadian rhythm in secretion of some hormones produces a functional hormone deficiency state
Telomere shortening	Aging is related to a decline in the ability of cells to replicate
Defective host defenses	The failure of the immune system to respond to infectious agents and the overactivity of natural immunity create vulnerability to environmental stresses
Accumulation of senescent cells	Renewing tissues become dysfunctional through loss of ability to renew

syndrome, Bloom syndrome, Cockayne syndrome, Hutchinson-Gilford progeria, and Rothmund-Thomson syndrome. Hutchinson-Gilford progeria involves a mutation in lamin A, a component of the nuclear envelope. The symptoms have an onset in early childhood, and median survival is only about 13 years. All the other well-studied progeria syndromes involve mutations in DNA helicases, which are involved in DNA repair and recombination. The syndromes have features of accelerated aging and are associated with an increased risk of cancers. Werner syndrome has accelerated atherosclerosis as a prominent feature. Whether these conditions can reveal secrets of normal aging is not yet clear. However, they suggest that the maintenance of the integrity of the genome is a vulnerable function that can lead to premature aging if it is performed suboptimally.

Genetics and Exceptional Longevity Just as genetics is revealing information about premature aging, family studies may also identify features of delayed or successful aging. Twin studies suggest that ~30% of the variation in longevity can be attributed to genetic factors, with the remainder being attributable to environmental and behavioral factors. Long life span runs in families, and studies of centenarians and their offspring may define particularly adaptive phenotypes. For example, centenarians are less likely to be carriers of the apolipoprotein E ε4 allele, which is associated both with risk for heart disease and Alzheimer's disease. Ashkenazi Jewish centenarians and their offspring have been found to have larger high-density lipoprotein (HDL) and low-density lipoprotein (LDL) particle sizes; a lower prevalence of hypertension, cardiovascular disease, and the metabolic syndrome; and a greater likelihood of carrying an atheroprotective variant of the cholesteryl ester transfer protein gene. As studies of genetically more homogeneous populations such as those in Iceland and Sardinia progress, additional genetic contributions to healthy aging may be identified.

Frailty, Disabilty, and Comorbid Illness Frailty is defined as a clinical syndrome in which three or more of the following are present: unintentional weight loss of ≥4.5 kg (≥10 lb) in the past year (reflecting poor nutrition, catabolic metabolism, and sarcopenia), feeling exhausted (poor endurance), poor grip strength (weakness), slow walking speed, and low physical activity. Frailty overlaps with disability and comorbid illness but is not synonymous with them. Frailty is associated with a high risk of falls, disability, and death. It is unknown whether frailty is a single clinical syndrome or multiple syndromes and whether it has a central cause or multiple causes. Frail patients often share many physical and biochemical characteristics, and studies are underway to assess whether the syndrome or parts of it are responsive to interventions.

CHRONIC DISEASES AND THEIR IMPLICATIONS

The incidence, prevalence, and burden of chronic diseases increase with age, and this increased burden of disease is also associated with an increased risk of disability and decreased ability to recover from disability once it occurs.

The Global Perspective In 2005, chronic diseases accounted for 20 million deaths worldwide among those ≥70 years. The major disease contributors were cardiovascular disease (30%), cancer (13%), chronic respiratory disease (7%), and diabetes mellitus (2%). These diseases, driven to a large extent by tobacco use and obesity, are not concentrated in the developed world; rather, they are a large and growing problem in developing/low-income countries that lack the resources to prevent and manage chronic diseases and their consequences.

General Considerations Hypertension and diabetes mellitus are two common chronic conditions whose prevalence increases with age. In the United States, the National Health and Nutrition Examination Survey estimates that the prevalence of hypertension is between 60 and 84% and the prevalence of diabetes mellitus is between 18 and 21% in adults >65 years. The prevalence of both hypertension and diabetes is projected to increase substantially based on the demographics of aging and obesity. Moreover, rates of uncontrolled blood pressure in older adults are increasing, not decreasing. Both hypertension and diabetes accelerate functional decline in older adults, with hypertension accelerating cognitive decline and diabetes accelerating physical decline. Diabetes is also associated with a greater risk and severity of urinary incontinence (UI) and of falls in older women. Moreover, diabetes and stroke are the conditions most consistently associated with a diminished capacity for functional recovery in the aged.

The incidence of most cancers and cancer-specific mortality both increase with age. The age-adjusted incidence of cancer is ten times higher in the 65+ population than in those <65, and the age-adjusted cancer mortality is 15-fold higher. As a result, the incidence of cancer is expected to increase disproportionately in relation to overall population growth, and this trend is observed in countries throughout the world. Moreover, the majority of cancer survivors (>60%) are 65+ years of age.

In 2000, the leading causes of death among older Americans were heart disease (33%), cancer (22%), and cerebrovascular disease (8%). The death rate from heart disease has continued to decline; in 2006, cancer was the leading cause of death in persons <85 years. The management of chronic disease in older adults is particularly challenging. As examples, both hypertension and diabetes are established risk factors for micro- and macrovascular disease. Randomized clinical trials have demonstrated treatment efficacy, and guidelines for therapy are well established. Yet substantial evidence indicates that both conditions are inadequately treated, particularly in older adults with comorbidity. A portion of the problem is related to the fact that most clinical trials omit patients with comorbidities, making their results difficult to extrapolate to older patients with comorbid illness who are taking several other medications. The risks of drug-drug or drug-food interactions increase as a function of the number of medications used and patient age. In addition, the physician must take into account the impact of the disease and its treatment on the quality of life. Here, current functional status and rate of previous decline are helpful factors in estimating the level of functioning to which the patient may return. In concert with patient preferences and life goals, this information can help physicians and patients make decisions that are optimal at the individual patient level.

One attempt to develop an evidence-based quality of care framework for older adults cared for in ambulatory settings has been the Assessing Care of Vulnerable Elders (ACOVE) project. Designed to inform the care of persons >65 years who are at high risk for death or functional decline over a 2-year period, based on age, self-rated health, self-report of physical capability, and functional limitations, the ACOVE indicators cover 22 topics, including diseases, syndromes, impairments, and clinical situations that are prevalent, have strong influence on health/quality of life, and are amenable to available interventions. The tool has drawbacks. The indicators are generally focused on the care of one disease or condition at a time, and the total number of indicators is overwhelmingly large (236). However, it appears that better quality of care is associated with improved survival. Better strategies to target clusters of interventions to those who will benefit most are needed.

APPROACH TO: The Geriatric Patient

FUNCTIONAL ASSESSMENT While the geriatric patient may have multiple chronic illnesses, functional status is the best indicator of prognosis and longevity. Functional status is defined as how well a person is able to provide for his or her own daily needs. Changes in function may signal a medical illness, advancing cognitive impairment, changes in social support, depression, substance abuse, or a combination of these. These changes should not be accepted as "just part of getting old." Documentation of a patient's baseline functional status is essential so that changes can be identified and addressed.

TABLE 9-2 SUGGESTED BRIEF GERIATRIC ASSESSMENT INSTRUMENTS

Domain	Instrument	Sensitivity	Specificity	Time (min)	Cutpoint	Comments
Cognition						
Dementia	MMSE	79–100%[a]	46–100%	9	<24[b]	Widely studied and accepted
	Timed time and change test	94–100%	37–46%	<2	<3 s for time and <10 s for change	Sensitive and quick
Delirium	CAM	94–100%	90–95%	<5		Sensitive and easy to apply
Affective disorders	GDS 5-question form	97%	85%	1	2	Rapid screen
Visual impairment	Snellen chart	"Gold standard"	"Gold standard"	2	Inability to read at 20/40 line	Universally used
Hearing impairment	Whispered voice	80–90%	70–89%	0.5	50% correct	No special equipment needed
	Pure tone audiometry	94–100%	70–94%	<5	Inability to hear >2 of 4 40-db tones (0.5, 1, 2, and 3 kHz)	Can be performed by trained office staff
Dental health	DENTAL[c]	82%	90%	<2 (estimated)	Score >2	
Nutritional status	Weight loss of >4.5 kg (>10 lb) in 6 months or weight <45 kg (<100 lb)	65–70%	87–88%		Yes to either	
Gait and balance	"Timed Get Up and Go" test	88%	94%	<1	>20s	Requires no special equipment

[a]Some studies have found lower sensitivities, but most studies of dementia subjects fall in this range.
[b]Cutoff is dependent on a number of variables including age, education, and racial or ethnic background.

Table 9-2 lists some suggested brief screening strategies for assessing functional status.

The first opportunity to assess the functional status of an older adult is when the patient is greeted and taken for a short walk into an examination room. In what way is the greeting received? Does the patient need assistance in getting out of a chair? Does he or she use an assistive device, such as a cane or walker? What is the patient's gait speed? How stable is the patient's gait? Is the patient fatigued after a short walk? These observations provide important initial information about how chronic illnesses affect the life of an older adult.

The basic activities of daily living (ADLs), which comprise activities essential for physical independence, and the instrumental activities of daily living (IADLs), which are necessary for independence in the community, are the most commonly used tools to assess functional status. The ADLs are dressing, bathing, feeding, toileting, transferring, and ambulating. The IADLs are money management, medication administration, using transportation, using the telephone, shopping, housekeeping, and meal preparation. These activities should be reviewed with the patient at the initial encounter and at periodic intervals. Cognitive deficits and psychosocial factors, however, may invalidate a patient's self-report, requiring the assistance of a third party for an accurate assessment. When functional deficits are identified, services provided by community (formal) or familial (informal) supports can be implemented to help the older adult continue to live in the least restrictive setting possible.

Other dimensions of the geriatric functional assessment include assessments of gait and balance, cognition, vision and hearing, dental and nutritional health, and driving ability. The Timed Get Up and Go Test is a valid clinical measure of balance in older adults. The patient is observed and timed as he or she rises from a chair, walks 3 m, turns around, and returns to sit down in the chair. A healthy older adult should be able to complete the test in <10 s. Difficulty performing this test is associated with increased fall risk and warrants further evaluation of mobility.

The screening tools to assess cognition in the older adult assist in identifying dementia and delirium, two common geriatric syndromes, both of which have a major effect on the functional status of the older adult. In addition, history-taking can be inaccurate and misleading if cognitive impairment is not recognized before a medical evaluation. The Mini-Mental State Examination (MMSE) is the most commonly used test to assess cognitive function (Chap. 26). The Mini-Cog assessment instrument is an alternative to the MMSE and may be superior in assessing culturally diverse populations. The Mini-Cog consists of repeating three unrelated words, followed by a clock-drawing test (CDT) showing a specific time. The times 11:10 or 8:20 are often used. The patient is then asked to recall the three words. The patient receives one point for each recalled word after the CDT and two points for a normal clock. A score of 0–2 is a positive screen for dementia.

Delirium can cause loss of independence, prolonged hospitalizations, and increased health care costs and can be life threatening. It is often undiagnosed by health care providers and not recognized as a symptom of other medical illnesses. The Confusion Assessment Method (CAM) is highly sensitive and specific for identifying delirium. Delirium is diagnosed when the confusional state is both (1) acute in onset with a fluctuating course and (2) associated with inattention, and either (3) manifested by disorganized thinking or (4) an altered level of consciousness. Simple tests of attention include having the patient repeat a series of numbers or stating the months of the year backwards.

While specialists perform full vision and hearing assessments, any provider caring for an older adult should be able to screen for deficits in these areas because they commonly present in older patients, they can lead to loss of patient independence, and they often result from treatable conditions. Basic tests for visual acuity such as the handheld Jaeger card for testing near vision and the wall-mounted Snellen chart for testing far vision are the tests most commonly used in office-based practices. Visual impairment is defined as being unable to read the 20/40 line or worse. Visual acuity itself has not been associated with increased fall risk in most studies; however, binocular vision, depth perception, and contrast sensitivity contribute to postural stability and object recognition. Hearing impairment can lead to decreased physical function, depression, and social isolation. The whisper test and testing with a handheld audioscope are used frequently as screening tests. To perform the whisper test, the examiner covers the opposite ear of the patient being tested, exhales completely, and then whispers an easily answered question from a distance of 60 cm (2 ft) from the ear being tested. Treatment of hearing loss with amplification by a hearing

aid has been shown to improve quality of life. Patients demonstrating vision or hearing impairment should be referred for full ophthalmologic and audiologic evaluation. Hearing and vision impairment together are associated with lower functional status than either impairment alone.

Malnutrition is not uncommon in older adults and is associated with increased mortality, morbidity, and admission to nursing homes. In community-dwelling adults, the following definitions of malnutrition may be used: (1) involuntary weight loss [e.g., ≥4.5 kg (≥10 lb) over 6 months, ≥4% over 1 year], (2) abnormal body mass index [BMI: weight/height^2 (in kg/m^2) (e.g., BMI < 22 or BMI > 27], (3) hypoalbuminemia [e.g., ≤38 g/L (≤3.8 g/dL)], (4) hypocholesterolemia [e.g., <4.1 mmol/L (<160 mg/dL)], or (5) specific vitamin or micronutrient deficiency (e.g., vitamin B_{12}). When any one of these is present, a multidimensional assessment should be undertaken. The clinician should review the patient's access to food. Are there economic or other barriers to receiving high-quality food? Are there dental problems that might interfere with eating such as loose dentures, missing teeth, or other oral pathology? Many medical illnesses interfere with digestion or absorption of food, increase nutritional requirements, or require dietary restrictions. Is the patient unable to shop, prepare meals, or feed him- or herself? Does the patient have cultural habits or food preferences that could affect his or her nutritional status? Poor appetite may be related to medications, medical illnesses, or depression.

For many older adults, being independent depends on driving an automobile. However, the traffic violation rate per driver is increased in both teenagers and older drivers. One study has identified poor design copying on the MMSE, fewer blocks walked, and more foot abnormalities as the best predictors of adverse driving events. While a patient can undergo a formal driving assessment, often done by rehabilitation experts, the clinician can also indirectly assess a patient's driving skills by performing vision, cognition, and motor assessments in the office. Making the decision that an older adult is no longer able to drive is often done by the patient, but when the patient has limited insight into his or her physical and/or cognitive impairments, family, friends, health care providers, and sometimes government employees are responsible for keeping the older patient, as well as other drivers, safe.

GERIATRIC SYNDROMES

Geriatric syndrome refers to a symptom presentation that is common in older adults; most are multifactorial in origin. Several of these topics are covered in more detail elsewhere in the text.

Dementia and Delirium Dementia is a syndrome of progressive decline in which multiple intellectual abilities deteriorate, causing both cognitive and functional impairment. While dementia is a state of chronic confusion, delirium is an acute state of confusion. It is important to differentiate delirium from dementia. Early identification and treatment of the underlying causes of delirium can improve outcomes. Delirium may be the only manifestation of a life-threatening illness in the older adult. Both dementia and delirium are characterized by disorientation, memory impairment, paranoia, hallucinations, emotional lability, and sleep-wake cycle reversal. Key features of delirium are acute onset, impaired attention, and an altered level of consciousness. **Dementia and delirium are described more fully in Chaps. 365 and 26, respectively.**

The main goals of care of a patient with dementia are to maintain an optimal quality of life and to maximize cognitive and physical functioning. Therefore, when an older patient presents with cognitive impairment, a key goal is to identify and treat reversible causes of cognitive impairment, such as infections, electrolyte abnormalities, vitamin deficiencies, thyroid disease, substance abuse, medication, and psychiatric illnesses. The clinician must then ask key questions: (1) Is the patient safe in the community? (2) Is the patient able to perform his or her own ADLs and IADLs? (3) What assistance is needed to maximize the patient's functioning in his or her living situation? The patient may not be able to answer these questions accurately, so an objective, cognitively intact informant will be helpful.

If the patient has dangerous behaviors, such as leaving the stove on or getting lost, a plan of care involving increased patient supervision should be put in place. As dementia progresses, more caregiving services, both formal and informal, will need to be added to support the patient in the community. *Formal caregivers* are paid care providers. Examples are visiting nurses, home health aides who assist with personal hygiene, homemakers who assist with housework and meal preparation, Meals-on-Wheels, adult day programs, state aging services, and hospice services. *Informal caregivers* are persons who provide an older adult with unpaid care. Examples are family members, friends, neighbors, or church members.

The primary caregiver of a patient with dementia may need more physician support than the patient. Caring for a disabled spouse or parent is associated with an increased risk of depression or anxiety. Caregivers experiencing mental or emotional strain have an increased risk of dying compared to non-caregivers. Predictors of nursing home admission for patients with Alzheimer's disease include aggression, assault, paranoia, nighttime wandering, and loss of capacity to recognize the caregiver. Adult day care and respite programs may help to alleviate some caregiver burden. Support groups, through organizations such as the Alzheimer's Association, can also help to educate caregivers and decrease stress.

When patients with dementia exhibit agitated behaviors, medical illnesses, such as infections, pain syndromes, and drug side effects, must be ruled out as causes. These behaviors are, however, often part of a dementing illness. If the agitated behavior is harmful to the patient or others and does not respond to non-pharmacologic therapies, such as redirecting the patient, providing a calm environment, or familiar surroundings, then low doses of psychotropic medication may be helpful. Antipsychotics, anxiolytics, or antidepressants can be used, depending on the type of symptoms. Low-dose risperidone (0.25–1.5 mg/d) or olanzapine (2.5–10 mg/d) can be used if a patient has upsetting delusions or hallucinations. Antidepressants such as citalopram (10–30 mg/d) can be used for depressive symptoms. Patients on antipsychotics should be monitored closely for the development of extrapyramidal side effects, such as tremor, rigidity, and bradykinesia. The lowest dose possible should be used; dosage reductions should be attempted, if possible, at 6-month intervals. Sometimes, as cognitive functioning worsens, patients will no longer have the psychoses or the depression causing the agitated behaviors.

Falls This discussion of falls excludes falls occurring from seizure, stroke, syncope, or an insurmountable environmental hazard (Chap. 24). Fall rates and risk of injury from falls increase with age. Annually, ~30% of community dwelling adults >65 years fall, while 50% of individuals >80 years fall. Injuries in 20–30% of fallers reduce subsequent mobility and independence, with 3–5% of falls resulting in fracture. Falling is an independent risk factor for nursing home placement. Often the occurrence of a fall does not come to the attention of the health care provider. Given fall frequency and resulting morbidity and mortality from falling in older adults, all older patients should have a fall risk assessment and be asked about falls in the past year.

While most falls are multifactorial, falling is sometimes a symptom of another disease, such as an infection or neurologic disorder, or a medication side effect. In addition, age-related physiologic changes contribute to fall risk. These include decreased proprioception, increased postural sway, and declines in baroreflex sensitivity resulting in orthostatic hypotension. The evaluation of a fall should begin with a history, including the circumstances at the time of the fall, any associated symptoms, and a thorough medication review of both prescription and over-the-counter medications. The physical examination should include postural vital signs, vision evaluation, gait and balance testing, and a musculoskeletal evaluation of joint stability and range of motion. An environmental assessment of the patient's home by a visiting nurse or other health care provider can reveal additional hazards that can increase fall risk, such as clutter, loose carpets, and poor lighting.

Interventions designed to reduce fall rates must also preserve mobility and independence. Physical restraint use has been found to be strongly associated with increased fall risk and increased risk for serious injury from a fall in nursing home residents. The major risk factors for falls are shown in Table 9-3. Several factors associated with increased risk for falling include low creatinine clearance [<1.1 mL/s (< 65 mL/min)], low serum 25-hydroxyvitamin D levels (< 39 nmol/L) and high serum parathyroid hormone levels, insomnia, and fear of falling. Table 9-3 also outlines suggested interventions targeted at common fall risk factors. General exercise and balance training; t'ai chi; psychotropic medication elimination; and multidisciplinary, multifactorial, risk factor screening and intervention have been shown to reduce fall risk.

TABLE 9-3 RECOMMENDED COMPONENTS OF CLINICAL ASSESSMENT AND MANAGEMENT FOR OLDER PERSONS LIVING IN THE COMMUNITY WHO ARE AT RISK FOR FALLING

Assessment and Risk Factor	Management
Circumstances of previous falls[a]	Changes in environment and activity to reduce the likelihood of recurrent falls
Medication use High-risk medications (e.g., benzodiazepines, other sleeping medications, neuroleptics, antidepressants, anticonvulsants, or class IA antiarrhythmics)[a,b,c] Four or more medications[c]	Review and reduction of medications
Vision[a] Acuity <20/60 Decreased depth perception Decreased contrast sensitivity Cataracts	Ample lighting without glare; avoidance of multifocal glasses while walking; referral to an ophthalmologist
Postural blood pressure (after ≥5 min in a supine position, immediately after standing, and 2 min after standing)[c] ≥20 mmHg (or ≥20%) drop in systolic pressure, with or without symptoms, either immediately or after 2 min of standing	Diagnosis and treatment of underlying cause, if possible; review and reduction of medications; modification of salt restriction; adequate hydration; compensatory strategies (e.g., elevation of head of bed, rising slowly, or dorsiflexion exercises); pressure stockings; pharmacologic therapy if the above strategies fail
Balance and gait[b,c] Patient's report or observation of unsteadiness Impairment on brief assessment (e.g., the Get-Up and Go test or performance-oriented assessment of mobility)	Diagnosis and treatment of underlying cause, if possible; reduction of medications that impair balance; environmental interventions; referral to physical therapist for assistive devices and for gait and progressive balance training
Targeted neurologic examination Impaired proprioception[a] Impaired cognition[a] Decreased muscle strength[b,c]	Diagnosis and treatment of underlying cause, if possible; increase in proprioceptive input (with an assistive device or appropriate footwear that encases the foot and has a low heel and thin sole); reduction of medications that impede cognition; awareness on the part of caregivers of cognitive deficits; reduction of environmental risk factors; referral to physical therapist for gait, balance, and strength training
Targeted musculoskeletal examination: examination of legs (joints and range of motion) and examination of feet[a]	Diagnosis and treatment of the underlying cause, if possible; referral to physical therapist for strength, range-of-motion, and gait and balance training and for assistive devices; use of appropriate footwear; referral to podiatrist
Targeted cardiovascular examination[b] Syncope Arrhythmia (if there is known cardiac disease, an abnormal electrocardiogram, and syncope)	Referral to cardiologist; carotid-sinus massage (in the case of syncope)
Home-hazard evaluation after hospital discharge[b,c]	Removal of loose rugs and use of nightlights; nonslip bath-mats, and stair rails; other interventions as necessary

[a]Recommendation of this assessment is based on observational data that the finding is associated with an increased risk of falling.
[b]Recommendation of this assessment is based on one or more randomized controlled trials of a single intervention.
[c]Recommendation of this assessment is based on one or more randomized controlled trials of a multifactorial intervention strategy that included this component.

Urinary Incontinence UI is a major problem for older adults, afflicting up to 30% of community-dwelling elders and 50% of nursing home residents. Up to age 80 years, UI affects women twice as commonly as men; after age 80, the sexes are equally affected. In addition to the great impact of UI on a patient's well-being, including embarrassment, social isolation, and depression, UI is also a risk factor for nursing home placement. While certainly not a normal part of aging, advanced age, functional impairment, dementia, obesity, smoking, affective disorder, constipation, certain medical illnesses (such as chronic obstructive pulmonary disease and heart failure), and a history of pelvic surgery are associated with UI. UI is often due to a combination of these risk factors.

Older patients must be asked directly whether they have symptoms of UI, since only half of community-dwelling women with incontinence will discuss their incontinence with a health care provider. UI can then be determined to be either *transient* or *established*, although "transient" UI may be misdiagnosed as "established" if left untreated. The "DRIIIPP" mnemonic (Table 9-4) is very useful when evaluating a patient for reversible conditions that may cause or contribute to UI. If these conditions are identified and treated, the older adult benefits from relief of UI and symptoms of other comorbidities.

Leaking of urine occurs in four ways. The bladder can be limited in its ability to empty *or* in its ability to store urine; or one or both of the urethral sphincters may be unable to allow storage of urine *or* to allow passage of urine. Impairments can exist in one or in several of the urine storage mechanisms of the lower urinary tract. Four classifications of established UI have been proposed based on this understanding of the lower urinary tract: stress incontinence, urge incontinence, mixed stress and urge incontinence, and overflow incontinence.

Stress incontinence, which is rare in men, results when the urethral sphincter mechanisms are inadequate to hold urine during bladder filling. Patients describe symptoms of leaking small amounts of urine during activities that increase intraabdominal pressure, such as coughing, laughing, sneezing, lifting, or standing up. Patient history is very sensitive (0.906) but not very specific (0.511) in diagnosing stress incontinence. A stress test in the office can be performed by having the patient stand with a full bladder and cough. The test is positive if urine leakage coincides with the cough. An involuntary bladder contraction induced by the cough may cause leakage several seconds after the cough. The most common causes of stress incontinence in women are insufficient pelvic support due to childbearing, gynecologic surgery, and the decreased effects of estrogen on tissues of the lower urinary tract. Surgical interventions are the most effective treatments; pelvic muscle exercises can be helpful, although treatment failure is higher in patients who have two or more leakages per day.

Urge incontinence, also known as detrusor overactivity (DO), is characterized by uninhibited bladder contractions and is the most common form of UI in older adults. Patients often describe symptoms of an uncontrollable need to void. Urinary frequency and nocturnal incontinence are common, particularly accompanied by loss of larger urine

TABLE 9-4 REVERSIBLE CONDITIONS ASSOCIATED WITH URINARY INCONTINENCE

*D*elirium
*R*estricted mobility—illness, injury, gait disorder, restraint
*I*nfection—acute, symptomatic urinary tract infection
*I*nflammation—atrophic vaginitis
*I*mpaction—of feces
*P*olyuria—diabetes, caffeine intake, volume overload
*P*harmaceuticals—diuretics, α-adrenergic agonists or antagonists, anticholinergic agents (psychotropics, antidepressants, anti-Parkinsonians)

Source: After DB Reuben et al.

volumes (>100 mL). Urge incontinence may be idiopathic, associated with lesions of the central nervous system, such as a stroke, or be due to bladder irritation from infection, stones, or tumors. The term *detrusor hyperactivity with impaired contractility* (DHIC) is a type of urge incontinence characterized by involuntary bladder contractions with a weak detrusor muscle leading to incomplete emptying of the bladder. The diagnosis is primarily based on a patient's symptoms in the absence of urinary retention and the leakage of urine with stress maneuvers.

Measurement of postvoid residual (PVR) should be part of an incontinence evaluation in all patients. Under sterile conditions, the patient's bladder is catheterized 5–10 min after the patient has voided. Generally, a PVR > 200 mL suggests detrusor underactivity or obstruction. The patient should be referred for further urologic evaluation.

Initial treatment of urge incontinence should be bladder retraining by encouraging the patient to void every 2 h or based on the patient's symptom frequency. The patient can also try urgency control by sitting or standing quietly while focusing on allowing the urgency to pass before slowly walking to the bathroom to void. If the patient has no incontinence for 2 days, the voiding interval can be increased by 30–60 minutes until the patient is only voiding every 3–4 h. The anticholinergic drugs, oxybutinin and tolterodine, which cause bladder relaxation, can be added to this therapy. Their use in older adults may be limited by anticholinergic symptoms such as urinary retention, confusion, constipation, and dry mouth. Patients using tolterodine have a reduced risk of dry mouth and fewer withdrawals due to side effects, but the efficacy of oxybutinin and tolterodine is similar.

Mixed incontinence refers to UI where symptoms of both stress and urge incontinence are present. A simple, quick questionnaire consisting of three incontinence questions (3IQ) may help to classify urge and stress incontinence in women in the primary care setting. Question one asks if the patient has leaked urine in the past 3 months. Question two familiarizes patients with types of incontinence: stress, urge, or other. Question three asks the patient for the category of incontinence based on her symptoms during the past 3 months: stress, urge, mixed, or other. The 3IQ improved the likelihood of a positive diagnosis of urge incontinence (+likelihood ratio of 3.29) and of stress incontinence (+likelihood ratio of 2.13).

Overflow incontinence is due to either bladder outlet obstruction or an atonic bladder. Male patients, but rarely females, may complain of dribbling after voiding, an incessant urge to urinate, or straining to urinate. On physical examination, patients may have a palpable distended bladder. Prostatic hypertrophy, prostate cancer, and urethral strictures are the most common causes of overflow incontinence in men, while a cystocele can cause this problem in women. Detrusor atonicity or underactivity can be caused by spinal cord disease, autonomic neuropathy of diabetes, alcoholism, vitamin B_{12} deficiency, Parkinson's disease, tabes dorsalis, or chronic outlet obstruction. Urodynamic testing is helpful in distinguishing urethral obstruction from detrusor underactivity. The most effective treatment for bladder outlet obstruction is surgical removal of the obstruction. Intermittent or indwelling catheterization may be required for nonoperative candidates with obstruction or for patients with detrusor underactivity. For men who have benign prostatic hypertrophy (BPH) and are not in retention, α-adrenergic blockers such as terazosin, doxazosin, or tamulosin can decrease symptoms of urinary frequency and nocturia. Finasteride, a 5α-reductase inhibitor, may be useful in combination with doxazosin for decreasing lower urinary tract symptoms due to BPH in men with a total prostate volume of ≥25 mL.

The diagnosis of *functional incontinence* describes individuals who have UI and have either cognitive or functional impairments which limit their ability to toilet themselves. However, other treatable causes of UI may be missed if one assumes dementia or immobility is the cause of UI in these patients.

Pressure Ulcers Pressure ulcers, also known as pressure sores, bedsores, or decubitus ulcers, occur in older patients with reduced mobility. A pressure ulcer occurs when increased pressure between skin and a bony prominence produces tissue necrosis. While pressure ulcers can occur anywhere, 80% of pressure ulcers occur over the heels, lateral malleoli, sacrum, ischia, and greater trochanters. Shear forces, causing stretching and angulation of blood vessels, and frictional forces, causing separation of the epidermal or dermal layers, can also lead to tissue necrosis and open ulceration. Moisture can increase friction leading to maceration and superficial skin erosions.

Reported incidence data for the United States vary widely by site of care: general acute care, 0.4–38%; long-term care, 2.2–23.9%; and home care, 0–17%. Prevalence rates range from 10–18% in general acute care, 2.3–28% in long-term care, and 0–29% in home care. In older adults and nursing home residents, the development of a pressure ulcer increases mortality by fourfold. Osteomyelitis and sepsis are important, morbid complications of pressure ulcers.

The notion that all pressure ulcers are preventable is controversial. While repositioning patients at risk for developing pressure ulcers every 2 h and providing bedbound patients mattresses with pressure-relieving capabilities are standard interventions to prevent pressure ulcers, other immutable risk factors may ultimately contribute to skin breakdown in certain patients. Major risk factors associated with the development of pressure ulcers are listed in Table 9-5.

When an ulcer is identified, one must try to identify its etiology. Pressure ulcers lie at sites of pressure. Diabetic ulcers can also be caused by pressure in extremities compromised by neuropathy and vascular disease, including both large and small blood vessels. Venous stasis ulcers develop on the lower extremities with or without edema due to incompetent valves of the veins. Arterial ischemic ulcers develop at sites of decreased blood flow. Since adequate blood supply is necessary for tissue to heal, assessment of pulses and ankle-brachial indices (ABI) for ulcers of the lower extremities can provide prognostic information. An ABI of <0.4 is associated with a low likelihood of wound healing. If the patient is not a surgical candidate for revascularization, the goal of care must be to keep the wound free of infection and to alleviate any related patient discomfort.

When an ulcer is identified as a pressure ulcer, the ulcer should be staged so that the appropriate therapy may be instituted. The staging in

TABLE 9-5 MAJOR RISK FACTORS ASSOCIATED WITH THE DEVELOPMENT OF PRESSURE ULCERS IN THE OLDER ADULT

Alterations in sensation or response to discomfort
- Degenerative neurologic disease
- Cerebrovascular disease
- Central nervous system (CNS) injury
- Depression
- Drugs that adversely affect alertness

Alterations in mobility
- Neurologic disease/injury
- Fractures
- Pain
- Restraints

Significant changes in weight (≥5% in 30 days or ≥10% in the previous 180 days)
- Protein-calorie undernutrition
- Edema

Incontinence
- Bowel and bladder

TABLE 9-6 STAGING SYSTEM FOR PRESSURE ULCERS

Stage 1
Nonblanchable erythema of intact skin, or dislocation, edema, induration, and warmth over a bony prominence among patients with darker skin; the heralding lesion of skin ulceration.

Stage 2
Partial thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.

Stage 3
Full thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, fascia. The ulcer presents clinically as a deep crater with or without undermining adjacent tissue.

Stage 4
Full thickness skin loss with extensive destruction, tissue necrosis or damage to muscle, bone, or supporting structures (e.g., tendon, joint capsule). Undermining and sinus tracts also may be associated with Stage 4 pressure ulcers.

Source: From American Medical Directors Association (AMDA): *Pressure Ulcers.* Columbia, MD, American Medical Directors Association, 1996.

Table 9-6 is based on a system developed in 1989 by the National Pressure Ulcer Advisory Panel. Nonblanching erythema constitutes vascular damage and hemorrhage. Stage 1 ulcers can progress to stage 4 ulcers in as little as a day or two, depending on how deeply the necrosis extends. Once a hard, dark eschar develops, the ulcer cannot be staged until the necrotic tissue is removed. Three major steps in pressure ulcer management lead to wound healing: debridement, cleansing, and dressing. *Debridement*, either surgical or chemical, is necessary to remove necrotic tissue to allow new granulation tissue to grow. Necrotic tissue can also contain bacteria that impede wound healing. *Cleansing* the wound helps to lower bacteria counts. Normal saline is best, as its use protects new granulation tissue. In foul-smelling, infected wounds, bacteriocidal agents such as 1% povidine-iodine, 0.25% acetic acid, or 0.5% sodium hypochlorite (Dakin's solution) can be used as disinfectants, but not for more than a week at a time as they are cytotoxic to fibroblasts and delay wound healing. A discussion of which *dressing* to use is beyond the scope of this chapter, but the choice of a dressing should be based on the ulcer stage, whether or not local infection is present, whether or not excessive exudate is present, and whether continued debridement is necessary. Management of pressure ulcers should be interdisciplinary involving physicians, nurses, wound care specialists, occupational or physical therapists, and nutritionists. Usually, stage 1 and 2 pressure ulcers heal in days to weeks, whereas healing of stage 3 and 4 ulcers may be seen at 2–4 weeks, but they often take many months to heal.

PREVENTION AND HEALTHY AGING

Central to the care of older adults is the prevention of functional decline, accidents, and the development of new diseases or worsening of prevalent ones. When asked, most older adults identify maintenance of independence as their top priority. Thus, although the U.S. Preventive Services Task Force (USPSTF) has 30 recommendations for primary and secondary disease prevention in older adults, those most likely to help elders achieve their goal of maintaining independence are emphasized here. Specific discussions of vision and hearing, safe driving, and falls risk are discussed elsewhere in this chapter.

Nutrition Adequate nutrition is fundamental to healthy aging. In general, energy requirements decrease with age due to a decline in lean body mass and decreased physical activity. Despite this decrease, older adults may be at risk of undernutrition due to medication side effects; functional, visual, or cognitive impairment; oral disease, swallowing disorders, or loss of smell/taste; depression and social isolation; and chronic illnesses.

Although the proportional requirements of protein, fat, and carbohydrates do not change with age, calories from carbohydrate sources gradually substitute for those from fat. To maintain adequate caloric intake and also promote cardiovascular health, substitution of monounsaturated (olive oil, canola oil, peanuts, avocados, nuts, seeds), omega-3 (sardines, mackerel, salmon, tuna, flounder, haddock), and omega-6 (liquid vegetable oils) fatty acids (the so-called "Mediterranean Diet") for *trans* fatty acids may be beneficial. As older adults tend to have lower intakes of both dietary fiber and fluids, increased intake of both should be encouraged, particularly as antidotes for age-related constipation. Although vitamin requirements do not change with age, older adults are particularly prone to inadequate intake of vitamins D and B_{12} and calcium, and supplementation should be considered.

Functional Decline There are 14 million noninstitutionalized older adults with functional disabilities, with a greater proportion of women being disabled (43%) than men (40%). Exercise improves body composition, psychological well-being, and disease outcomes, and reduces risk of injurious falls. Physical and cognitive exercise may also reduce the risk of dementia. Even the most sedentary of individuals appear to benefit from increasing physical activity. All patients should be asked about their level of physical activity, e.g., the number of days during an average week that they spend at least 15 min walking, bicycling, swimming, weight training, etc. An exercise prescription may be beneficial. It should consider flexibility, endurance, strength, and balance but should be preceded by attention to musculoskeletal problems, footwear, and risk factors for cardiovascular disease. Guidelines for such a prescription are shown in Table 9-7.

An exercise program should be initiated gradually. Increasingly, community organizations provide supervised group programs. The National Institute on Aging also has a range of on-line and video resources for older adults.

Accident Prevention In addition to exercise, attention to accident prevention is critical. Falls risk assessment is addressed above. In addition, exercise, particularly directed at balance, resistance, and aerobic training, decreases risk. Seatbelt use should be encouraged. Per mile driven, older adults are at highest risk of serious injury or death as a result of motor vehicle accidents. Assessment of the ability to drive safely is critical to motor vehicle safety (see above). With many older adults riding bicycles, motorcycles, and mopeds, patients should be encouraged to use helmets. Head injuries are common among riders and are particularly devastating to older adults; helmets mitigate this risk.

Although moderate alcohol consumption has been associated with many salutary effects, it is not without consequences for older adults who, because of age-related changes in alcohol distribution, increased brain sensitivity to its effects, and the potential for medication-alcohol interactions, are at risk for alcohol side effects at lower levels of consumption than their younger counterparts. When the definition of at least 12 drinks per year is used, 29% of older adults are classified as regular consumers: 40% of men and 21% of women. The National Institute on Alcohol Abuse and Alcoholism recommends that both men and women aged ≥65 consume no more than three drinks in a day and no more than seven drinks in a week, while the American Geriatrics Society recommends no more than two drinks on any single drinking occasion. Lower drinking limits or abstinence is recommended for those who take medications that interact with alcohol or who have a health condition exacerbated by alcohol. An approach to screening for heavy drinking is first to ask about heavy drinking days in the past year. If a man reports that he consumed five or more drinks in a day, or a woman reports that she consumed four or more drinks in a day, further questioning is warranted. The 10-item AUDIT (Alcohol Use Disorders Identification Test) is a validated strategy for identifying unhealthy drinking.

DISEASE PREVENTION AND EARLY DETECTION

Immunizations Although vaccine efficacy declines with age, the risks of no vaccination far outweigh the consequences of less than complete protection. Influenza vaccination is thus recommended annually, and all adults ≥65 should receive the pneumococcal vaccine at least once. In addition, a one-time revaccination should be given if the original vaccination was ≥5 years earlier and persons were ≤65 years at the time of primary vaccination. Tetanus vaccinations should be administered every 10 years.

TABLE 9-7 RECOMMENDATIONS FOR OPTIMAL AGING AND PREVENTION AND TREATMENT OF DISEASE IN OLDER ADULTS

Modality	Resistance Training	Cardiovascular Endurance Training	Flexibility Training	Balance Training
Dose				
Frequency	2–3 days/week	3–7 days/week	1–7 days/week	3–7 days/week
Volume	1–3 sets of 8–12 repetitions, 8–10 major muscle groups	20–60 min per session	Major muscle groups 1 sustained stretch (20 s) of each	1–2 sets of 4–10 different exercises emphasizing dynamic postures[a]
Intensity	15–18 on Perceived Exertion Scale (70–80% 1 RM), 6 s/repetition, 1–2 min rest between sets	12–14 on Perceived Exertion Scale (50–60% heart rate reserve or maximal exercise capacity)	Progressive neuromuscular facilitation technique[b]	Progressive difficulty as tolerated, at the level that is not yet mastered[c]
Requirements for safety and maximal efficacy	Slow speed, no ballistic movements, day of rest between sessions Good form, no substitution of muscles No breath holding, Valsalva maneuver Increase weight progressively to maintain relative intensity at high load If possible, power training (high-velocity, high-loading) provides benefits of increased strength, power, endurance, balance, and bone density	Low-impact activity if arthritis present; high impact more potent for bone remodeling Weight-bearing, best include hills/stairs if possible Increase workload progressively to maintain relative intensity Perceived exertion better than monitoring pulse to gauge intensity May accumulate short bouts (10 min) of exercise to reach volume goal One hour/week high-intensity endurance exercise equivalent to 3–4 hours/week moderate-intensity endurance exercise for cardiovascular/metabolic benefits	Static rather than ballistic stretching Stretch warmed muscles after other exercises are complete, as part of cool-down	Safe environment or monitoring Dynamic as well as static modes of training Gradual increase in difficulty as competence is demonstrated

[a]Examples of balance enhancing activities include t'ai chi movements, standing yoga or ballet movements, tandem walking, standing on one leg, stepping over objects, climbing up and down steps slowly, turning, standing on heels and toes, walking on compliant surface such as foam mattresses, maintaining balance on moving vehicle such as bus or train, and dual tasking (addition of a cognitive distractor such as naming animals while balancing), etc.
[b]Proprioceptive neuromuscular facilitation involves stretching as far as possible, then relaxing the involved muscles, then attempting to stretch further, and finally holding the maximal stretch position for at least 20 s.
[c]Intensity is increased by decreasing the base of support (e.g., progressing from standing on two feet while holding onto the back of a chair to standing on one foot with no hand support); by decreasing other sensory input (e.g., closing eyes or standing on a foam pillow); or by perturbing the center of mass (e.g., holding a heavy object out to one side while maintaining balance, standing on one leg while lifting other leg out behind body, or leaning forward as far as possible without falling or moving feet).
Note: 1 RM, one repetition maximum that is a measure of maximal dynamic strength: the maximal weight one can lift with a particular muscle group one time in good form; the Perceived Exertion Scale of is a self-rating of how hard one's body is working.
Source: From MAF Singh: J Gerontol: Med Sci 57A:M274, 2002; with permission.

Bone Health Some 70% of women ≥80 years have osteoporosis. Given this substantial risk, the significant morbidity and mortality associated with osteoporotic fractures, and the proven efficacy of bisphosphonates in increasing bone mineral density and preventing fractures, all women >65 years should receive dual-energy x-ray absorptiometry (DEXA) screening at least once. The most appropriate interval between screening tests has not been determined, although a minimum of 2 years is recommended to reliably measure a change in bone density. Although routine measurement of vitamin D levels is not recommended, women who are at high risk for deficiency by virtue of dietary insufficiency and/or lack of sun exposure should be considered for screening.

Cancer Screening The effect of cancer screening is not evident for at least 3–5 years; thus, screening is not likely to be of benefit in persons with a limited life expectancy. Individual values and preferences are clearly also important considerations.

BREAST CANCER The incidence of breast cancer increases with age and peaks in the eighth decade. The sensitivity and specificity of mammography reaches its maximum in the ninth decade. Over 25% of breast cancer deaths occur in women ≥80 years. These facts suggest that mammographic screening would be of benefit in older women; however, only two clinical trials have examined the efficacy of mammographic screening in women ≥70 years, and both were inconclusive. The best supporting observational evidence comes from two Surveillance, Epidemiology, and End Results Medicare studies that found an association between screening mammography and decreased breast cancer mortality. Mammography screening in the 2 years preceding a diagnosis of breast cancer eliminated the age-related disparities in size and stage of the breast tumor at diagnosis.

Annual clinical breast examination (CBE) is a potentially attractive screening alternative to mammography, since the postmenopausal atrophy of breast tissue improves CBE sensitivity in older women compared to younger women. It is also less uncomfortable and cheaper than a mammogram. However, it should be used to complement mammographic screening and reserved as a stand alone strategy only for women who refuse or cannot undergo mammography.

PROSTATE CANCER Prostate cancer screening in older men is a particularly challenging topic as many more older men die with prostate cancer than from it. Nonetheless, 92% of prostate cancer deaths occur in men who are >65 years. Although prostate cancer can be detected earlier via prostate-specific antigen testing, mortality from prostate cancer has not been reduced as a result of screening. The U.S. Preventive Services Task Force has concluded that evidence to recommend for or against screening is lacking. Other organizations such as the American Cancer Society and American Urological Society recommend screening among those with at least a 10-year life expectancy. The matter is complicated by the fact that techniques to treat prostate cancer often greatly affect quality of life. Furthermore, we are not able to reliably predict whether a particular prostate cancer is life-threatening. Given the uncertainties, PSA screening should be reserved for the most robust of older men and only after a thorough discussion of the arguments for and against screening.

COLORECTAL CANCER Annual or biennial fecal occult blood testing (FOBT) reduces mortality in those up to age 80. Other screening options include sigmoidoscopy (every 5 years), FOBT and sigmoidoscopy (every 5 years), double-contrast barium enema (every 5–10 years), and colonoscopy (every 10 years). No one method has been shown to be superior, and all methods are cost effective. Digital rectal examination (DRE) alone or with a FOBT is not recommended (though DRE is used

to screen for prostate cancer). The choice of a colorectal cancer screening strategy is based on many considerations, including procedure risk. Colonoscopy might seem the most attractive option; the colon can be completely visualized and biopsies taken if the examination is positive. If the examination is negative, it does not need to be repeated for 10 years. However, adequate preparation requires lower extremity strength and mobility, and the ability to tolerate substantial fluid losses. Furthermore, the procedure has a small risk of bowel perforation or bleeding. Yet about half of colon cancers occur beyond the reach of a sigmoidoscope.

LUNG CANCER Although lung cancer is also a leading killer, no screening interventions have been shown to be effective.

Disease Risk Modification Longitudinal studies are providing evidence that risk factor modification, especially smoking cessation and blood pressure reduction, particularly in mid-life but also up to age 75, results in greater gains in life-years than do medical and surgical therapies, especially in men. In addition, lower levels of risk factors in mid-life are associated with survival free of major morbidity to age 85. Although lifestyle modifications in mid-life are important, modifications even late in life may make a difference. A person is never too old to benefit from smoking cessation.

Older adults are also at risk for obesity, which is becoming more common among successive birth cohorts. Among men, 33.4% of those 65–74 years are obese compared to 20.4% among those >75 years. For women, the comparable figures are 38.8% and 25.1%. Weight loss in obese older adults has the potential advantage of improving mobility and decreasing the severity of comorbidities. Nonetheless, it should be pursued cautiously and be coupled with aerobic and resistance training, since many obese persons are relatively sarcopenic. No data confirm the efficacy and safety of pharmacotherapies for obesity in older persons. Although bariatric surgery has higher perioperative morbidity/mortality in older adults, if successful it can also result in improvements in the severity of comorbidities.

10 Complementary and Alternative Medicine

Stephen E. Straus†

BACKGROUND

Medicine, not long ago the domain of solitary generalists and their nurse assistants, now engages scores of specialists and allied professionals—radiation physicists, cytologists, nurse practitioners, psychiatric social workers, dental hygienists, and many more—who wield tools of unprecedented ability to extend life and sustain its quality. This evolution of the health care system has been achieved, in part, by a formidable enterprise of critical observation and formal investigation that disproves some once-accepted practices and stimulates emergence of new approaches that compete for acceptance. One need only peruse the serial editions of this textbook to comprehend the scope of these changes.

Other factors have also affected evolutionary changes in medicine. Immigration and related demographic changes yield increasingly diverse populations who value their own health traditions. The public's expectations of health and the nature of the health care system itself have been altered by unprecedented access to sources of information, goods, and services; the disposable income to afford them; and a patchwork quilt of regulations and laws that constrain medical practice on the one hand and facilitate increased choice in health care on the other. The emergence of complementary and alternative medicine is one manifestation of these changes in health care.

DEFINITIONS

In every generation, medical practices exist that are not accepted by the mainstream: they are viewed with suspicion and dismissed as implausible or irrational. For a time, approaches that evoked some appeal, but which had not been thoroughly tested, were deemed *unconventional*. Over the past decade or so, they have been called *complementary and alternative medicine* (CAM), to reflect their use as adjuncts to or as substitutes for more generally accepted practices, respectively. CAM does not encompass practices that have yet to be translated fully from the laboratory into the clinic or practices that were well studied and disproved, but which manage to sustain some public appeal. Rather, CAM entails approaches with surprising pervasiveness, many of which can claim at least some evidentiary support. Until recently, CAM could also be defined as practices that are neither widely taught in medical schools nor reimbursed. However, medical students increasingly seek and receive some instruction about CAM, while third-party payers have identified in CAM a marketing tool to attract new, well-heeled clients. In the past few years, another term has been coined—*integrative medicine*—to suggest encouragingly that some CAM approaches, and the practitioners who deliver them, will be shown worthy of being added to the health care repertoire.

SCOPE

The myriad practices and products that encompass CAM **(Table 10-1)** can be organized into five somewhat overlapping domains. Special diets, high doses of vitamins and minerals, and extracts of animal or botanical products are grouped together as *biologically based* CAM approaches. Massage, osteopathic and chiropractic manipulation, and cranial-sacral therapies are grouped as *manipulative and body-based* CAM approaches. Diverse forms of meditation, spirituality, and various uses of hypnosis are CAM approaches that attempt to harness brain pathways to affect health and behavior. All three of these CAM domains have well-accepted analogues in conventional medicine—low-fat, low-cholesterol diets; physical therapy; and psychotherapy, to name but a few.

A fourth CAM domain is known as *energy medicine*, to reflect its exploitation of veritable or putative energy fields. Today, magnets are increasingly popular health products. Over 2000 years ago, however, while Greek physicians believed that health requires a balance of vital humors, Asian practitioners postulated the flow and balance of vital energies and described tools to restore them. Acupuncture aims to correct energies that flow through special meridians, or channels. Reiki, a Japanese approach, and healing touch, a modern variant, purport to diagnose and correct one's energy by passing the hands of an adept therapist over the patient.

†Deceased. Dr. Straus was a contributor to *Harrison's* since the 13th edition. He died on May 14, 2007.

TABLE 10-1 SOME COMPLEMENTARY AND ALTERNATIVE MEDICAL PRACTICES

Type	Description
Acupuncture	A Chinese medical practice that involves the insertion of hair-thin needles into nonanatomic energy channels, called meridians
Alexander technique	A movement therapy that emphasizes efficient use of muscles to relieve pain, decrease skeletal strain, and improve posture
Anthroposophic medicine	A spiritually based system of medicine that incorporates herbs, homeopathy, diet, and a movement therapy called eurythmy
Aromatherapy	The use of essential plant oils (distilled concentrates) in massage, baths, or inhalation
Ayurvedic medicine	The major East Indian traditional medicine system, utilizing pulse and tongue diagnosis; treatment includes diet, exercise, herbs, oil massages, and elimination regimens (utilizing emetics, diarrheals, etc.)
Bach flower remedies	Dilute flower infusions used to treat emotional conditions
Biofeedback	The use of machinery that translates physiologic processes into audio or visual signals
Chiropractic	Adjustments of spinal vertebrae in an effort to affect neuromuscular function
Cranial-sacral therapy	Gentle manipulation of the cranium and spine
Curanderismo	A spiritual healing tradition common in Mexican-American communities that utilizes ritual cleansing, herbs and incantations
Dance therapy	Therapeutic method that uses movement to facilitate emotional expression and release
Feldenkrais bodywork	Highly structured movement sequences that emphasize proper head positioning
Guided imagery	The use of imagination to invoke specific images that are hoped to affect physiologic function
Hydropathy	Treatment utilizing water at various temperatures, sometimes aerated or under pressure, sometimes with added salts or other substances
Hypnosis	The induction of an altered state of mind within which a subject becomes receptive to specific suggestions
Massage	The use of specific gliding and kneading strokes and friction to achieve muscle relaxation
Meditation	A process by which one tries to achieve awareness without thought
Music therapy	Singing, playing instruments, or listening to music
Naturopathy	A mixture of modalities that may include herbs, homeopathy, acupuncture, hydropathy, diet, and exercise
Native American medicine	Diverse systems, many of which incorporate prayer, chant, music, healing ceremonies, counseling, herbs, laying on of hands, and smudging (ritual cleansing with smoke from sacred plants)
Osteopathy	A medical field incorporating manipulative techniques for correcting abnormalities of the musculoskeletal system
Reflexology/zone therapy	Manual stimulation of points on the hands or feet, believed to affect distant organs
Rolfing/structural integration	A manual therapy that attempts to realign the body by deep tissue manipulation of fasciae
Shiatsu/acupressure	Finger pressure at points along nonanatomic meridians
Siddha medicine	An East Indian medical system (prevalent among Tamil-speaking people) utilizing breathing techniques, incantations, herbs, and muppu (a tri-salt preparation)
T'ai chi ch'aun	Chinese dancelike exercises described as a "moving meditation"
Therapeutic touch	Secular version of the laying on hands, described as a "healing meditation"
Tibetan medicine	A medical system that utilizes diagnosis by pulse and urine examination; therapies include herbs, diet, and massage
Traditional Chinese medicine	A medical system that utilizes examination of the tongue and pulses for diagnosis and acupuncture, herbal mixtures, massage, exercise, and diet
Trager bodywork	Light massage combined with gentle passive movements to help patients maximize freedom of movement
Unani medicine	An East Indian medical system, derived from Persian medicine, practiced primarily in the Muslim community; also called "hikmat"
Yoga	An Indian practice that includes postures (asanas), breathing exercises (pranayama), and cleansing practices (kriyas)

The fifth domain, termed *alternative systems of medicine*, combines elements of the four other domains and aims to provide primary approaches to all health needs, rather than just adjunctive solutions to them. Western variants include practices developed by Native Americans, homeopathy, and naturopathic medicine. Eastern variants such as Ayurvedic medicine of India, traditional Chinese medicine, and Tibetan medicine are rich in their use of meditative exercises and herbal products.

PATTERNS OF USE

Despite its enormous success in prolonging life and sustaining its quality, contemporary western biomedicine has features that discourage some patients: many diseases, especially chronic ones, are neither curable nor well palliated; existing treatments can impose serious adverse reactions; and provision of care is fragmented and impersonal. CAM, despite lack of proof of efficacy, appeals to many because its practitioners are optimistic, and they invest the time to speak with and touch their patients. CAM empowers patients to make their own health choices, its natural products are believed to be inherently healthier and safer than synthetic ones, and care is provided in a "holistic" fashion, meaning that the broader medical, social, and emotional contexts of illness are considered in designing the treatment plan.

The first large survey by Eisenberg in 1993 surprised the medical community by showing that >30% of Americans use CAM approaches. Many studies since then have extended these conclusions by surveying specific demographic groups and patient populations. The Centers for Disease Control and Prevention (CDC) study of nearly 31,000 American adults revealed that in 2002 36% had used one or more modalities, with spiritual approaches, herbal medicine, chiropractic, and massage being the most prevalent. Over 1% underwent acupuncture treatment that year. Surveys among patients with cancer showed that 30 to 86% used CAM, with highest rates in those with more advanced disease and undergoing aggressive treatments. Similarly, among AIDS patients, 36 to 91% are reported to use CAM. In devastating chronic illnesses like these, CAM is called upon to provide hope of cures when conventional medicine cannot, to extend life, to ameliorate treatment side effects, and to provide emotional and physical comfort. While somewhat subject to vagaries of definition as to what counts as a CAM treatment, surveys have shown that Americans are willing to pay for these services out of pocket, with an estimated $7 billion each year on vitamins and mineral supplements, $4 billion on herbals and other natural products, and nearly $4 billion more on sports supplements. Eisenberg reported that total CAM expenditures in 1997 approached $30 billion, with more visits to practitioners for CAM services than to physicians in general.

FIELDS OF PRACTICE

Osteopathic Medicine Founded in 1892 in the American heartland by the physician Andrew Taylor Still, osteopathic medicine was based originally on the belief that manipulation of soft tissue and bone can correct a wide range of diseases of the musculoskeletal and other organ systems. Over the ensuing century, osteopathy evolved progressively towards conventional (allopathic) medicine. Today, the training, practice, credentialing, licensure, and reimbursement of osteopathic physicians is virtually indistinguishable from those of allopathic physicians,

with 4 years of osteopathic medical school followed by specialty and subspecialty training and certification by organizations such as the American Board of Internal Medicine. Some osteopathic physicians continue to practice spinal manipulation, primarily as a tool to address specific musculoskeletal complaints.

Chiropractic Medicine In 1895, Daniel David Palmer founded in Missouri the first school of chiropractic medicine to teach manipulation of the spine. Palmer believed that subluxations, or partial dislocations of vertebrae, cause disease by impinging on key nerve roots. Today, chiropractors undertake 5 years of training in basic and relevant clinical sciences. Increasingly, they complete additional postgraduate training in radiology and outpatient therapeutics, primarily of musculoskeletal conditions, although within the discipline there are factions that continue to perform manipulation for many other pathologic entities. Chiropractors also advise on nutrition, exercise, and other health maintenance approaches. Over 70,000 doctors of chiropractic medicine are licensed to practice in the United States.

Acupuncture A venerable component of traditional Chinese medicine, acupuncture emerged in recent decades as a free-standing clinical discipline. Over 3000 American physicians have acquired targeted postgraduate training that permits them to practice acupuncture in over 40 states and the District of Columbia. Over 4000 non-MDs have taken far more extended training, leading to licensure to practice independently or under the supervision of a physician.

Massage Therapy Drawing upon millennia of empirical knowledge, some 80 American schools instruct students in an array of the soft tissue manipulative approaches that constitute massage. Thirty-one states and the District of Columbia license trainees to perform therapeutic massage.

Naturopathic Medicine Twelve states license practitioners of naturopathy, a discipline that emerged in central Europe in the late eighteenth century. That conventional treatments of the day were usually ineffective, if not overtly harmful, stimulated the search for safer and more "natural" approaches—naturopathy is one of them. The concept underlying this discipline is that the body possesses powerful mechanisms for self-healing that a properly instructed practitioner could harness. About 1400 naturopathic physicians have completed 4 years of education in basic and clinical sciences and are licensed to manage a predominantly outpatient population. Conventional and unconventional diagnostic tests and medications are prescribed with an emphasis on relatively low doses of drugs, herbal medicines, special diets, and exercises.

Homeopathic Medicine The late eighteenth century also witnessed the emergence of homeopathy, another discipline that arose at least in part as a reaction to the toxicity inherent to many of the allopathic approaches of the day. Homeopathy was developed by Samuel Hahnemann, a German physician, who postulated that substances that cause particular side effects in a well person may be used to treat or prevent such symptoms in an ill person if administered in miniscule amounts—what is known as "the doctrine of similars." For example, contact with poison ivy (*Rhus toxicodendron*) causes susceptible persons to experience an itchy, blistering rash. Homeopathy espouses administration of highly diluted extracts of poison ivy to treat other blistering, pruritic eruptions such as varicella. During the early nineteenth century, the then-nascent field of homeopathy used blinded tests on volunteers, presaging wider use of placebo-controlled trials, to "prove" which materials were the most able to induce or relieve symptoms. By the mid-nineteenth century homeopathy had gained considerable presence in the American medical establishment and may, in fact, have facilitated the development of immunization and allergen desensitization, both of which utilize very small quantities of materials to elicit measurable biologic outcomes. Today, however, homeopathy is accepted less fully in the United States than in some other countries: it is the largest of all CAM practices in the United Kingdom, Germany, and France and is widely used in India. In America, only three states currently license the practice of homeopathy. The relative decline of homeopathy relates, at least in part, to the field's inability to articulate a rational mechanism as to why products that are diluted more than 10^{60}-fold, greater than Avogadro's number, could incite biologic effects. Nonetheless, homeopathic remedies are readily available and commonly recommended by naturopathic physicians and other licensed and unlicensed practitioners.

Other Disciplines There are numerous other CAM practices, among which some involve formal training, such as that leading to a Doctorate of Oriental Medicine, or extended apprenticeships, as in learning herbal medicine. Unfortunately, most of the other fields have not agreed upon practice standards, credentialing processes, requirements for continuing education, or external accountability.

REGULATION

As indicated above, some CAM disciplines are carefully regulated. CAM products, however, are not strongly regulated. Herbal medicines, and dietary supplements more generally, occupy a unique regulatory status that affords the public remarkable freedom of choice but also many undesired challenges, summarized below.

Elements of virtually all traditional healing approaches, herbal medicines were presumed safe long before the implementation of stringent drug regulations by the U.S. Food and Drug Administration (FDA). In 1994, the United States Congress passed the Dietary Supplements Health and Education Act (DSHEA) that permits sale of dietary supplements "over-the-counter," as it were, but without the requirement imposed on manufacturers of prescription or conventional over-the-counter drugs to prove their products to be safe and effective before marketing. Supplements can be removed by the FDA from the market only if they are proven to be hazardous. Purveyors of dietary supplements cannot claim them to prevent or treat any disease. They can, however, claim that they maintain "normal structure and function" of body systems. For example, a product cannot claim to treat arthritis, but it can claim to maintain "normal joint health."

Homeopathic products predate FDA drug regulations and are sold with no requirement that they be proven effective. It would be reasonable to assume, however, given the extent to which homeopathic products are diluted, that most of them are safe.

SAFETY

Despite their lack of apparent toxicities, homeopathic products, like all other CAM products and practices, do convey one type of risk, namely, that individuals will pursue them in lieu of more conventional modalities that are proven to be beneficial. Members of the public have considerable freedom to determine what is in their own best interest, even if those decisions deny them effective treatment, although the courts have found the rights of parents to withhold treatment of their children to be limited in instances of life-threatening illnesses. Investigators have a broad ethical obligation to not withhold proven treatments for serious illnesses for the sake of testing unproven ones.

Additional risks are imposed by the use of other CAM approaches: injuries inflicted by a practice, inherent toxicities of the modality, and interference by the modality with more conventional treatments.

Injury Physical and manipulative interventions can harm patients. In past decades, reused acupuncture needles transmitted hepatitis B virus infection; today, the standard of care requires disposable needles. Aggressive massage can cause soft tissue injuries. Spinal manipulation of patients with unrecognized vertebral lesions has been associated with cord injuries, and cervical manipulation has been associated with stroke. These appear to be rare events.

Inherent Toxicity While the public may believe that "natural" equates with "safe," it is abundantly clear that natural products can be toxic.

Misidentification of medicinal mushrooms has led to liver failure. Contamination of tryptophan supplements caused the eosinophilia-myalgia syndrome. Herbal products containing particular species of *Aristolochia* were associated with genitourinary malignancies. In 2001, extracts of kava, long used by Pacific Islanders for its mild anxiolytic and sedative properties, were associated with fulminant liver failure. A number of products, including the popular *Ginkgo biloba*, are known to prolong bleeding times and have been associated with postoperative hemorrhage. Among the most controversial of dietary supplements is *Ephedra sinica*, or ma huang, a product used in traditional Chinese medicine for short-term treatment of asthma and bronchial congestion. The scientific basis for these indications was revealed when ephedra was shown to contain the ephedrine alkaloids, especially ephedrine and pseudoephedrine. With the promulgation of the DSHEA regulations, supplements containing ephedra and herbs rich in caffeine sold widely in the U.S. marketplace, because of their claims to promote weight loss and to enhance athletic performance. Reports of severe and fatal adverse events associated with use of ephedra-containing products led to an evidence-based review of the data surrounding them, and finally, in 2004, the FDA banned their sale in the United States.

Herbal-Drug Interactions The constituents of a few natural products are toxic; others are known to interfere with the metabolism of life-saving drugs. This effect was illustrated most compellingly with the demonstration in 2000 that consumption of St.-John's-wort interferes with the bioavailability of the HIV protease inhibitor indinavir. Later studies showed its similar interference with metabolism of topoisomerase inhibitors such as irinotecan, with cyclosporine, and with many other drugs. The breadth of interference stems from the ability of hyperforin in St.-John's-wort to upregulate expression of the pregnane X receptor, a promiscuous nuclear regulatory factor that promotes the expression of many hepatic oxidative, conjugative, and efflux enzymes engaged in drug and food metabolism.

ACQUIRING EVIDENCE

CAM evolved through an entirely different epistemologic framework than contemporary biomedicine. Empirical observations of individual patients constitute the primary evidentiary base on which CAM practices are guided and taught. Nonetheless, over the past few decades, thousands of studies have been performed of various CAM approaches, including hundreds of trials involving herbals, acupuncture, or homeopathy. To date, very few CAM approaches have been proved effective. Several factors contribute to this lack of convincing evidence. The vast majority of CAM studies have been seriously flawed by lack of appropriate controls, bias on the part of the investigators, small sample sizes, reliance on highly subjective and nonvalidated measures of benefit, and by inappropriate statistical tests.

In addition, a series of methodologic issues challenge even the better-designed CAM studies. No uniform practice guidelines exist, and the herbal products marketed in the United States are highly variable in quality and composition. Some CAM practices are not amenable to blinding. For example, both the patient and the practitioner would know if spinal manipulation had been performed. These problems are not unique to CAM, as they also complicate attempts to study conventional practices such as psychotherapy or surgery. Efforts are now being made to randomize patients to other equally demanding control interventions, and acupuncture at traditional needling points is being compared to needling at what are arguably irrelevant points.

Even with ongoing improvements in study design and conduct, issues of belief stand in the way of comprehending and accepting the results of some CAM studies. Many physicians are reluctant to believe positive outcomes of clinical approaches that have not emerged through the classic experimental paradigm by which drugs and biologic agents are developed, namely, the orderly progression from preclinical testing through serial phases of clinical trials. More importantly, it is difficult to accept results that are counterintuitive or whose underlying mechanism still defies rational explanation. As suggested above, an example of this dilemma involves studies of homeopathy. Some clinical trials of homeopathy for asthma, infantile diarrhea, and other common conditions reported positive results. Two systematic reviews of homeopathy trials gleaned an overall favorable impression of the clinical trials data, concluding that the treatments were more beneficial than placebo. Even the best trials and these reviews have been criticized on methodologic grounds. It remains unclear what evidence could compel a change in belief about the benefits of homeopathy when there remain no cogent explanations for how substances diluted beyond the point at which only solute remains could exert physiologic effects.

By contrast, while methodologic problems continue to plague acupuncture trials, belief has been growing even in academic centers that acupuncture may be effective. The emerging acceptance of acupuncture results, in part, from its widespread availability and use in the United States today, even within the walls of major medical centers where it is used as an ancillary approach to pain management. Yet, its acceptance appears to stem from more than just its communal appeal. Since the mid-1970s, biochemical and imaging studies began to yield evidence that needling can trigger release of endogenous opioids that bind to specific receptors in the very brain regions that mediate the beneficial effects of narcotic analgesics.

EXISTING EVIDENCE

While it is difficult to conclude decisively that a particular CAM approach lacks any merit, it is quite feasible to discern that its effect size, or degree of benefit, is too small or inconsistent to be worth pursuing further. Over the past century, many once unconventional medical approaches failed—one need only think back to the exotic electrical devices, procedures, and tonics that fell out of fashion. Two questions are often asked: (1) Whether any of the more contemporary CAM modalities deserve to be rejected? (2) Whether data showing them to be ineffective would change anyone's mind about using them?

The case of laetrile is instructive. This extract of apricot seeds was touted in the 1970s as a cure for solid tumors. Thousands crossed the Mexican border to secure laetrile for their own use. The lack of any positive preclinical data discouraged oncologists from agreeing at first to study laetrile, until public pressure required that an answer be obtained. Two studies in the 1980s showed no benefit of laetrile treatment. Today, some continue to seek the product, but the numbers are vastly smaller than before meaningful data were obtained. A similar fate befell a cocktail of drugs used for cancer patients through the 1970s and 1980s by Dr. Luigi DiBella in Italy, once large studies revealed it to have no detectable impact on the course of a variety of advanced cancers.

In contrast, modalities that have been well tested and found ineffective are still in fairly common practice. For example, the renowned biochemist Linus Pauling proclaimed vitamin C able to effectively treat and even prevent the common cold. Several high-quality studies failed to demonstrate clinically important effects of vitamin C in preventing or treating viral colds. The early studies were criticized for using too little of the vitamin, yet doses that well exceeded its bioavailability also proved negative. Nonetheless, ingestion of extra vitamin C remains a common habit of individuals who perceive the onset of cold symptoms. For most people, this practice is wasteful but not harmful; however, people with iron overload (either hemochromatosis or chronic transfusion requirement) can be damaged by vitamin C, which generates free radicals in the setting of iron excess.

Despite the failure of some CAM approaches, early studies have yielded positive or at least encouraging data for a number of them. Good sources of information include the Natural Medicines Comprehensive Database (*www.NaturalDatabase.com*) and National Institutes of Health (NIH) websites such as *http://ods.od.nih.gov*; *http://nccam.nih.gov/health/* and *http://www3.cancer.gov/occam/information.html*.

Vitamins/Minerals

- *Vitamin A:* Large studies in a number of developing nations proved that vitamin A deficiency is prevalent and associated with increased

risks of mortality in young children. Prospective trials showed that ingestion of 100,000 to 200,000 IU of vitamin A twice a year reduces the overall death rate in early childhood and possibly also the progression of HIV/AIDS significantly.

- *Folic acid:* Rates of neural tube defects in newborns are significantly diminished by folate food supplementation.
- *Folic acid, vitamin B_6, and vitamin B_{12}:* Some high-quality randomized, double-blind, controlled trials suggested that this vitamin combination lowers serum homocysteine levels, but this has not lowered the risk of cardiovascular end points.
- *Vitamins C and E, β-carotene, and zinc:* A large randomized controlled trial showed that these supplements combined reduce the progression of age-related macular degeneration.

Even vitamins and minerals, which are presumed safe in moderate doses, can have unexpected adverse effects. Two large controlled trials of β-carotene for prevention of cancer or retinal diseases found increased rates of lung cancer in those randomized to the supplement. Ongoing large prospective trials are seeking benefits from ingestion of supplements on rates of prostate cancer (vitamin E and selenium) and Alzheimer's disease (vitamin E).

Herbals and Other Natural Products

- *Glucosamine and/or chondroitin sulfate:* Systematic surveys of smaller controlled trials led to a large multicenter trial that concluded that these products are superior to placebo in improving performance and slowing the narrowing of the joint space in patients with moderate to severely painful and disabling osteoarthritis of the knee. It remains uncertain whether their use also slows degradation of joint cartilage.
- *Ginkgo biloba:* Americans spent nearly $250 million on this herbal product in 2000. The literature shows no evidence that it improves cognition, but over 3000 older Americans currently participate in a randomized blinded trial to ascertain whether its use can reduce the rate of onset and progression of dementia.
- *Saw palmetto (Serenoa repens) and African plum (Pygeum africanum):* Each of these botanicals has been advocated for aging men to obtain symptomatic relief treatment of benign prostatic hyperplasia. Sales of saw palmetto are growing, with an estimated $131 million spent on the product consumed by Americans in 2000. However, clinical trials have shown that saw palmetto is ineffective in this setting.
- *St.-John's-wort (Hypericum perforatum):* Among the most popular herbal products worldwide, numerous small studies and systematic reviews suggested it to benefit patients with a wide range of depressive syndromes. High-quality, randomized, placebo-controlled trials found St.-John's-wort to not be superior to placebo for treatment of major depression of moderate severity, a spectrum of illness that clearly warrants professional evaluation and treatment.
- *Echinacea species: Echinacea* roots are widely used to treat or prevent respiratory infections, with over $200 million in sales in 2000. Although in vitro studies have shown that *Echinacea* constituents stimulate humoral and cellular immune responses, systematic reviews of the clinical trials have not concluded that they are beneficial.

Other Modalities

- *Acupuncture:* A frequently cited NIH-led consensus development conference in 1997 concluded that acupuncture relieves nausea from chemotherapy and pain following extraction of molars. Some subsequent studies confirmed these earlier impressions regarding acute nausea and vomiting, but the data regarding pain management have been mixed, with little evidence that it benefits neuropathic pain. A well-conducted study reported in 2004, however, concluded that acupuncture provides significant adjunctive relief for patients with osteoarthritis of the knee.
- *Mind-body medicine:* Clinical trials support the use of biofeedback for incontinence, headache, and stroke rehabilitation. Hypnosis may be beneficial in relieving pain due to minor surgical interventions, chemotherapy-associated nausea, and irritable bowel syndrome.
- *Spinal manipulation:* Systematic reviews of some well-designed trials concluded that chiropractic or osteopathic manipulation provides significant improvement for patients with uncomplicated acute back pain. No proof exists that they are superior to, or more cost-effective than, other conventional approaches, nor do they alter the long-term outcome.

SUMMARY

An array of unproven modalities will always be used by the patients under our care. Physicians must approach each encounter as an opportunity to better understand their patient's beliefs and expectations and use those insights to help guide their personal health care practices in a constructive way. Many of these choices are entirely innocuous and can be accommodated in the context of the established diagnostic and therapeutic interventions. Some of these choices should be actively discouraged. Along the way, scientific evidence will drive many CAM approaches out of favor. Some modalities will garner sufficient support to become part of mainstream care: the next generation of physicians will never know they were once controversial.

11 Palliative and End-of-Life Care

Ezekiel J. Emanuel, Joshua Hauser, Linda L. Emanuel

EPIDEMIOLOGY

In 2003, 2,448,288 individuals died in the United States (Table 11-1). Over 70% of all deaths occur in those >65 years of age. The epidemiology of mortality is similar in most developed countries; cardiovascular diseases and cancer are the predominant causes of death, a marked change since 1900, when heart disease caused ~8% of all deaths and cancer accounted for <4% of all deaths. In 2003, AIDS accounted for <1% of all deaths, although among those age 35–44, it remains a leading cause of death.

It is estimated that in developed countries ~70% of all deaths are preceded by a disease or condition such that it is reasonable to plan for dying in the foreseeable future. Cancer has served as the paradigm for terminal care, but it is not the only type of illness with a recognizable and predictable terminal phase. Since heart failure, chronic obstructive pulmonary disease (COPD), chronic liver failure, dementia, and many

TABLE 11-1 TEN LEADING CAUSES OF DEATH IN THE UNITED STATES AND BRITAIN

	United States			Britain	
Cause of Death	Number of Deaths	Percent of Total	Number of Deaths Among People ≥65 Years of Age	Number of Deaths	Percent of Total
All deaths	2,448,288	100	1,804,373	538,254	100
Heart disease	685,089	28	563,390	129,009	24
Cancer	556,902	22.7	388,390	135,955	25.3
Stroke	157,689	6.4	138,134	57,808	10.7

other conditions have recognizable terminal phases, a systematic approach to end-of-life care should be part of all medical specialties. Many patients with illness-related suffering can also benefit from palliative care, regardless of prognosis. Ideally, palliative care should be considered as a part of comprehensive care for all patients.

Over the past few decades in the United States, a significant change in the site of death has occurred that coincides with patient and family preferences. Nearly 60% of Americans died as inpatients in hospitals in 1980. By 2000, the trend was reversing, with ~40% of Americans dying as hospital inpatients (Fig. 11-1). This shift has been most dramatic for those dying from cancer and COPD and for younger and very old individuals. In the past decade, it is associated with the increased use of hospice care; in 2005, ~33% of all decedents in the United States received such care. Cancer patients currently constitute ~50% of hospice users, with ~60% of all terminal cancer patients receiving hospice care. About 70% of patients receiving hospice care die out of the hospital. In addition, with shortening of hospital stays, many serious conditions are being treated at home or on an outpatient basis. Consequently, providing optimal palliative and end-of-life care requires ensuring that appropriate services are available in a variety of settings, including noninstitutional settings.

HOSPICE AND THE PALLIATIVE CARE FRAMEWORK

Central to this type of care is an interdisciplinary team approach that typically encompasses pain and symptom management, spiritual and psychological care for the patient, and support for family caregivers during the patient's illness and the bereavement period.

Terminally ill patients have a wide variety of advanced diseases, often with multiple symptoms demanding relief, and require noninvasive therapeutic regimens to be delivered in flexible care settings. Fundamental to ensuring quality palliative and end-of-life care is a focus on four broad domains: (1) physical symptoms; (2) psychological symptoms; (3) social needs that include interpersonal relationships, caregiving, and economic concerns; and (4) existential or spiritual needs.

A comprehensive assessment screens for and evaluates needs in each of these four domains. Goals for care are established in discussion with the patient and/or family based on the assessment in each of these domains. Interventions are then aimed at improving or managing symptoms and needs. While physicians are responsible for certain especially technical interventions, and for coordinating the interventions, they cannot be responsible for providing all of them. Since failing to address any one of the domains is likely to preclude a good death, a well coordinated, effectively communicating interdisciplinary team takes on special importance in end-of-life care. Depending on the setting, critical members of the interdisciplinary team will include physicians, nurses, social workers, chaplains, nurse's aides, physical therapists, bereavement counselors, and volunteers.

ASSESSMENT AND CARE PLANNING

Comprehensive Assessment Standardized methods for conducting a comprehensive assessment focus on evaluating the patient's condition in all four domains affected by illness: physical, psychological, social, and spiritual. The assessment of physical and mental symptoms should follow a modified version of the traditional medical history and physical examination that emphasizes symptoms. Questions should aim at elucidating symptoms and discerning sources of suffering and gauging how much these symptoms interfere with the patient's quality of life. Standardized assessment is critical. Currently, there are 21 symptom assessment instruments for cancer alone. Instruments with good psychometric properties that assess a wide range of symptoms include the Memorial Symptom Assessment Scale (MSAS), the Rotterdam Symptom Checklist, the Worthing Chemotherapy Questionnaire, and the Computerized Symptom Assessment Instrument. These are long and may be useful for initial clinical or for research assessments. Shorter instruments are useful for patients whose performance status does not permit comprehensive assessments. Suitable shorter instruments include the Condensed Memorial Symptom Assessment Scale, the Edmonton Symptom Assessment System, the M.D. Anderson Symptom Assessment Inventory, and the Symptom Distress Scale. Using such instruments ensures that the assessment is comprehensive and does not just focus on pain and a few other physical symptoms. Invasive tests are best avoided in end-of-life care, and even minimally invasive tests should be carefully evaluated for their benefit-to-burden ratio for the patient. Aspects of the physical examination that are uncomfortable and unlikely to yield useful information can also be omitted.

Regarding social needs, health care providers should assess the status of important relationships, financial burdens, care-giving needs, and access to medical care. Relevant questions will include: *How often is there someone to feel close to? How has this illness been for your family? How has it affected your relationships? How much help do you need with things like getting meals or getting around? How much trouble do you have getting the medical care you need?* In the area of existential needs,

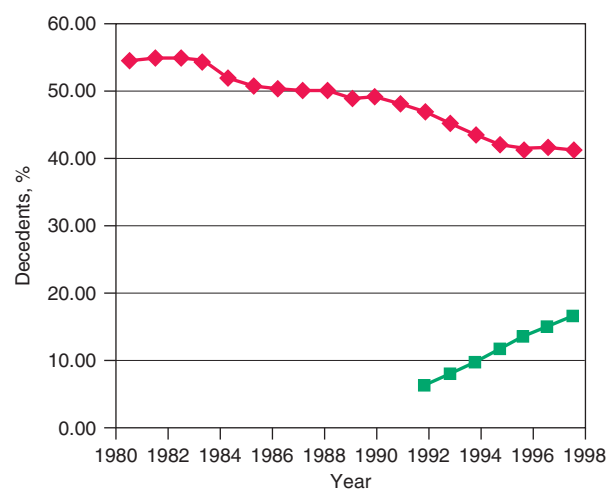

FIGURE 11-1 Graph showing trends in the site of death in the past two decades. ◆, percentage of hospital inpatient deaths; ■, percentage of decendents enrolled in a hospice.

providers should assess distress and the patient's sense of being emotionally and existentially settled and of finding purpose or meaning. Helpful assessment questions can include: *How much are you able to find meaning since your illness began? What things are most important to you at this stage?* In addition, it can be helpful to ask about how well the patient perceives his or her care to be: *How much do you feel your doctors and nurses respect you? How clear is the information from us about what to expect regarding your illness? How much do you feel that the medical care you are getting fits with your goals?* If concern is detected in any of these areas, deeper evaluative questions are warranted.

Communication Especially when an illness is life-threatening, there are many emotionally charged and potentially conflict-creating moments, collectively called "bad news" situations, in which empathic and effective communication skills are essential. These moments include communicating to the patient and/or family about a terminal diagnosis, the patient's prognosis, any treatment failures, deemphasizing efforts to cure and prolong life while focusing more on symptom management and palliation, advance care planning, and the patient's death.

Just as surgeons plan and prepare for major operations or investigators rehearse a presentation of research results, physicians and health care providers caring for patients with significant or advanced illness can develop a practiced approach to sharing important information and planning interventions. In addition, families identify as important both how well the physician was prepared to deliver bad news and the setting in which it was delivered. For instance, 27% of families making critical decisions for patients in an intensive care unit (ICU) desired better and more private physical space to communicate with physicians, and 48% found having clergy present reassuring.

An organized and effective procedure for communicating bad news with seven steps goes by the acronym P-SPIKES: (1) ***p***repare for the discussion, (2) ***s***et up a suitable environment, (3) begin the discussion by finding out what the ***p***atient and/or family understand, (4) determine how they will comprehend new ***i***nformation best and how much they want to know, (5) provide needed new ***k***nowledge accordingly, (6) allow for ***e***motional responses, and (7) ***s***hare plans for the next steps in care. Table 11-2 provides a summary of these steps along with suggested phrases and underlying rationales for each.

Continuous Goal Assessment Major barriers to ensuring quality palliative and end-of-life care include difficulty in providing an accurate prognosis and emotional resistance of patients and their families to accepting the implications of a poor prognosis. A practical solution to these barriers is to integrate palliative care with curative care regardless of prognosis. With this approach, palliative care no longer conveys the message of failure, having no more treatments, or "giving up hope." Fundamental to integrating palliative care with curative therapy is to include continuous goal assessment as part of the routine patient reassessment that occurs at most patient-physician encounters.

Goals for care are numerous, ranging from cure of a specific disease, to prolonging life, to relief of a symptom, to delaying the course of an incurable disease, to adapting to progressive disability without disrupting the family, to finding peace of mind or personal meaning, to dying in a manner that leaves loved ones with positive memories. Discernment of goals for care can be approached through a seven-step protocol: (1) ensure that medical and other information is as complete as reasonably possible and understood by all relevant parties (see above); (2) explore what the patient and/or family are hoping for while identifying relevant and realistic goals; (3) share all the options with the patient and family; (4) respond with empathy as they adjust to changing expectations; (5) make a plan, emphasizing what can be done toward the realistic

TABLE 11-2 ELEMENTS OF COMMUNICATING BAD NEWS—THE P-SPIKES APPROACH

Acronym	Steps	Aim of the Interaction	Preparations, Questions, or Phrases
P	Preparation	Mentally prepare for the interaction with the patient and/or family.	Review what information needs to be communicated. Plan how you will provide emotional support. Rehearse key steps and phrases in the interaction.
S	Setting of the interaction	Ensure the appropriate setting for a serious and potentially emotionally charged discussion.	Ensure patient, family, and appropriate social supports are present. Devote sufficient time. Ensure privacy and prevent interruptions by people or beeper. Bring a box of tissues.
P	Patient's perception and preparation	Begin the discussion by establishing the baseline and whether the patient and family can grasp the information. Ease tension by having the patient and family contribute.	Start with open-ended questions to encourage participation. Possible phrases to use: *What do you understand about your illness?* *When you first had symptom X, what did you think it might be?* *What did Dr. X tell you when he sent you here?* *What do you think is going to happen?*
I	Invitation and information needs	Discover what information needs the patient and/or family have and what limits they want regarding the bad information.	Possible phrases to use: *If this condition turns out to be something serious, do you want to know?* *Would you like me to tell you all the details of your condition? If not, then who would you like me to talk to?*
K	Knowledge of the condition	Provide the bad news or other information to the patient and/or family sensitively.	Do not just dump the information on the patient and family. Check for patient and family understanding. Possible phrases to use: *I feel badly to have to tell you this, but…* *Unfortunately, the tests showed…* *I'm afraid the news is not good…*
E	Empathy and exploration	Identify the cause of the emotions—e.g., poor prognosis. Empathize with the patient and/or family's feeling. Explore by asking open-ended questions.	Strong feelings in reaction to bad news are normal. Acknowledge what the patient and family are feeling. Remind them such feelings are normal, even if frightening. Give them time to respond. Remind patient and family you won't abandon them. Possible phrases to use: *I imagine this is very hard for you to hear.* *You look very upset. Tell me how you are feeling.* *I wish the news were different.* *We'll do whatever we can to help you.*
S	Summary and planning	Delineate for the patient and the family the next steps, including additional tests or interventions.	It is the unknown and uncertain that can increase anxiety. Recommend a schedule with goals and landmarks. Provide your rationale for the patient and/or family to accept (or reject). If the patient and/or family are not ready to discuss the next steps, schedule a follow-up visit.

Source: Adapted from Buckman.

goals; (6) follow through with the plan; and (7) review and revise this plan periodically, considering at every encounter whether the goals of care should be reviewed with the patient and/or family. Each of these steps need not be followed in rote order, but together they provide a helpful framework for interactions with patients and their families about goals for care. It can be especially challenging if a patient or family member has difficulty letting go of an unrealistic goal. One strategy is to help them refocus on more realistic goals, and also suggest that, while hoping for the best, it is still prudent to plan for other outcomes as well.

TABLE 11-3 STEPS IN ADVANCE CARE PLANNING

Step	Goals to be Achieved and Measures to Cover	Useful Phrases or Points to Make
Introducing advance care planning	Ask the patient what he or she knows about advance care planning and if he or she has already completed an advanced care directive. Indicate that you as a physician have completed advance care planning. Indicate that you try to perform advance care planning with all patients regardless of prognosis. Explain the goals of the process as empowering the patient and ensuring you and the proxy understand the patient's preferences. Provide the patient relevant literature including the advance care directive that you prefer to use. Recommend the patient identify a proxy decision-maker who should attend the next meeting.	*I'd like to talk with you about something I try to discuss with all my patients. It's called advance care planning. In fact, I feel that this is such an important topic that I have done this myself. Are you familiar with advance care planning or living wills?* *Have you thought about the type of care you would want if you ever became too sick to speak for yourself? That is the purpose of advance care planning.* *There is no change in health that we have not discussed. I am bringing this up now because it is sensible for everyone, no matter how well or ill, old or young.* Have many copies of advance care directives available, including in the waiting room, for patients and families. Know resources for state-specific forms (available at *www.nhpco.org*).
Structured discussion of scenarios and patient	Affirm that the goal of the process is to follow the patient's wishes if the patient loses decision-making capacity. Elicit the patient's overall goals related to health care. Elicit the patient's preferences for specific interventions in a few salient and common scenarios. Help the patient define the threshold for withdrawing and withholding interventions. Define the patient's preference for the role of the proxy.	Use a structured worksheet with typical scenarios. Begin the discussion with persistent vegetative state and consider other scenarios, such as recovery from an acute event with serious disability, asking the patient about his or her preferences regarding specific interventions, such as ventilators, artificial nutrition, and CPR, and then proceeding to less-invasive interventions, such as blood transfusions and antibiotics.
Review the patient's preferences	After the patient has made choices of interventions, review them to ensure they are consistent and the proxy is aware of them.	
Document the patient's preferences	Formally complete the advance care directive and have witness sign it. Provide a copy for the patient and the proxy. Insert a copy into the patient's medical record and summarize in a progress note.	
Update the directive	Periodically, and with major changes in health status, review the directive with the patient and make any modifications.	
Apply the directive	The directive goes into effect only when the patient becomes unable to make medical decisions for him- or herself. Re-read the directive to be sure about its content. Discuss your proposed actions based on the directive with the proxy.	

Note: CPR, cardiopulmonary resuscitation.

Advance Care Planning • *PRACTICES*

Advance care planning is a process of planning for future medical care in case the patient becomes incapable of making medical decisions. Ideally, such planning would occur before a health care crisis or the terminal phase of an illness. Unfortunately, diverse barriers prevent this. While 80% of Americans endorse advance care planning and completing living wills, only 29% have actually done so. Most patients expect physicians to initiate advance care planning and will wait for physicians to broach the subject. Patients also wish to discuss advance care planning with their families. Yet patients with unrealistic expectations are significantly more likely to prefer aggressive treatments. Fewer than one-third of health care providers have completed advance care planning for themselves. Hence, a good first step is for health care providers to complete advance care planning for themselves. This makes providers aware of the critical choices in the process and the issues that are especially charged and allows them to tell their patients truthfully that they have done advance planning themselves.

Steps in effective advance care planning center on (1) introducing the topic, (2) structuring a discussion, (3) reviewing plans that have been discussed by the patient and family, (4) documenting the plans, (5) updating them periodically, and (6) implementing the advance care directives (Table 11-3). Two of the main barriers to advance care planning are problems in raising the topic and structuring a succinct discussion. Raising the topic can be done efficiently as a routine matter, noting that it is recommended for all patients, analogous to purchasing insurance or estate planning. Almost all of the most difficult cases have involved unexpected, acute episodes of brain damage in young individuals.

Structuring a focused discussion is a central communication skill. Identify the health care proxy and recommend his or her involvement in the advance care planning process. Select a worksheet, preferably one that has been evaluated and demonstrated to produce reliable and valid expressions of patient preferences, and orient the patient and proxy to it. Such worksheets exist for both general and disease-specific situations. Discuss with the patient and proxy one scenario as an example to demonstrate how to think about the issues. It is often helpful to begin with a scenario in which the patient is likely to have settled preferences for care, such as being in a persistent vegetative state. Once the patient's preferences for interventions in this scenario are determined, suggest that the patient and proxy discuss and complete the worksheet for the others. If appropriate, suggest they involve other family members in the discussion. On a return visit, go over the patient's preferences, checking and resolving any inconsistencies. After having the patient and proxy sign the document, place it in the medical chart and be sure that copies are provided to relevant family members and care sites. Since patients' preferences can change, these documents need to be reviewed periodically.

TYPES OF DOCUMENTS Advance care planning documents are of two broad types. The first includes living wills or instructional directives; these are advisory documents that describe the types of decisions that should direct care. Some are more specific, delineating different scenarios and interventions for the patient to choose from. Among these, some are for general use and others are designed for use by

patients with a specific type of disease, such as cancer or HIV. Less specific directives can be general statements of not wanting life-sustaining interventions or forms that describe the values that should guide specific terminal care decisions. The second type of advance directive allows the designation of a health care proxy (sometimes also referred to as a durable attorney for health care) who is an individual selected by the patient to make decisions. The choice is not either/or; a combined directive that includes a living will and designates a proxy is often used, and the directive should clearly indicate whether the specified patient preferences or the proxy's choice takes precedence if they conflict.

A potentially misleading distinction relates to statutory as opposed to advisory documents. Statutory documents are drafted to fulfill relevant state laws. Advisory documents are drafted to reflect the patient's wishes. Both are legal, the first under state law, and the latter under common or constitutional law.

LEGAL ASPECTS As of 2006, 48 states and the District of Columbia had enacted living will legislation. Many states have their own statutory forms. Massachusetts and Michigan do not have living will laws, although both have health care proxy laws. In 25 states, the laws state that the living will is not valid if a woman is pregnant. However, like all other states except Alaska, these states have enacted durable power of attorney for health care laws that permit patients to designate a proxy decision-maker with authority to terminate life-sustaining treatments. Only in Alaska does the law prohibit proxies from terminating life-sustaining treatments.

The U.S. Supreme Court has ruled that patients have a constitutional right to decide about refusing and terminating medical interventions, including life-sustaining interventions, and that mentally incompetent patients can exercise this right by providing "clear and convincing evidence" of their preferences. Since advance care directives permit patients to provide such evidence, commentators agree that they are constitutionally protected. Most commentators believe that a state is required to honor any clear advance care directive, whether or not it is written on an "official" form. Many states have enacted laws to explicitly honor out-of-state directives. If a patient is not using a statutory form, then it might be advisable to attach a statutory form to the advance care directive being used. State-specific forms are readily available free of charge for health care providers and patients and families through the website of the National Hospice and Palliative Care Organization (*http://www.nhpco.org*).

INTERVENTIONS

PHYSICAL SYMPTOMS AND THEIR MANAGEMENT

Great emphasis has been placed on addressing dying patients' pain. Some institutions have made pain assessment a fifth vital sign to emphasize its importance. This has also been advocated by large health care systems, such as the Veterans' Administration and accrediting bodies such as the Joint Commission on the Accreditation of Health Care Organizations (JCAHO). Although this embrace of pain as the fifth vital sign has been symbolically important, no data document that it has changed pain management practices. While good palliative care requires good pain management, it also requires more. The frequency of symptoms varies by disease and other factors. The most common physical and psychological symptoms among all terminally ill patients include pain, fatigue, insomnia, anorexia, dyspnea, depression, anxiety, and nausea and vomiting. In the last days of life, terminal delirium is also common. Assessments of patients with advanced cancer have shown that patients experienced an average of 11.5 different physical and psychological symptoms (Table 11-4).

Evaluations to determine the etiology of these symptoms can usually be limited to the history and physical examination. In some cases, radiologic or other diagnostic examinations will provide sufficient benefit in directing optimal palliative care to warrant the risks, potential discomfort, and inconvenience especially to the seriously ill patient. Only a few of the common symptoms presenting difficult management issues will be addressed in this chapter. **Additional information on the management of other symptoms, such as nausea and vomiting, insomnia, and diarrhea can be found in Chaps. 39 and 77, Chap. 28, and Chap. 40, respectively.**

TABLE 11-4 COMMON PHYSICAL AND PSYCHOLOGICAL SYMPTOMS OF TERMINALLY ILL PATIENTS

Physical Symptoms	Psychological Symptoms
Pain	Anxiety
Fatigue and weakness	Depression
Dyspnea	Hopelessness
Insomnia	Meaninglessness
Dry mouth	Irritability
Anorexia	Impaired concentration
Nausea and vomiting	Confusion
Constipation	Delirium
Cough	Loss of libido
Swelling of arms or legs	
Itching	
Diarrhea	
Dysphagia	
Dizziness	
Fecal and urinary incontinence	
Numbness/tingling in hands/feet	

Pain • ***FREQUENCY*** The frequency of pain among terminally ill patients varies widely. Substantial pain occurs in 36–90% of patients with advanced cancer. In the SUPPORT study of hospitalized patients with diverse conditions and an estimated survival of ≤6 months, 22% reported moderate to severe pain, and caregivers of these patients noted that 50% had similar levels of pain during the last few days of life.

ETIOLOGY *Nociceptive pain* is the result of direct mechanical or chemical stimulation of nociceptors and normal neural signaling to the brain. It tends to be localized, aching, throbbing, and cramping. The classic example is bone metastases. *Visceral pain* is caused by nociceptors in gastrointestinal, respiratory, and other organ systems. It is a deep or colicky type of pain classically associated with pancreatitis, myocardial infarction, or tumor invasion of viscera. *Neuropathic pain* arises from disordered nerve signals. It is described by patients as burning, electrical, or shocklike pain. Classic examples are post-stroke pain, tumor invasion of the brachial plexus, and herpetic neuralgia.

ASSESSMENT Pain is a subjective experience. Depending upon the patient's circumstances, perspective, and physiologic condition, the same physical lesion or disease state can produce different levels of reported pain and need for pain relief. Systematic assessment includes eliciting the following: (1) type: throbbing, cramping, burning, etc. (2) periodicity: continuous, with or without exacerbations, or incident; (3) location; (4) intensity; (5) modifying factors; (6) effects of treatments; (7) functional impact; and (8) impact on patient. Several validated pain assessment measures may be used, such as the Visual Analogue Scale, the Brief Pain Inventory, and the pain component of one of the more comprehensive symptom assessment instruments. Frequent reassessments are essential to assess the effects of interventions.

INTERVENTIONS Interventions for pain must be tailored to each individual with the goal of preempting chronic pain and relieving breakthrough pain. At the end of life, there is rarely reason to doubt the patient's report of pain. Pain medications are the cornerstone of management. If these are failing and nonpharmacologic interventions—including radiotherapy, anesthetic or neurosurgical procedures, such as peripheral nerve blocks or epidural medications—are required, a pain consultation is appropriate.

Pharmacologic interventions follow the World Health Organization three-step approach involving nonopioid analgesics, mild opioids, and strong opioids, with or without adjuvants (Chap. 12). Nonopioid an-

algesics, especially nonsteroidal anti-inflammatory drugs (NSAIDs), are the initial treatments for mild pain. They work primarily by inhibiting peripheral prostaglandins, reducing inflammation, but may also have central nervous system (CNS) effects. They have a ceiling effect. Ibuprofen, up to 1600 mg/d qid, has a minimal risk of bleeding and renal impairment and is a good initial choice. In patients with a history of severe gastrointestinal (GI) or other bleeding, it should be avoided. In patients with a history of mild gastritis or gastroesophageal reflux disease (GERD), acid-lowering therapy, such as a proton-pump inhibitor, should be used. Acetaminophen is an alternative in patients with a history of GI bleeding and can be used safely at up to 4 g/d, qid. In patients with liver dysfunction due to metastases or other causes or in patients with heavy alcohol use, doses should be reduced.

If nonopioid analgesics are insufficient, then opioids should be introduced. They work by interacting with mu opioid receptors in the CNS to activate pain-inhibitory neurons; most are receptor antagonists. The mixed agonist/antagonist opioids useful for post-acute pain should not be used for the chronic pain in end-of-life care. Weak opioids, such as codeine, can be used initially. However, if these are escalated and fail to relieve pain, then strong opioids, such as morphine 5–10 mg every 4 h, should be used. Nonopioid analgesics should be combined with opioids because they potentiate the effect of opioids.

For continuous pain, opioids should be administered on a regular, around-the-clock basis consistent with their duration of analgesia. They should not be provided only when the patient experiences pain; the goal is to prevent patients from experiencing pain. Patients should also be provided rescue medication, such as liquid morphine, for breakthrough pain that should generally be 20% of the baseline dose. Patients should be informed that using the rescue medication does not obviate their taking the next standard dose of pain medication. If after 24 h the patient's pain remains uncontrolled and recurs before the next dose, requiring the patient to utilize the rescue medication, the daily opioid dose can be increased by the total dose of rescue medications used by the patient, or by 50% for moderate pain and 100% for severe pain of the standing opioid daily dose.

It is inappropriate to start with extended-release preparations. Instead, an initial focus on using short-acting preparations in order to determine how much is required in the first 24–48 h will allow clinicians to determine opioid needs. Once pain relief is obtained with short-acting preparations, then switch to extended-release preparations. Even with a stable extended-release preparation regimen, the patient may have incident pain, such as during movement or dressing changes. Short-acting preparations should be taken before such predictable episodes. Although less common, patients may have "end-of-dose failure" with long-acting opioids, meaning that they develop pain after 8 h in the case of an every 12-h medication. In these cases, a trial of giving an every 12-h medication every 8 h is appropriate.

Because of differences in opioid receptors, cross-tolerance among opioids is incomplete and patients may experience different side effects with different opioids. Therefore, if a patient is not experiencing pain relief or is experiencing too many side effects, change to another opioid preparation is appropriate. When switching, begin with 50–75% of the published equianalgesic dose of the new opioid.

Unlike NSAIDs, opioids have no ceiling effect; therefore, there is no maximum dose no matter how many milligrams the patient is receiving. The appropriate dose is the dose needed to achieve pain relief. This is an important point for clinicians to explain to patients and families. Addiction or excessive respiratory depression is extremely unlikely in the terminally ill; fear of these side effects should neither prevent escalating opioid medications when the patient is experiencing insufficient pain relief nor justify using opioid antagonists.

Opioid side effects should be anticipated and treated preemptively. Nearly all patients experience constipation that can be debilitating (see below). Failure to prevent constipation often results in noncompliance with opioid therapy. Methylnaltrexone is a drug that targets opioid- induced constipation by blocking peripheral opioid receptors but not central receptors for analgesia. In placebo-controlled trials, it has been shown to cause laxation within 24 h of administration. As with the use of opioids, about a third of patients using methylnaltrexone experience nausea and vomiting, but unlike constipation, tolerance develops, usually within a week. Therefore, when beginning opioids, an antiemetic, such as metoclopramide or a serotonin antagonist, is often prescribed prophylactically and stopped after 1 week. Olanzapine has also been shown to have anti-nausea properties and can also be effective in countering delirium or anxiety, with the advantage of some weight gain.

Drowsiness, a common side effect of opioids, also usually abates within a week. During this period, drowsiness can be treated with psychostimulants, such as dextroamphetamine, methylphenidate, or modafinil. Modafinil has the advantage of every day dosing. Pilot reports suggest that donepezil may also be helpful for opiate-induced drowsiness, as well as relieving fatigue and anxiety. Metabolites of morphine and most opioids are cleared renally; doses may need to be adjusted for patients with renal failure.

Seriously ill patients with chronic pain relief rarely if ever become addicted. Suspicion of addiction should not be a reason to withhold pain medications from terminally ill patients. Patients and families may withhold prescribed opioids for fear of addiction or dependence. Physicians and health care providers should reassure patients and families that the patient will not become addicted to opioids if used as prescribed for pain relief; this fear should not prevent the patient from taking the medications around the clock. However, diversion of drugs for use by other family members or illicit sale may occur. It may be necessary to advise the patient and caregiver about secure storage of opioids. Contract writing with the patient and family can help. If that fails, transfer to a safe facility may be necessary.

Tolerance is the need for increasing medication dosage for the same pain relief without a change in disease. In the case of patients with advanced disease, the need for increasing opioid dosage for pain relief is usually caused by disease progression rather than tolerance. Physical dependence is indicated by symptoms from the abrupt withdrawal of opioids and should not be confused with addiction.

Adjuvant analgesic medications are nonopioids that potentiate the analgesic effects of opioids. They are especially important in the management of neuropathic pain. Gabapentin, an anticonvulsant initially studied in the setting of herpetic neuralgia, is now the first-line treatment for neuropathic pain from a variety of causes. It is begun at 100–300 mg bid or tid, with 50–100% dose increments every 3 days. Usually 900–3600 mg/d in two or three doses is effective. One potential side effect to be aware of is confusion and drowsiness, especially in the elderly. Other effective adjuvant medications include pregabalin, which has the same mechanism of action as gabapentin but is more efficiently absorbed from the GI tract. Lamotrigine is a novel agent whose mechanism of action is unknown, but it has shown effectiveness. It is recommended to begin at 25–50 mg/d increasing to 100 mg/d. Carbamazepine, a first-generation agent, has been proven effective in randomized trials for neuropathic pain. Other potentially effective anticonvulsant adjuvants include topiramate (25–50 mg qd or bid rising to 100–300 mg/d) and oxcarbazepine (75–300 mg bid, rising to 1200 mg bid). Glucocorticoids, preferably dexamethasone given once a day, can be useful in reducing inflammation that causes pain while elevating mood, energy, and appetite. Its main side effects include confusion, sleep difficulties, and fluid retention. Glucocorticoids are especially effective for bone pain and abdominal pain from distention of the GI tract or liver. Other drugs, including clonidine and baclofen, can be effective in pain relief. These drugs are adjuvants and should generally be used in conjunction with—not instead of—opioids. Methadone, carefully dosed because of unpredictable half-life in many patients, has activity at the *N*-methyl D-aspartamate (NMDA) receptor and is useful for complex pain syndromes and neuropathic pain. It is generally reserved for cases when first-line opioids (morphine, oxycodone, hydromorphone) are either ineffective or unavailable.

Radiation therapy can treat bone pain from single metastatic lesions. Bone pain from multiple metastases can be amenable to radiopharmaceuticals, such as strontium 89 and samarium 153. Bisphosphonates [such as pamidronate (90 mg every 4 weeks)] and calcitonin (200 IU intranasally once or twice a day) also provide relief from bone pain but have onset of action of days.

Constipation • ***FREQUENCY*** Constipation is reported in up to 90% of terminally ill patients.

ETIOLOGY While hypercalcemia and other factors can cause constipation, it is most frequently a predictable consequence of the use of opioids for the relief of pain and dyspnea and of tricyclic antidepressants, from their anticholinergic effects, as well as of the inactivity and poor diet that are common among seriously ill patients. If untreated, constipation can cause substantial pain and vomiting and is also associated with confusion and delirium. Whenever opioids and other medications known to cause constipation are used, preemptive treatment for constipation should be instituted.

ASSESSMENT Establish the patient's previous bowel habits, including the frequency, consistency, and volume. Abdominal and rectal examinations should be performed to exclude impaction or acute abdomen. Radiographic assessments beyond a simple flat plate of the abdomen in cases where obstruction is suspected are rarely necessary.

TABLE 11-5 MEDICATIONS FOR THE MANAGEMENT OF CONSTIPATION

Intervention	Dose	Comment
Stimulant laxatives		These agents directly stimulate peristalsis and may reduce colonic absorption of water.
Prune juice	120–240 mL/d	
Senna (Senokot)	2–8 tablets PO bid	
Bisacodyl	5–15 mg/d PO, PR	Work in 6–12 h.
Osmotic laxatives		These agents are not absorbed. They attract and retain water in the gastrointestinal tract. Lactulose may cause flatulence and bloating. Lactulose works in 1 day; magnesium products in 6 h.
Lactulose	15–30 mL PO q4–8h	
Magnesium hydroxide (Milk of Magnesia)	15–30 mL/d PO	
Magnesium citrate	125–250 mL/d PO	
Stool softeners		These agents work by increasing water secretion and as detergents increasing water penetration into the stool. Work in 1–3 days.
Sodium docusate (Colace)	300–600 mg/d PO	
Calcium docusate	300–600 mg/d PO	
Suppositories and enemas		
Bisacodyl	10–15 PR qd	
Sodium phosphate enema	PR qd	Fixed dose, 4.5 oz, Fleet's.

INTERVENTION While physical activity, adequate hydration, and dietary treatments with fiber can be helpful, each is limited in its effectiveness for most seriously ill patients, and fiber may exacerbate problems in the setting of dehydration and if impaired motility is the etiology. Fiber is contraindicated in the presence of opioid use. Stimulant and osmotic laxatives, stool softeners, fluids, and enemas are the mainstays of therapy (Table 11-5). When preventing constipation from opioids and other medications, a combination of a laxative and stool softener (such as senna and docusate) should be used. If after several days of treatment a bowel movement has not occurred, a rectal examination to remove impacted stool and to place a suppository is necessary. For patients with impending bowel obstruction or gastric stasis, octreotide to reduce secretions can be helpful. For patients in whom the suspected mechanism is dysmotility, metoclopramide can be helpful.

Nausea • ***FREQUENCY*** Up to 70% of patients with advanced cancer have nausea, defined as the subjective sensation of wanting to vomit.

ETIOLOGY Nausea and vomiting are both caused by stimulation at one of four sites: the GI tract, the vestibular system, the chemoreceptor trigger zone (CTZ), and the cerebral cortex. Medical treatments of nausea are aimed at receptors at each of these sites: The GI tract contains mechanoreceptors, chemoreceptors, and 5-hydroxytryptamine type 3 (5-HT3) receptors; the vestibular system likely contains histamine and acetylcholine receptors; and the CTZ contains chemoreceptors, dopamine type 2 receptors, and 5-HT3 receptors. An example of nausea that is most likely mediated by the cortex is anticipatory nausea before a dose of chemotherapy or other noxious stimuli.

Specific causes of nausea include metabolic changes (liver failure, uremia from renal failure, hypercalcemia), bowel obstruction, constipation, infection, GERD, vestibular disease, brain metastases, medications (including antibiotics, NSAIDs, proton-pump inhibitors, opioids, chemotherapy), and radiation therapy. Anxiety can also contribute to nausea.

INTERVENTION Medical treatment of nausea is directed at the anatomic and receptor-mediated cause that a careful history and physical examination reveals. When a single specific cause is not found, many advocate beginning treatment with dopamine antagonists such as haloperidol or prochlorperazine. Prochlorperazine is usually more sedating than haloperidol. When decreased motility is suspected, metoclopramide can be an effective treatment. When inflammation of the GI tract is suspected, glucocorticoids such as dexamethasone are an appropriate treatment. For post-chemotherapy and -radiation therapy nausea, one of the 5-HT3 receptor antagonists (ondansetron, granisetron, dolasetron) is recommended. When a vestibular cause (such as "motion sickness" or labyrinthitis) is suspected, antihistamines such as meclizine (whose primary side effect is drowsiness) or anticholinergics such as scopolamine can be effective. In anticipatory nausea, a benzodiazepine such as lorazepam is indicated. As with antihistamines, drowsiness and confusion are the main side effects.

Dyspnea • ***FREQUENCY*** Dyspnea is a subjective experience of being short of breath. Nearly 75% of dying patients experience dyspnea at some point in their illness. Dyspnea is among the most distressing of physical symptoms and can be even more distressing than pain.

ASSESSMENT As with pain, dyspnea is a subjective experience that may not correlate with objective measures of P_{O_2}, P_{CO_2}, or respiratory rate. Consequently, measurements of oxygen saturation through pulse oximetry or blood gases are rarely helpful in guiding therapy. Potentially reversible or treatable causes of dyspnea include infection, pleural effusions, pulmonary emboli, pulmonary edema, asthma, or tumor encroachment on the airway. However, the risk-benefit ratio of the diagnostic and therapeutic interventions for patients with little time left to live must be carefully considered before undertaking diagnostic steps. Frequently, the specific etiology cannot be identified, and dyspnea is the consequence of progression of the underlying disease that cannot be treated. The anxiety caused by dyspnea and the choking sensation can significantly exacerbate the underlying dyspnea in a negatively reinforcing cycle.

INTERVENTIONS When reversible or treatable etiologies are diagnosed, they should be treated as long as the side effects of treatment, such as repeated drainage of effusions or anticoagulants, are less burdensome than the dyspnea itself. More aggressive treatments, such as stenting a bronchial lesion may be warranted if it is clear that the dyspnea is due to tumor invasion at that site and if the patient and family understand the risks of such a procedure. Usually, treatment will be symptomatic (Table 11-6). Low-dose opioids reduce the sensitivity of the central respiratory center and the sensation of dyspnea. If patients are not receiving opioids, weak opioids can be initiated; if patients are already receiving opioids, then morphine or other strong opioids should be used. Controlled trials do not support the use of nebulized opioids for dyspnea at the end of life. Phenothiazines and chlorpromazine may be helpful when combined with opioids. Benzodiazepines can be helpful if anxiety is present but should be neither first-line therapy nor used alone in the treatment of dyspnea. If the patient has a history of COPD or asthma, inhaled bronchodilators and glucocorticoids may also be helpful. If the patient has pulmonary edema due to heart failure, di-

TABLE 11-6 MEDICATIONS FOR THE MANAGEMENT OF DYSPNEA

Intervention	Dose	Comments
Weak opioids		For patients with mild dyspnea
Codeine (or codeine with 325 mg acetaminophen)	30 mg PO q4h	For opioid-naïve patient
Hydrocodone	5 mg PO q4h	
Strong opioids		For opioid-naïve patients with moderate to severe dyspnea
Morphine	5–10 mg PO q4h	
	30–50% of baseline opioid dose q4h	For patients already taking opioids for pain or other symptoms
Oxycodone	5–10 mg PO q4h	
Hydromorphone	1–2 mg PO q4h	
Anxiolytics		Give a dose every hour until the patient is relaxed, then provide a dose for maintenance
Lorazepam	0.5–2.0 mg PO/SL/IV qh then q4–6h	
Clonazepam	0.25–2.0 mg PO q12h	
Midazolam	0.5 mg IV q15min	

uresis with a medication such as furosemide is indicated. Excess secretions can be dried with scopolamine, transdermally or intravenously. Oxygen can be used, although it may only be an expensive placebo. For some families and patients, oxygen is distressing; for some it is reassuring. More general interventions that medical staff can do include: sitting the patient upright, removing smoke or other irritants such as perfume, ensuring a supply of fresh air with sufficient humidity, and minimizing other factors that can increase anxiety.

Fatigue • ***FREQUENCY*** More than 90% of terminally ill patients experience fatigue and/or weakness. Fatigue is frequently cited as among the most distressing of symptoms.

ETIOLOGY The multiple causes of fatigue in the terminally ill can be categorized as resulting from the underlying disease; from disease-induced factors, such as tumor necrosis factor and other cytokines; and from secondary factors such as dehydration, anemia, infection, hypothyroidism, and drug side effects. Apart from low caloric intake, loss of muscle mass and changes in muscle enzymes may play an important role in fatigue of terminal illness. The importance of changes in the CNS, especially the reticular activating system, have been hypothesized based on reports of fatigue in patients receiving cranial radiation, experiencing depression, or with chronic pain in the absence of cachexia or other physiologic changes. Finally, depression and other causes of psychological distress can contribute to fatigue.

ASSESSMENT Fatigue is subjective; objective changes, even in body mass, may be absent. Consequently, assessment must rely on patient self-reporting. Scales used to measure fatigue, such as the Edmonton Functional Assessment Tool, the Fatigue Self-Report scales, or the Rhoten Fatigue scale, are usually appropriate for research rather than clinical purposes. In clinical practice, a simple performance assessment such as the Karnofsky Performance Status or the Eastern Cooperative Oncology Group's question "How much of the day does the patient spend in bed?" may be the best measure. In this 0–4 performance status assessment, a 0 = normal activity; 1 = symptomatic without being bedridden; 2 = requiring some, but <50%, bed time; 3 = bedbound more than half the day; and 4 = bedbound all the time. Such a scale allows for assessment over time and correlates with overall disease severity and prognosis.

INTERVENTIONS At the end of life, fatigue will not be "cured." The goal is to ameliorate it and help patients and families to adjust expectations. Behavioral interventions should be utilized to avoid blaming the patient for inactivity and to educate both the family and patient that the underlying disease causes physiologic changes producing low energy levels. Understanding that the problem is physiologic not psychological can help to alter expectations regarding the patient's level of physical activity. Practically, this may mean reducing routine activities, such as housework and cooking, or social events outside the house, and making it acceptable to receive guests lying on a couch. At the same time, institution of exercise regimens and physical therapy can raise endorphins, reduce muscle wasting, and reduce the risk of depression. In addition, ensuring good hydration without worsening edema may help reduce fatigue. Discontinuing medications that worsen fatigue may help, including cardiac medications, benzodiazepines, certain antidepressants or opioids, if pain is well-controlled.

Only a few pharmacologic interventions target fatigue and weakness. Glucocorticoids can increase energy and enhance mood. Dexamethasone is preferred for its once-a-day dosing and minimal mineralocorticoid activity. Benefit, if any, will usually be seen within the first month. Psychostimulants, such as dextroamphetamine (5–10 mg PO) and methylphenidate (2.5–5 mg PO), may also enhance energy levels, although a randomized trial did not show methylphenidate beneficial compared to placebo in cancer fatigue. Dosages should be given in the morning and at noon to minimize the risk of counterproductive insomnia. Modafinil, developed for narcolepsy, has shown some promise in the treatment of fatigue and has the advantage of once-daily dosing. Its precise role in the fatigue at the end of life is yet to be determined. Anecdotal evidence suggests that L-carnitine might improve fatigue, depression, and sleep disruption.

PSYCHOLOGICAL SYMPTOMS AND THEIR MANAGEMENT

Depression • ***FREQUENCY*** Depression at the end of life presents an apparently paradoxical situation. Many people believe that depression is normal among seriously ill patients because they are dying. People frequently say "wouldn't you be depressed?" However, depression is not a necessary part of terminal illness and can contribute to needless suffering. While sadness, anxiety, anger, and irritability are normal responses to a serious condition, they are typically of modest intensity and transient. Persistent sadness and anxiety and the physically disabling symptoms that these can lead to are abnormal and suggestive of major depression. While as many as 75% of terminally ill patients experience depressive symptoms, <25% of terminally ill patients have major depression.

ETIOLOGY Previous history of depression, family history of depression or bipolar disorder, and prior suicide attempts are associated with increased risk for depression among terminally ill patients. Other symptoms, such as pain and fatigue, are associated with higher rates of depression; uncontrolled pain can exacerbate depression, and depression can cause patients to be more distressed by pain. Many medications used in the terminal stages, including glucocorticoids, and some anticancer agents, such as tamoxifen, interleukin 2, interferon α, and vincristine, are also associated with depression. Some terminal conditions, such as pancreatic cancer, certain strokes, and heart failure have been reported to be associated with higher rates of depression, although this is controversial. Finally, depression may be attributable to grief over the loss of a role or function, social isolation, or loneliness.

ASSESSMENT Diagnosing depression among seriously ill patients is complicated because many of the vegetative symptoms in the DSM-IV criteria for clinical depression—insomnia, anorexia and weight loss, fatigue, decreased libido, and difficulty concentrating—are associated with the dying process itself. The assessment of depression in seriously ill patients should therefore focus on the dysphoric mood, helplessness, hopelessness, and lack of interest and enjoyment and concentration in normal activities. The single questions "how often do you feel downhearted and blue?" (more than a good bit of the time or similar responses) or "do you feel depressed most of the time?" are appropriate for screening.

Certain conditions may be confused with depression. Endocrinopathies, such as hypothyroidism or Cushing's syndrome, electrolyte ab-

normalities such as hypercalcemia, and akathisia, especially from dopamine-blocking antiemetics such as metoclopramide and prochlorperazine, can mimic depression and should be excluded.

INTERVENTIONS Physicians must treat any physical symptom, such as pain, that may be causing or exacerbating depression. Fostering adaptation to the many losses that the patient is experiencing can also be helpful. Nonpharmacologic interventions, including group or individual psychological counseling, and behavioral therapies, such as relaxation or imagery, can be helpful, especially in combination with drug therapy.

Pharmacologic interventions remain the core of therapy. The same medications are used to treat depression in terminally ill as in non-terminally ill patients. Psychostimulants may be preferred for patients with a poor prognosis or for those with fatigue or opioid-induced somnolence. Psychostimulants are comparatively fast acting, working within a few days, instead of the weeks required for selective serotonin reuptake inhibitors (SSRIs). Dextroamphetamine or methylphenidate should be started at 2.5–5.0 mg in the morning and at noon, the same starting dosages used for treating fatigue. The dose can be escalated up to 15 mg bid. Modafinil is started at 100 mg qd and can be increased to 200 mg if there is no effect at the lower dose. Pemoline is a nonamphetamine psychostimulant with minimal abuse potential. It is also effective as an antidepressant beginning at 18.75 mg in the morning and at noon. Because it can be absorbed through the buccal mucosa, it is preferred for patients with intestinal obstruction or dysphagia. If used for prolonged periods, liver function must be monitored. The psychostimulants can also be combined with more traditional antidepressants, while waiting for the latter to become effective, and then tapered after a few weeks if necessary. Psychostimulants have side effects, particularly initial anxiety, insomnia, and rarely paranoia, which may necessitate lowering the dose or discontinuing treatment.

Mirtazapine, an antagonist at the postsynaptic serotonin receptors, is a promising psychostimulant. It should be started at 7.5 mg before bed. It has sedating, antiemetic and anxiolytic properties with few drug interactions. Its side effect of weight gain may also be beneficial for seriously ill patients; it is available in orally disintegrating tablets.

For patients with a prognosis of several months or longer, SSRIs, including fluoxetine, sertraline, paroxetine and citalopram, and serotonin-noradrenaline reuptake inhibitors, such as venlafaxine, are the preferred treatment because of their efficacy and comparatively few side effects. Because low doses of these medications may be effective for seriously ill patients, use half the usual starting dose for healthy adults. The starting dose for fluoxetine is 10 mg once a day. In most cases, once-a-day dosing is possible. The choice of which SSRI to use should be driven by (1) the patient's past success or failure with the specific medication, and (2) the most favorable side effect profile for that specific agent. For instance, for a patient in whom fatigue is a major symptom, a more activating SSRI (fluoxetine) would be appropriate. For a patient in whom anxiety and sleeplessness are major symptoms, a more sedating SSRI (paroxetine) would be appropriate.

Atypical antidepressants are recommended only in selected circumstances, usually with the assistance of a specialty consultation. Trazodone can be an effective antidepressant but is sedating and can cause orthostatic hypotension and, rarely, priapism. Therefore, it should be used only when a sedating effect is desired and is often used for patients with insomnia, at a dose starting at 25 mg. In addition to its antidepressant effects, bupropion is energizing, making it useful for depressed patients suffering from fatigue. However, it can cause seizures, preventing its use for patients with a risk of CNS neoplasms or terminal delirium. Finally, alprazolam, a benzodiazepine, starting at 0.25–1.0 mg tid, can be effective in seriously ill patients suffering from a combination of anxiety and depression. While it is potent and works quickly, it has many drug interactions and may cause delirium, especially among very ill patients, because of its strong binding to the benzodiazepine–GABA receptor complex.

Unless used as adjuvants for the treatment of pain, tricyclic antidepressants are not recommended. Similarly, the monoamine oxidase (MAO) inhibitors are not recommended because of their side effects and dangerous drug interactions.

Delirium

FREQUENCY In the weeks or months before death, delirium is uncommon, although it may be significantly underdiagnosed. However, delirium becomes relatively common in the hours and days immediately before death. Up to 85% of patients dying from cancer may experience terminal delirium.

ETIOLOGY Delirium is a global cerebral dysfunction characterized by alterations in cognition and consciousness. It is frequently preceded by anxiety, changes in sleep patterns (especially reversal of day and night), and decreased attention. In contrast to dementia, delirium has an acute onset, fluctuating consciousness and inattention, and is reversible, although reversibility may be more theoretical than real for patients near death. Delirium may occur in a patient with dementia; indeed, patients with dementia are more vulnerable to delirium.

Causes of delirium include metabolic encephalopathy arising from liver or renal failure, hypoxemia, or infection; electrolyte imbalances such as hypercalcemia; paraneoplastic syndromes; dehydration; and primary brain tumors, brain metastases, or leptomeningeal spread of tumor. Commonly, among dying patients, delirium can be caused by side effects of treatments, including radiation for brain metastases, and medications, including opioids, glucocorticoids, anticholinergic drugs, antihistamines, antiemetics, benzodiazepines, and chemotherapeutic agents. The etiology may be multifactorial; e.g., dehydration may exacerbate opioid-induced delirium.

ASSESSMENT Delirium should be recognized in any terminally ill patient with new onset of disorientation, impaired cognition, somnolence, fluctuating levels of consciousness, or delusions with or without agitation. Delirium must be distinguished from acute anxiety and depression, as well as dementia. The central distinguishing feature is altered consciousness, which is not usually noted in anxiety, depression, and dementia. Although "hyperactive" delirium characterized by overt confusion and agitation is likely more common, patients should also be assessed for "hypoactive" delirium characterized by sleep-wake reversal and decreased alertness.

In some cases, use of formal assessment tools such as the Mini-Mental Status Examination (which does not distinguish delirium from dementia) or the Delirium Rating Scale (which does distinguish delirium from dementia) may be helpful in distinguishing delirium from other processes. The patient's list of medications must be carefully evaluated. Nonetheless, a reversible etiologic factor for delirium is found in fewer than half of terminally ill patients. Because most terminally ill patients experiencing delirium will be very close to death and may be at home, extensive diagnostic evaluations, such as lumbar punctures or neuroradiologic examinations, are usually inappropriate.

INTERVENTIONS One of the most important objectives of terminal care is to provide terminally ill patients the lucidity to say goodbye to the people they love. Delirium, especially with agitation during the final days, is distressing to family and caregivers. A strong determinant of bereavement difficulties is witnessing a difficult death. Thus, terminal delirium should be treated aggressively.

At the first sign of delirium, such as day-night reversal with slight changes in mentation, let the family know that it is time to be sure that everything they want to have said has been said. The family should be informed that delirium is common just before death.

If medications are suspected of being a cause of the delirium, then unnecessary agents should be discontinued. Other potentially reversible causes such as constipation, urinary retention, and metabolic abnormalities should be treated. Supportive measures aimed at providing a familiar environment should be instituted, including restricting visits only to individuals with whom the patient is familiar and eliminating new experiences; orienting the patient, if possible, by providing a clock and calendar; and gently correcting the patient's hallucinations or cognitive mistakes.

Pharmacologic management focuses on the use of neuroleptics and, in the extreme, anesthetics (Table 11-7). Haloperidol remains first-line therapy. Usually, patients can be controlled with a low dose (1–3 mg/d),

TABLE 11-7 MEDICATIONS FOR THE MANAGEMENT OF DELIRIUM

Interventions	Dose
Neuroleptics	
Haloperidol	0.5–5 mg q2–12h, PO/IV/SC/IM
Thioridazine	10–75 mg q4–8h, PO
Chlorpromazine	12.5–50 mg q4–12h, PO/IV/IM
Atypical neuroleptics	
Olanzapine	2.5–5 mg qd or bid, PO
Risperidone	1–3 mg q12h, PO
Anxiolytics	
Lorazepam	0.5–2 mg q1–4h, PO/IV/IM
Midazolam	1–5 mg/h continuous infusion, IV/SC
Anesthetics	
Propofol	0.3–2.0 mg/h continuous infusion, IV

usually given every 6 h, although some may require as much as 20 mg/d. It can be administered PO, SC, or IV. IM injections should not be used, except when it is the only way to get a patient under control. Olanzapine, an atypical neuroleptic, has shown significant effectiveness in completely resolving delirium in cancer patients. It has other beneficial effects for terminally ill patients, including antinausea, antianxiety, and weight gain. It is useful for patients with longer anticipated life expectancy because it is less likely to cause dysphoria and has a lower risk of dystonic reactions. Also, because it is metabolized through multiple pathways, it can be used in patients with hepatic and renal dysfunction. Olanzapine has the disadvantage that it is only available orally and that it takes a week to reach steady state. The usual dose is 2.5–5 mg PO bid. Chlorpromazine (10–25 mg every 4–6 h) can be useful if sedation is desired and can be administered IV or PR in addition to PO. Dystonic reactions resulting from dopamine blockade are a side effect of neuroleptics, although they are reported to be rare when used to treat terminal delirium. If patients develop dystonic reactions, benztropine should be administered. Neuroleptics may be combined with lorazepam to reduce agitation when the delirium is the result of alcohol or sedative withdrawal.

If no response to first-line therapy is seen, a specialty consultation should be obtained with a change to a different medication. If patients fail to improve after a second neuroleptic, then sedation with an anesthetic such as propofol or continuous-infusion midazolam may be necessary. By some estimates, at the very end of life as many as 25% of patients experiencing delirium, especially restless delirium with myoclonus or convulsions, may require sedation.

Physical restraints should be used with great reluctance only when the patient's violence is threatening to self or others. If used, their appropriateness should be reevaluated frequently.

Insomnia • ***FREQUENCY*** Sleep disorders, defined as either difficulty initiating sleep or maintaining sleep, sleep difficulty at least 3 nights a week or sleep difficulty that causes impairment of daytime functioning, occurs in between 19 and 63% of patients with advanced cancer.

ETIOLOGY Patients with cancer may have changes in sleep efficiency such as an increase in stage I sleep. Other etiologies of insomnia are coexisting physical illness, such as thyroid disease, or coexisting psychological illnesses, such as depression and anxiety. Medications, including antidepressants, psychostimulants, steroids, and β agonists, are significant contributors to sleep disorders, as are caffeine and alcohol. Multiple over-the-counter medications contain caffeine and antihistamines, which can contribute to sleep disorders.

ASSESSMENT Assessment should include specific questions concerning sleep onset, sleep maintenance, and early morning wakening as these will provide clues to the causative agents and to management. Patients should be asked about previous sleep problems, screened for depression and anxiety, and asked about symptoms of thyroid disease. Caffeine and alcohol are prominent causes of sleep problems, and a careful history of these substances should be obtained. Both excessive use and withdrawal from alcohol can be causes of sleep problems.

INTERVENTIONS The mainstays of intervention include improvement of sleep hygiene (encouraging regular time for sleep, decreased nighttime distractions, elimination of caffeine and other stimulants and alcohol), intervention to treat anxiety and depression, and finally treatment for the insomnia itself. For patients with depression who have insomnia and anxiety, a sedating antidepressant such as mirtazapine can be helpful. In the elderly, trazodone, beginning at 25 mg at nighttime, is an effective sleep aid at doses lower than its antidepressant effect. Zolpidem may have a decreased incidence of delirium in patients compared with traditional benzodiazepines, but this has not been clearly established. When benzodiazepines are prescribed, short-acting ones (such as lorazepam) are favored over longer-acting (such as diazepam). Patients who receive these medications should be observed for signs of increased confusion and delirium.

SOCIAL NEEDS AND THEIR MANAGEMENT

Financial Burdens • ***FREQUENCY*** Dying can impose substantial economic strains on patients and families, causing distress. In the United States, with one of the least comprehensive health insurance systems among the developed countries, ~20% of terminally ill patients and their families spend >10% of family income on health care costs over and above health insurance premiums. Between 10 and 30% of families sell assets, use savings, or take out a mortgage to pay for the patient's health care costs. Nearly 40% of terminally ill patients in the United States report that the cost of their illness is a moderate or great economic hardship for their family.

The patient is likely to reduce and stop working. In 20% of cases, a family member of the terminally ill patient also stops working to provide care. The major underlying causes of economic burden are related to poor physical functioning and care needs, such as the need for housekeeping, nursing, and personal care. More debilitated patients and poor patients experience greater economic burdens.

INTERVENTION This economic burden should not be ignored as a private matter. It has been associated with a number of adverse health outcomes, including preferring comfort care over life-prolonging care as well as consideration of euthanasia or physician-assisted suicide. Economic burdens increase the psychological distress of families and caregivers of terminally ill patients, and poverty is associated with many adverse health outcomes. Assistance from a social worker, early on if possible, to ensure access to all available benefits may be helpful. Many patients, families, and health care providers are unaware of options for long-term care insurance, respite care, the Family Medical Leave Act (FMLA), and other sources of assistance. Some of these options (such as respite care) may be part of a formal hospice program but others (such as the FMLA) do not require enrollment in a hospice program.

Relationships • ***FREQUENCY*** Settling personal issues and closing the narrative of lived relationships are universal needs. When asked if sudden death or death after an illness is preferable, respondents often initially select the former but soon change to the latter as they reflect on the importance of saying goodbye. Bereaved family members who have not had the chance to say goodbye often have a more difficult grief process.

INTERVENTIONS Care of seriously ill patients requires efforts to facilitate the types of encounters and time spent with family and friends that are necessary to meet these needs. Family and close friends may need to be accommodated with unrestricted visiting hours, which may include sleeping near the patient even in otherwise regimented institutional settings. Physicians and other health care providers may be able to facilitate and resolve strained interactions between the patient and other family members. Assistance for patients and family members who are unsure about how to create or help preserve memories, whether by providing materials such as a scrap book or memory box or by offering them suggestions and informational resources, can be deeply appreciated. Taking photographs and creating videos can be especially helpful to terminally ill patients who have younger children or grandchildren.

Family Caregivers • ***FREQUENCY*** Caring for seriously ill patients places a heavy burden on families. Families are frequently required to provide transportation and homemaking as well as other services. Typically, paid professionals such as home health nurses and hospice workers supplement family care; only about a quarter of all care giving is exclusively paid professional assistance. The trend toward more out-of-hospital deaths will increase reliance on families for end-of-life care. Increasingly, family members are being called upon to provide physical care (such as moving and bathing patients) and medical care (such as assessing symptoms and giving medications) in addition to emotional care and support.

Three-quarters of family caregivers of terminally ill patients are women—wives, daughters, and even sisters. Since many are widowed, women themselves tend to be able to rely less on family for caregiving assistance and may need more paid assistance. About 20% of terminally ill patients report substantial unmet needs for nursing and personal care. The impact of caregiving on family caregivers is substantial: both bereaved and current caregivers have a higher mortality compared to non-caregiving controls.

INTERVENTIONS It is imperative to inquire about unmet needs and to try to ensure those needs are met either through the family or paid professional services when possible. Community assistance through houses of worship or other community groups can often be mobilized by one or two phone calls from the medical team to someone the patient or family identifies. Sources of support specifically for family caregivers should be identified through local sources or nationally through groups such as the National Family Caregivers Association (*www.nfcacares.org*), the American Cancer Society (*www.cancer.org*), and the Alzheimer's Association (*www.alz.org*).

EXISTENTIAL NEEDS AND THEIR MANAGEMENT

FREQUENCY Religion and spirituality are often important to dying patients. Nearly 70% of patients report becoming more religious or spiritual when they became terminally ill, and many find comfort in various religious or spiritual practices such as prayer. However, ~20% of terminally ill patients become less religious, frequently feeling cheated or betrayed by becoming terminally ill. For other patients, the need is for existential meaning and purpose that is distinct from and may even be antithetical to religion or spirituality. When asked, patients and family caregivers frequently report wanting their professional caregivers to be more attentive to religion and spirituality.

ASSESSMENT Health care providers are often hesitant about involving themselves in the religious, spiritual, and existential experiences of their patients, because it may seem private or not relevant to the current illness. But physicians and other members of the care team should be able to at least detect spiritual and existential needs. Screening questions have been developed for a physician's spiritual history taking. Spiritual distress can amplify other types of suffering and even masquerade as intractable physical pain, anxiety, or depression. The screening questions in the comprehensive assessment are usually sufficient. Deeper evaluation and intervention are rarely appropriate for the physician unless no other member of a care team is available or suitable. Pastoral care providers may be helpful, whether from the medical institution or the patient's own community.

INTERVENTIONS Precisely how religious practices, spirituality, and existential explorations can be facilitated and improve end-of-life care is not well established. What is clear is that for physicians, one main intervention is to inquire about the role and importance of spirituality and religion in a patient's life. This will help a patient feel heard and help physicians to identify specific needs. In one study, only 36% of respondents indicated that a clergy member would be comforting. Nevertheless, the increase in religious and spiritual interest among a substantial fraction of dying patients suggests inquiring of individual patients how this need can be addressed.

MANAGING THE LAST STAGES

WITHDRAWING AND WITHHOLDING LIFE-SUSTAINING TREATMENT

LEGAL ASPECTS For centuries, it has been deemed ethical to withhold or withdraw life-sustaining interventions. The current legal consensus is that patients have a constitutional and common law right to refuse medical interventions. Courts have also held that incompetent patients have a right to refuse medical interventions. For patients who are incompetent and terminally ill and who have not completed an advance care directive, next of kin can exercise this right, although this may be restricted in some states depending how clear and convincing the evidence is of the patient's preferences. Courts have limited families' ability to terminate life-sustaining treatments from patients who are conscious, incompetent, but not terminally ill. In theory, patients' right to refuse medical therapy can be limited by four countervailing interests: (1) preservation of life, (2) prevention of suicide, (3) protection of third parties such as children, and (4) preserving the integrity of the medical profession. In practice, these interests almost never override the right of competent patients and incompetent patients who have left explicit and advance care directives.

Regarding incompetent patients who either appointed a proxy without specific indications of their wishes or who never completed an advance care directive, three criteria have been suggested to guide the decision to terminate medical interventions. First, some commentators suggest that ordinary care should be administered but extraordinary care could be terminated. Because the ordinary/extraordinary distinction is too vague, courts and commentators widely agree that it should not be used to justify decisions about stopping treatment. Second, many courts have advocated use of the substituted-judgment criterion, which holds that the proxy decision-makers should try to imagine what the incompetent patient would do if he or she were competent. However, multiple studies indicate that many proxies, even close family members, cannot accurately predict what the patient would have wanted. Therefore, substituted judgment becomes more of a guessing game than a way of fulfilling the patient's wishes. Finally, the best-interests criterion holds that proxies should evaluate treatments by balancing their benefits and risks and select those treatments in which the benefits maximally outweigh the burdens of treatment. Clinicians have a clear and crucial role in this by carefully and dispassionately explaining the known benefits and burdens of specific treatments. Yet, even when information is as clear as possible, different individuals can have very different views of what is in the patient's best interests, and families may have disagreements or even overt conflicts. This criterion has been criticized because no single way exists of determining the balance between benefits and burdens; it depends on a patient's personal values. As a matter of practice, physicians rely on family members to make decisions that they feel are best and object only if these decisions seem to demand treatments that the physicians consider not beneficial.

PRACTICES Withholding and withdrawing acutely life-sustaining medical interventions from terminally ill patients are now standard practice. More than 90% of American patients die without cardiopulmonary resuscitation (CPR), and just as many forgo other potentially life-sustaining interventions. For instance, during 1987–1988 in ICUs, CPR was performed 49% of the time, but only 10% of the time in 1992–1993. On average, 3.8 interventions, such as vasopressors and transfusions, were stopped for each dying ICU patient. However, practices vary widely among hospitals and ICUs, suggesting an important element of physician preferences rather than objective data.

Mechanical ventilation may be the most challenging intervention to withdraw. The two approaches are *terminal extubation*, which is the removal of the endotracheal tube, and *terminal weaning*, which is the gradual reduction of the FI_{O_2} or ventilator rate. One-third of ICU physicians prefer to use the terminal wean technique, while 13% extubate; the majority of physicians utilize both techniques. Some recommend terminal weaning because patients do not develop upper airway obstruction and the distress caused by secretions or stridor; however, terminal weaning can also prolong the dying process and not allow a patient's family to

be with him or her unencumbered by an endotracheal tube. To ensure comfort for conscious or semiconscious patients before withdrawal of the ventilator, neuromuscular blocking agents should be terminated and sedatives and analgesics administered. Removing the neuromuscular blocking agents permits patients to show discomfort, facilitating the titration of sedatives and analgesics; it also permits interactions between patients and their families. A common practice is to inject a bolus of midazolam (2–4 mg) or lorazepam (2–4 mg) before withdrawal, followed by 5–10 mg of morphine and continuous infusion of morphine (50% of the bolus dose per hour) during weaning. In patients who have significant upper airway secretions, IV scopolamine at a rate of 100 μg/h can be administered. Additional boluses of morphine or increases in the infusion rate should be administered for respiratory distress or signs of pain. Higher doses will be needed for patients already receiving sedatives and opioids. Families need to be reassured about treatments for common symptoms after withdrawal of ventilatory support such as dyspnea or agitation and warned about the uncertainty of length of survival after withdrawal of ventilatory support: up to 10% of patients unexpectedly survive for 1 day or more after mechanical ventilation is stopped.

FUTILE CARE

Beginning in the late 1980s, some commentators argued that physicians could terminate futile treatments demanded by families of terminally ill patients. Although no objective definition or standard of futility exists, several categories have been proposed. Physiologic futility means that an intervention will have no physiologic effect. Some have defined qualitative futility as those that "fail to end a patient's total dependence on intensive medical care." Quantitative futility occurs "when physicians conclude (either through personal experience, experiences shared with colleagues, or consideration of reported empiric data) that in the last 100 cases, a medical treatment has been useless." The term conceals subjective value judgments about when a treatment is "not beneficial." Deciding whether a treatment that obtains an additional 6 weeks of life or a 1% survival advantage confers benefit depends upon patients' preferences and goals. Furthermore, physicians' predictions of when treatments were futile deviated markedly from the quantitative definition. When residents thought CPR was quantitatively futile, more than one in five patients had a >10% chance of survival to hospital discharge. Quantitative futility rarely applies in ICU settings. Many commentators reject using futility as a criterion of withdrawing care, preferring instead to consider futility situations as ones that represent conflict that can benefit from careful negotiation between families and health care providers.

Some hospitals have enacted "unilateral DNR" policies to allow clinicians to provide a do-not-resuscitate order in cases where consensus cannot be reached with families and medical opinion is that resuscitation would be futile if attempted. This type of a policy is not a replacement for careful and patient communication and negotiation, but recognizes that agreement cannot always be reached. Texas, Virginia, Maryland, and California and have enacted so-called medical futility laws that provide physicians a "safe harbor" from liability if they terminate life-sustaining treatments over the wishes of the patient's family. For instance, in Texas when a disagreement about terminating interventions between the medical team and family has not been resolved by an ethics consultation, then the hospital is supposed to try to facilitate transfer of the patient to another institution willing to provide treatment. If this fails after 10 days, then the hospital and physician may unilaterally withdraw treatments determined to be futile. The family may appeal to a state court. Early data suggest the law increases futility consultations for the ethics committee and that while most families concur with withdrawal, about 10–15% of families refuse to withdraw treatment. Approximately 12 cases have gone to court in Texas in 7 years after adoption of the law.

EUTHANASIA AND PHYSICIAN-ASSISTED SUICIDE

Euthanasia and physician-assisted suicide are defined in Table 11-8. Terminating life-sustaining care and providing opioid medications to manage symptoms have long been considered ethical by the medical profession and legal by courts and should not be confused with euthanasia or physician-assisted suicide.

LEGAL ASPECTS Euthanasia is legal in the Netherlands and Belgium. Euthanasia was legalized in the Northern Territory of Australia but then repealed. Euthanasia is not legal in any state in the United States. Physician-assisted suicide is legal in Oregon but only if multiple criteria are met and then only after a process that includes a 15-day waiting period. In Switzerland, a layperson can legally assist suicide. In all other countries and all other states in the United States, physician-assisted suicide and euthanasia are illegal explicitly or by common law.

PRACTICES Fewer than 10–20% of terminally ill patients actually consider euthanasia and/or physician-assisted suicide for themselves. In the Netherlands and Oregon, >70% of patients utilizing these interventions are dying of cancer; <5% of deaths by euthanasia or physician-assisted suicide involve patients with AIDS or amyotrophic lateral sclerosis. In the Netherlands, if all legal and illegal acts are grouped, euthanasia and physician-assisted suicide account for 3.5% of all deaths. In Oregon, ~0.1% of patients die by physician-assisted suicide, although this may be an underestimate.

Pain is not a primary motivator for patients' requests for or interest in euthanasia and/or physician-assisted suicide. Among the first patients to receive physician-assisted suicide in Oregon, only 1 patient of 15 had inadequate pain control compared to 15 of 43 patients in a control group experiencing inadequate pain relief. Depression, hopelessness, and, more profoundly, concerns about loss of dignity or autonomy or being a burden on family members, appear to be primary factors motivating a desire for euthanasia or physician-assisted suicide. A study from the Netherlands showed that depressed terminally ill cancer patients were four times more likely to request euthanasia, and confirmed that uncontrolled pain was not associated with greater interest in euthanasia.

Euthanasia and physician-assisted suicide are no guarantee of a painless, quick death. Data from the Netherlands indicate that in as many as 20% of cases technical and other problems arose, including patients waking from coma, not becoming comatose, regurgitating medications, and a prolonged time to death. Problems were significantly more common in physician-assisted suicide, sometimes requiring the physician to intervene and provide euthanasia.

Whether practicing in a setting where euthanasia is legal or not, over a career, between 12 and 54% of physicians will receive a request for euthanasia or physician-assisted suicide from a patient. Competency in dealing with such a request is crucial. While challenging, such a request can also be a chance to address intense suffering. After receiving a request for euthanasia and/or physician-assisted suicide, health care providers should carefully clarify the request with empathic, open-ended questions to help elucidate the underlying cause for the request such as: "What makes you

TABLE 11-8 DEFINITIONS OF ASSISTED SUICIDE AND EUTHANASIA

Term	Definition	Legal Status
Voluntary active euthanasia	Intentionally administering medications or other interventions to cause the patient's death with the patient's informed consent	Netherlands Belgium
Involuntary active euthanasia	Intentionally administering medications or other interventions to cause the patient's death when the patient was competent to consent but did not—e.g., the patient may not have been asked	Nowhere
Passive euthanasia	Withholding or withdrawing life-sustaining medical treatments from a patient to let him or her die (terminating life-sustaining treatments)	Everywhere
Physician-assisted suicide	A physician provides medications or other interventions to a patient with the understanding that the patient can use them to commit suicide	Oregon Netherlands Belgium Switzerland

want to consider this option?" Endorsing either moral opposition or moral support for the act tends to be counterproductive, either lending an impression of being judgmental or of endorsing the idea that the patient's life is worthless. Health care providers must reassure the patient of continued care and commitment. The patient should be educated about alternative, less controversial options, such as symptom management and withdrawing any unwanted treatments; the reality of euthanasia and/or physician-assisted suicide, since the patient may have misconceptions about their effectiveness; and also the legal implications of the choice. Depression, hopelessness, and other symptoms of psychological distress as well as physical suffering and economic burdens are likely factors motivating the request, and such factors should be assessed and treated aggressively. After these interventions and clarification of options, most patients proceed with another approach, declining life-sustaining interventions, possibly including refusal of nutrition and hydration.

CARE DURING THE LAST HOURS

Most laypersons have limited experiences with the actual dying process and death. They frequently do not know what to expect of the final hours, and afterwards. The family and other caregivers must be prepared, especially if the plan is for the patient to die at home.

Patients in the last days of life typically experience extreme weakness and fatigue and become bedbound; this can lead to pressure sores. The issue of turning patients who are near the end of life, however, must be balanced against the potential discomfort that movement may cause. Patients stop eating and drinking with drying of mucosal membranes and dysphagia. Careful attention to oral swabbing, lubricants for lips, and use of artificial tears can provide a form of care to substitute for attempts at feeding the patient. With loss of the gag reflex and dysphagia, patients may also experience accumulation of oral secretions, producing noises during respiration sometimes called "the death rattle." Scopolamine can reduce the secretions. Patients also experience changes in respiration with periods of apnea or Cheyne-Stokes breathing. Decreased intravascular volume and cardiac output cause tachycardia, hypotension, peripheral coolness, and livedo reticularis (skin mottling). Patients can have urinary and, less frequently, fecal incontinence. Changes in consciousness and neurologic function generally lead to two different paths to death (Fig. 11-2).

Each of these terminal changes can cause patients and families distress, requiring reassurance and targeted interventions (Table 11-9). Informing families that these changes might occur, and even providing them an information sheet, can help to preempt problems and minimize distress. Understanding that patients stop eating because they are dying, not dying because they have stopped eating, can reduce family and caregiver anxiety. Similarly, informing the family and caregivers that the "death rattle" may occur and that it is not indicative of suffocation or choking can reduce their worry from the breathing sounds.

Families and caregivers may also feel guilty about stopping treatments, fearing that they are "killing" the patient. This may lead to demands for interventions that may be ineffective. In such cases, the physician should remind the family and caregivers about the inevitability of events and the palliative goals. Interventions may prolong the dying process and cause discomfort. Physicians should also emphasize that withholding treatments is both legal and ethical, and that the family members are not the cause of the patient's death. This reassurance may need to be provided multiple times.

Hearing and touch are said to be the last senses to stop functioning. Whether this is the case or not, families and caregivers can be encouraged to communicate with the dying patient. Encouraging them to talk directly to the patient, even if he or she is unconscious, and hold the patient's hand or demonstrate affection in other ways can be an effective way to channel their urge "to do something" for the patient.

When the plan is for the patient to die at home, the physician must inform the family and caregivers how to determine that the patient has died. The cardinal signs are cessation of cardiac function and respiration; the pupils become fixed; the body becomes cool; muscles relax; and incontinence may occur. Remind the family and caregivers that the eyes may remain open even when the patient has died because the retroorbital fat pad may be depleted, permitting the orbit to fall posteriorly, which makes it difficult for the eyelids to cover the eyeball.

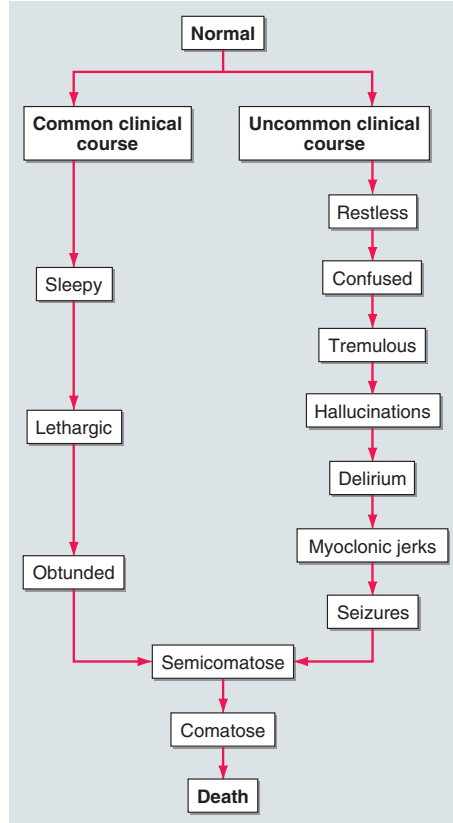

FIGURE 11-2 Common and uncommon clinical courses in the last days of terminally ill patients. (*Adapted from FD Ferris et al: Module 4: Palliative care, in Comprehensive Guide for the Care of Persons with HIV Disease. Toronto: Mt. Sinai Hospital and Casey Hospice, 1995, at www.cpsonline.info/content/resources/hivmodule4.html.*)

The physician should establish a plan for who the family or caregivers will contact when the patient is dying or has died. Without a plan, they may panic and call 911, unleashing a cascade of unwanted events from arrival of emergency personnel and resuscitation to hospital admission. The family and caregivers should be instructed to contact the hospice (if one is involved), the covering physician, or the on-call member of the palliative care team. They should also be told that the medical examiner need not be called, unless the state requires it for all deaths. Unless foul play is suspected, the health care team need not contact the medical examiner either.

Just after the patient dies, even the best-prepared family may experience shock and loss and be emotionally distraught. They need time to assimilate the event and be comforted. Health care providers may find it meaningful to write a bereavement card or letter to the family. The purpose is to communicate about the patient, perhaps emphasizing the patient's virtues, the honor it was to care for the patient, and express concern for the family's hardship. Some physicians attend the funerals of their patients. While this is beyond any medical obligation, the presence of the physician can be a source of support to the grieving family and provides an opportunity for closure for the physician.

Death of a spouse is a strong predictor of poor health, and even mortality, for the surviving spouse. It may be important to alert the spouse's physician about the death to be aware of symptoms that might require professional attention.

PALLIATIVE CARE SERVICES: HOW AND WHERE

Determining the best approach to providing palliative care to patients will depend upon patient preferences, the availability of caregivers and specialized services in close proximity, institutional resources, and re-

TABLE 11-9 MANAGING CHANGES IN THE PATIENT'S CONDITION DURING THE FINAL DAYS AND HOURS

Changes in the Patient's Condition	Potential Complication	Family's Possible Reaction and Concern	Advice and Intervention
Profound fatigue	Bedbound with development of pressure ulcers that are prone to infection, malodor, and pain, and joint pain	Patient is lazy and giving up.	Reassure family and caregivers that terminal fatigue will not respond to interventions and should not be resisted. Use an air mattress if necessary.
Anorexia	None	Patient is giving up; patient will suffer from hunger and will starve to death.	Reassure family and caregivers that the patient is not eating because he or she is dying; not eating at the end of life does not cause suffering or death. Forced feeding, whether oral, parenteral, or enteral, does not reduce symptoms or prolong life.
Dehydration	Dry mucosal membranes (see below)	Patient will suffer from thirst and die of dehydration.	Reassure family and caregivers that dehydration at the end of life does not cause suffering because patients lose consciousness before any symptom distress. Intravenous hydration can worsen symptoms of dyspnea by pulmonary edema and peripheral edema as well as prolong dying process.
Dysphagia	Inability to swallow oral medications needed for palliative care		Do not force oral intake. Discontinue unnecessary medications that may have been continued including antibiotics, diuretics, anti-depressants, and laxatives. If swallowing pills is difficult, convert essential medications (analgesics, antiemetics, anxiolytics, and psychotropics) to oral solutions, buccal, sublingual, or rectal administration.
"Death rattle"—noisy breathing		Patient is choking and suffocating.	Reassure the family and caregivers that this is caused by secretions in the oropharynx and the patient is not choking. Reduce secretions with scopolamine (0.2–0.4 mg SC q4h or 1–3 patches q3d) Reposition patient to permit drainage of secretions. Do not suction. Suction can cause patient and family discomfort, and is usually ineffective.
Apnea, Cheyne-Stokes respirations, dyspnea		Patient is suffocating.	Reassure family and caregivers that unconscious patients do not experience suffocation or air hunger. Apneic episodes are frequently a premorbid change. Opioids or anxiolytics may be used for dyspnea. Oxygen is unlikely to relieve dyspneic symptoms and may prolong the dying process.
Urinary or fecal incontinence	Skin breakdown if days until death Potential transmission of infectious agents to caregivers	Patient is dirty, malodorous, and physically repellent.	Remind family and caregivers to use universal precautions. Frequent changes of bedclothes and bedding. Use diapers, urinary catheter, or rectal tube if diarrhea or high urine output.
Agitation or delirium	Day/night reversal Hurt self or caregivers	Patient is in horrible pain and going to have a horrible death.	Reassure family and caregivers that agitation and delirium do not necessarily connote physical pain. Depending upon the prognosis and goals of treatment, consider evaluating for causes of delirium and modify medications. Manage symptoms with haloperidol, chlorpromazine, diazepam, or midazolam.
Dry mucosal membranes	Cracked lips, mouth sores, and candidiasis can also cause pain. Odor	Patient may be malodorous, physically repellent.	Use baking soda mouthwash or saliva preparation q15–30min. Use topical nystatin for candidiasis. Coat lips and nasal mucosa with petroleum jelly q60–90min. Use ophthalmic lubricants q4h or artificial tears q30min.

imbursement. Hospice is a leading, but not the only, model of palliative care services. In the United States, the vast majority of hospice care is provided in residential homes. By 2002, just over 20% of hospice was provided in nursing homes. In the United States, Medicare pays for hospice services under Part A, the hospital insurance part of reimbursement. Two physicians must certify that the patient has a prognosis of ≤6 months, if the disease runs its usual course. Prognoses are probabilistic by their nature; patients are not required to die within 6 months but rather to have a condition from which half the individuals with it would not be alive within 6 months. Patients sign a hospice enrollment form that states their intent to forgo curative services related to their terminal illness, but they can still receive medical services for other comorbid conditions. Patients can also withdraw enrollment and re-enroll later; the hospice Medicare benefit can be revoked later to secure traditional Medicare benefits. Payments to the hospice are per diem (or capitated), not fee-for-service. Payments are intended to cover physician services for the medical direction of the care team; regular home care visits by registered nurses and licensed practical nurses; home health aid and homemaker services; chaplain services; social work services; bereavement counseling; and medical equipment, supplies, and medications. No specific therapy is excluded and the goal is for each therapy to be considered for its symptomatic (as opposed to disease-modifying) effect. Additional clinical care, including services of the primary physician, is covered by Medicare Part B, even while the hospice Medicare benefit is in place.

By 2005, the mean length of enrollment in a hospice was 59 days, with the median being 26 days. Such short stays create barriers to establishing high-quality palliative services in patients' homes and also place financial strains on hospice providers since the initial assessments are resource intensive. Physicians should initiate early referrals to the hospice to allow more time for patients to receive palliative care.

Hospice care has been the main way of securing palliative services for terminally ill patients. However, efforts are now being made to ensure continuity of palliative care across settings and through time. Palliative care services are becoming available as consultative services and more rarely as palliative care units in hospitals, in day care and other outpatient settings, and in nursing homes. Palliative care consultations for non-hospice patients can be billed as for other consultations under Medicare

Part B, the physician reimbursement part. Many believe palliative care should be offered to patients regardless of their prognosis. A patient, his or her family, and physicians should not have to make a "curative vs. palliative care" decision because it is rarely possible to make such a decisive switch to embracing mortality.

FUTURE DIRECTIONS

OUTCOME MEASURES

Care near the end of life cannot be measured by most of the available validated outcome measures since palliative care does not consider death a bad outcome. Similarly, the family and patients receiving end-of-life care may not desire the elements elicited in current quality-of-life measurements. Symptom control, enhanced family relationships, and quality of bereavement are difficult to measure and are rarely the primary focus of carefully developed or widely used outcome measures. Nevertheless, outcomes are as important in end-of-life care as in any other field of medical care. Specific end-of-life care instruments are being developed both for assessment, such as The Brief Hospice Inventory and NEST (*n*eeds near the *e*nd of life *s*creening *t*ool), and for outcome measures, such as the Palliative Care Outcomes Scale, and for prognosis, such as the Palliative Prognostic Index. The field of end-of-life care is entering an era of evidence-based practice and continuous improvement through clinical trials.

e1 The Safety and Quality of Health Care

David W. Bates

The safety and quality of care are two of the central dimensions of health care. It is increasingly clear that both could be much better, and in recent years it has become easier to measure both safety and quality. In addition, the public is—with good justification—demanding measurement and accountability, and increasingly payment for services will be based on performance in these areas. Thus, physicians must learn about these two domains, how they can be improved, and the relative strengths and limitations of our current ability to measure them.

Safety and quality are closely related but do not completely overlap. The Institute of Medicine has suggested in a seminal series of reports that safety is the first part of quality, and that health care first must guarantee that it will deliver safe care, although quality is also pivotal. In the end, it is likely that more net clinical benefit may be derived from improving quality than safety, though both are important, and safety is in many ways more tangible to the public. Accordingly, the first section of this chapter will address issues relating to the safety of care, while the second will cover quality of care.

SAFETY IN HEALTH CARE

Safety Theory Safety theory clearly points out that individuals make errors all the time. Think of driving home from the hospital; you intend to stop and pick up a quart of milk on your way home, but you find yourself entering your driveway, without realizing how you got there. We all use low-level, semi-automatic behavior for many of our activities in daily life; this kind of error is called a "slip." Slips occur often during care delivery; e.g., when someone intends to write an order but forgets because they have to complete another action first. "Mistakes," by contrast, are errors of a higher level; they occur in new or non-stereotypic situations in which conscious decisions are being made. An example would be in dosing a medication with which the physician is not familiar. The strategies used to prevent slips and mistakes are often different.

Another theory relating to errors is human factors theory, which describes how activities are carried out and offers a variety of insights into how to make them safer and more reliable.

Systems theory suggests that most accidents occur as the result of a series of small failures, which happen to line up in an individual instance such that an accident can occur (Fig. e1-1). It also suggests that most individuals in an industry such as health care are trying to do the right thing (e.g., deliver safe care), and most accidents can be seen as the result of defects in the systems. Correspondingly, systems should be designed both to make errors less likely and to identify those that do occur, as some inevitably will.

Factors That Increase the Likelihood of Errors A number of factors ubiquitous in health care systems can increase the likelihood of errors, including fatigue, stress, interruptions, complexity, and transitions. The effects of fatigue in other industries are clear, but its effects in health care have until recently been more controversial. For example, the accident rate in truck drivers increases dramatically if they work over a certain number of hours in a week, and especially with prolonged shifts. A recent study of house officers in the intensive care unit demonstrated that they were about one-third more likely to make errors when they were on a 24-h shift than when they were on a schedule that allowed them to sleep 8 h the previous night. The American College of Graduate Medical Education (ACGME) has moved to address this issue by putting in place the 80-h work week. While this is a step forward, it does not address the most important cause of fatigue-related errors, i.e., extended-duty shifts. High levels of stress and workload can also increase error rates. Thus, in extremely high-pressure situations, such as cardiac arrests, errors are more likely to occur. Strategies

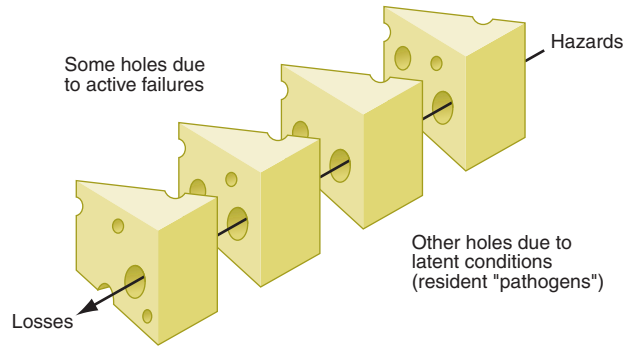

FIGURE e1-1 "Swiss cheese" diagram. Reason has argued that most accidents occur when a series of "latent failures" in a system are present, and that they happen to line up in a given instance, resulting in an accident. Examples of latent failures in the case of a fall might be that the unit was unusually busy that day, and that the floor happened to be wet. *(Adapted from J Reason: Human error: Models and management. BMJ 320:768–770, 2000; with permission.)*

such as using protocols in these settings can be helpful, as can simply recognizing that the situation is stressful.

Interruptions also increase the likelihood of error and are frequent in health care delivery. It is common to forget to complete an action when one is interrupted partway through it by a page, for example. Approaches that may be helpful in this area include minimizing the use of interruptions and setting up tools that help define the urgency of the interruption.

In addition, complexity represents a key issue that contributes to errors. Providers are confronted by streams of data, such as laboratory tests and vital signs, many of which provide little useful information, but some of which are important and require action or suggest a specific diagnosis. Tools that emphasize specific abnormalities or combinations of abnormalities may be helpful in this area.

Transitions between providers and settings are also frequent in health care, even more so with the advent of the 80-h work week, and generally represent vulnerabilities. Tools that provide structure in exchanging information, e.g., when transferring care between providers, may be helpful.

The Frequency of Adverse Events in Health Care Most of the large studies focusing on the frequency and consequences of adverse events have been performed in the inpatient setting; some data are available for nursing homes, and much less information is available in the outpatient setting. The Harvard Medical Practice Study was one of the largest studies to address this issue, and was performed with hospitalized patients in New York. The primary outcome was the adverse event, which is an injury caused by medical management, rather than the patient's underlying disease. In this study, an event either resulted in death or disability at discharge, or prolonged the length of stay by at least 2 days. Key findings were that the adverse event rate was 3.7%, and 58% of adverse events were considered preventable. Although there was some concern that New York is not representative of the rest of the country, the study was replicated later in Colorado and Utah, where the rates were essentially similar. Since then, other studies have been performed in a variety of developed nations using analogous methodologies, and the rates in most countries appear to be ~10%.

In the Medical Practice Study, adverse drug events (ADEs) were the most frequent type, accounting for 19% of adverse events, followed by wound infections (14%) and technical complications (13%). Almost half of the adverse events were associated with a surgical procedure. Among the nonoperative events, 37% were ADEs, 15% were diagnostic mishaps, 14% were therapeutic mishaps, 13% were procedure-related, and 5% were falls.

ADEs have been studied more than any other category. Studies focusing specifically on ADEs have found that they appear to be much

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

more frequent than was suggested by the Medical Practice Study, although most other studies use more inclusive criteria. Detection approaches in the research setting include chart review and use of a computerized ADE monitor, which is a tool that explores the database and identifies signals that suggest an ADE may have occurred. Studies that use multiple approaches find more ADEs than any individual approach, suggesting that the true underlying rate in the population is higher than would be identified by any individual approach. About 6–10% of patients admitted in U.S. hospitals suffer an ADE.

Injuries caused by drugs are also frequent in the outpatient setting. One study found a rate of 21 ADEs per every 100 patients per year when patients were called to assess whether or not they had had a problem with one of their medications. The severity level was lower than in the inpatient setting, but approximately one-third of the ADEs were preventable.

Another area that appears to be very risky is the period immediately after the patient is discharged from the hospital. One recent study of patients hospitalized on a medical service found an adverse event rate of 19%; about a third of these were preventable, and another third were ameliorable in that they could have been made less severe. ADEs were the single leading category.

Prevention Strategies Most of the work on adverse event prevention strategies has targeted specific types of adverse events in the inpatient setting, with ADEs and nosocomial infections having received the most attention. For ADEs, several strategies have been found to reduce the medication error rate, although it has been harder to demonstrate that they reduce the ADE rate, and studies with adequate power to demonstrate a clinically meaningful reduction have not been published as yet.

Computerized physician order entry (CPOE) linked with clinical decision support has been found to reduce the serious medication error rate—serious medication errors are those that harm someone or have the potential to do so. In one study, CPOE, even with limited decision support, decreased the serious medication error rate by 55%. CPOE can prevent medication errors by suggesting a default dose, ensuring that all orders are complete (e.g., include a dose, route, and frequency), and checking orders for allergies, drug-drug interactions, and drug-laboratory issues. In addition, clinical decision support can suggest the right dose for the patient, tailoring it to the patient's level of renal function and age. In one study, without decision support patients with renal insufficiency received the appropriate dose only one-third of the time, while this fraction increased to approximately two-thirds with decision support, and patients with renal insufficiency were discharged from the hospital one-half day earlier. As of 2006, only about 15% of U.S. hospitals had implemented CPOE, but many more have plans to do so.

Another technology that can improve medication safety is bar-coding linked with an electronic medication administration record. Bar-coding can help ensure that the right patient gets the right medication at the right time. Electronic medication administration records can make it much easier to determine what medications a patient has received. Studies to assess the impact of bar-coding on medication safety are underway, and the early results are promising. Another technology that can be used to improve the safety of medication administration is "smart pumps." These are pumps that can be instructed in which medication is being given, and at what dose; if the nurse tries to administer too high a dose, he or she will receive a warning.

Non-technology-oriented interventions can also be highly effective. For example, having a pharmacist round with the team in the intensive care unit has been shown to decrease the ADE frequency substantially in that setting; this oversight is now a Joint Commission of Accreditation of Healthcare Organizations (JCAHO) requirement.

The National Picture around Safety Several organizations, including the National Quality Forum (NQF) and the JCAHO, have made recommendations about how to improve safety. In particular, the NQF has released recommendations to the country's hospitals about what practices will most improve the safety of care, which all hospitals are expected to implement (Table e1-1). Many of these practices arise frequently in routine care. One example is "readback," which is the practice of recording all verbal orders and immediately reading them back to the physician to verify the accuracy of what was heard. Another is to use only standard abbreviations and dose designations, since some abbreviations and dose designations are particularly prone to error; for example, 7U may be read as 70.

Measurement of Safety Measuring the safety of care is quite difficult and expensive, since adverse events are fortunately rare. Most hospitals rely on spontaneous reporting to identify errors and adverse events, but this approach has a very low sensitivity, with only ~1 in 20 ADEs reported. There are promising research techniques that involve searching the electronic record for signals suggesting that an adverse event has occurred, which will likely be routine in the future but are not yet in wide use. Claims data have been used to identify the frequency of adverse events; this approach works much better for surgical care than for medical care and still requires additional validation. The net result is that except for a few specific types of events, such as falls and nosocomial infections, hospitals have little idea about the true frequency of safety issues.

Nonetheless, all providers have the responsibility to report problems with safety as they are identified. All hospitals have spontaneous reporting systems, and if providers report events as they occur, these events can be used as lessons for subsequent improvement.

Conclusions about Safety It is now abundantly clear that the safety of health care can be improved substantially; as more areas are studied closely, more problems are identified. Compared to the outpatient setting, much more is known about the epidemiology of safety in the inpatient setting, and a number of effective strategies for improving safety have been identified and are being used increasingly. Some effective strategies are also available in the outpatient setting. Transitions appear to be especially risky. The solutions to improving care will often involve leveraging information technology, but they will also involve many other domains, such as use of human factors techniques, team training, and building a culture of safety.

QUALITY IN HEALTH CARE

Quality of care has remained somewhat elusive, although the tools for measuring it have increasingly improved. Selecting health care and measuring its quality is a complex process.

Quality Theory Donabedian has suggested that quality of care can be divided by type of measurement into structure, process, and outcome. *Structure* refers to whether or not a particular characteristic is present, e.g., whether a hospital has a catheterization laboratory or whether a clinic uses an electronic health record. *Process* refers to the way that care is delivered, and examples of process measures are whether a Pap smear was performed at the recommended interval or whether an aspirin was given to a patient with a suspected myocardial infarction. *Outcomes* refer to what actually happens, e.g., the mortality rate in myocardial infarction. It is important to note that good structure and process do not always result in good outcomes. For instance, a patient may present with a suspected myocardial infarction to an institution with a catheterization laboratory and receive recommended care, including aspirin, but still die because of their infarction.

Quality theory also suggests that overall quality will be improved more in the aggregate by raising the level of performance of all providers rather than finding a few poor performers and punishing them. This view suggests that systems changes are especially likely to be helpful in improving quality, since large numbers of providers may be affected simultaneously.

The theory of continuous quality improvement suggests that organizations should be evaluating the care they deliver on an on-going basis and continually making small changes to improve their individual processes. This approach can be very powerful if embraced over time.

TABLE e1-1 SAFE PRACTICES FOR BETTER HEALTH CARE[a]

1. Create a health care culture of safety.
2. For designated high-risk, elective surgical procedures or other specified care, patients should be clearly informed of the likely reduced risk of an adverse outcome at treatment facilities that have demonstrated superior outcomes and should be referred to such facilities in accordance with the patient's stated preference.
3. Specify an explicit protocol to be used to ensure an adequate level of nursing based on the institution's usual patient mix and the experience and training of its nursing staff.
4. All patients in general intensive care units (both adult and pediatric) should be managed by physicians having specific training and certification in critical care medicine ("critical care certified").
5. Pharmacists should actively participate in the medication-use process, including, at a minimum, being available for consultation with prescribers on medication ordering, interpretation and review of medication orders, preparation of medications, dispensing of medications, and administration and monitoring of medications.
6. Verbal orders should be recorded whenever possible and immediately read back to the prescriber—i.e., a health care provider receiving a verbal order should read or repeat back the information that the prescriber conveys in order to verify the accuracy of what was heard.
7. Use only standardized abbreviations and dose designations.
8. Patient care summaries or other similar records should not be prepared from memory.
9. Ensure that care information, especially changes in orders and new diagnostic information, is transmitted in a timely and clearly understandable form to all of the patient's current health care providers who need that information to provide care.
10. Ask each patient or legal surrogate to recount what he or she has been told during the informed consent discussion.
11. Ensure that written documentation of the patient's preference for life-sustaining treatments is prominently displayed in his or her chart.
12. Implement a computerized prescriber order entry system.
13. Implement a standardized protocol to prevent the mislabeling of radiographs.
14. Implement standardized protocols to prevent the occurrence of wrong-site procedures or wrong-patient procedures.
15. Evaluate each patient undergoing elective surgery for risk of an acute ischemic cardiac event during surgery, and provide prophylactic treatment of high-risk patients with beta blockers.
16. Evaluate each patient upon admission, and regularly thereafter, for the risk of developing pressure ulcers. This evaluation should be repeated at regular intervals during care. Clinically appropriate preventive methods should be implemented consequent to the evaluation.
17. Evaluate each patient upon admission, and regularly thereafter, for the risk of developing deep vein thrombosis (DVT)/venous thromboembolism (VTE). Utilize clinically appropriate methods to prevent DVT/VTE.
18. Utilize dedicated anti-thrombotic (anti-coagulation) services that facilitate coordinated care management.
19. Upon admission, and regularly thereafter, evaluate each patient for the risk of aspiration.
20. Adhere to effective methods of preventing central venous catheter–associated bloodstream infections.
21. Evaluate each preoperative patient in light of his or her planned surgical procedure for the risk of surgical site infection, and implement appropriate antibiotic prophylaxis and other preventive measures based on that evaluation.
22. Utilize validated protocols to evaluate patients who are at risk for contrast media-induced renal failure, and utilize a clinically appropriate method for reducing risk of renal injury based on the patient's kidney function evaluation.
23. Evaluate each patient upon admission, and regularly thereafter, for risk of malnutrition. Employ clinically appropriate strategies to prevent malnutrition.
24. Whenever a pneumatic tourniquet is used, evaluate the patient for the risk of an ischemic and/or thrombotic complication, and utilize appropriate prophylactic measures.
25. Decontaminate hands with either a hygienic hand rub or by washing with a disinfectant soap prior to and after direct contact with the patient or objects immediately around the patient.
26. Vaccinate health care workers against influenza to protect both them and patients from influenza.
27. Keep workspaces where medications are prepared clean, orderly, well lit, and free of clutter, distraction, and noise.
28. Standardize the methods for labeling, packaging, and storing medications.
29. Identify all "high alert" drugs (e.g., intravenous adrenergic agonists and antagonists, chemotherapy agents, anticoagulants and anti-thrombotics, concentrated parenteral electrolytes, general anesthetics, neuromuscular blockers, insulin and oral hypoglycemics, narcotics and opiates).
30. Dispense medications in unit-dose or, when appropriate, unit-of-use form, whenever possible.

[a] These 30 practices are the recommendations from the National Quality Forum (NQF) for improving the safety of health care; the NQF believes these should be universally utilized in applicable care settings to reduce the risk of patient harm. The practices all have strong supporting evidence and are likely to have a significant benefit.

A number of specific tools have been developed to help improve process performance. One of the most important of these tools is the Plan-Do-Check-Act cycle (Fig. e1-2). This approach can be used to perform what is called rapid cycle improvement for a process, e.g., the time for a patient with pneumonia to receive antibiotics after diagnosis. Often, specific statistical tools, such as control charts, are used in conjunction to determine whether or not progress is being made. Most medical care comprises one or many processes, making this tool especially important for improvement.

Factors Relating to Quality Many factors can decrease the level of quality, including stress to providers, high or low levels of production pressure, and poor systems, to name but a few examples. Stress can adversely affect quality because it can lead providers to omit important steps, as can a high level of production pressure. Low levels of production pressure can also sometimes result in worse quality, as providers may be bored or have little experience with a specific problem. Poor systems can have a tremendous impact on quality, and even extremely dedicated providers typically cannot achieve high levels of performance if they are operating within a poor system.

Data about the Current State of Quality A recent RAND study has provided the most complete picture of quality of care delivered in the United States to date. The results were sobering. The authors found that across a wide range of quality parameters, patients in the United States received only 55% of recommended care overall; there was little variation by subtype, with scores of 54% for preventive care, 54% for acute care, and 56% for care of chronic conditions, leading the authors to conclude that the chances of getting high-quality care in the United States broadly were little better than those of winning a coin flip.

Strategies for Improving Quality and Performance A number of specific strategies can be used to improve quality at the individual level, including rationing, education, feedback, incentives, and penalties. *Rationing* has been effective in some specific areas, such as convincing physicians to prescribe within a formulary, but it generally has been resisted. *Education* is effective in the short run and is necessary for changing opinions, but its effect decays fairly rapidly with time. *Feedback* on performance can be given either at the group or individual level. Feedback is most effective if it is individualized and if it is given in close temporal proximity to the original events. *Incentives* can be effective, and many believe that this will be a key to improving quality, especially if pay-for-performance with sufficient incentives is broadly implemented (see below). *Penalties* produce provider resentment and are rarely used in health care.

Another set of strategies for improving quality involves changing the systems of care. An example would be introducing reminders about which specific actions need to be taken at a visit for a specific patient, which is a strategy that has been demonstrated to improve performance in certain situations, e.g., in delivery of preventive services. Another approach that has been effective is the development of "bundles" or groups of quality measures that can be implemented together with a high degree of fidelity. A number of hospitals have now implemented a bundle for ventilator-associated pneumonia in the intensive care unit, which includes five measures, including, for example, ensuring that the head of the bed is elevated. The hospitals have found that they were able to substantially improve performance.

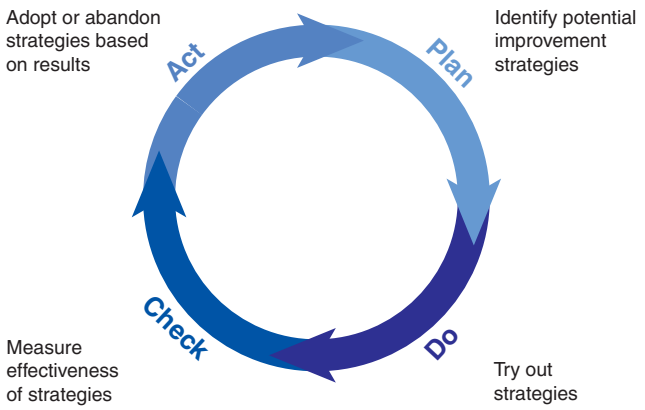

FIGURE e1-2 Plan-do-check-act (or PDCA) cycle. The PDCA cycle approach can be used to improve a specific process rapidly. First, planning is performed, and several potential improvement strategies are identified. Next, these strategies are trialed in small "tests of change." "Checking" is measuring whether or not they appeared to make a difference, and "act" refers to acting on the results.

Perhaps the most pressing need is to improve the quality of care for chronic diseases. The Chronic Care Model has been developed by Wagner and colleagues (Fig. e1-3); it suggests that a combination of strategies will be necessary, including self-management support, changes in delivery system design, decision support, and information systems, and that these must be delivered by a practice team composed of several providers, not just a physician.

Recent evidence about the relative efficacy of strategies in reducing hemoglobin A_{1c} (HbA_{1c}) in outpatient diabetes care (Fig. e1-4) supports this general premise. It is especially notable that the outcome was HbA_{1c}, as it has generally been much more difficult to improve outcome measures than process measures (such as whether a HbA_{1c} was performed). In this meta-analysis, a variety of strategies were effective, but the most effective ones were the use of team changes and use of a case manager. When cost-effectiveness is considered in addition, it appears likely that an amalgam of strategies will be needed. However, the more expensive strategies, such as use of case managers, will likely be implemented widely only if pay-for-performance takes hold.

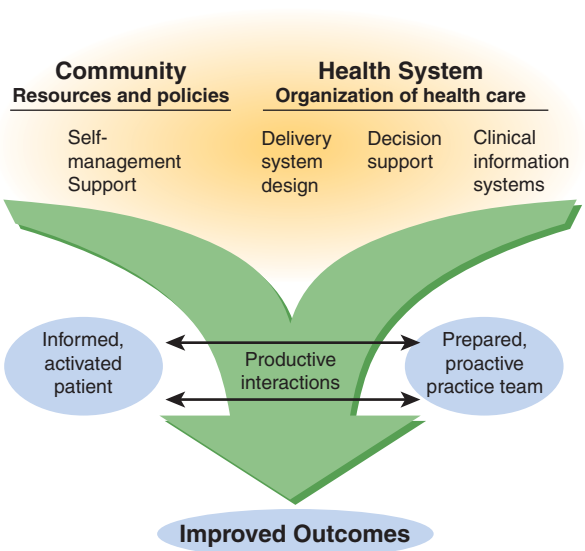

FIGURE e1-3 The chronic care model. The chronic care model, which focuses on improving care for chronic diseases, suggests that delivery of high-quality care demands a range of strategies that must closely involve and engage the patient, and, in addition, that team care is essential. *(From Wagner et al: Eff Clin Pract 1:2, 1998.)*

National State of Quality Measurement In the inpatient setting, quality measurement is now being performed by a very large proportion of hospitals for several conditions, including myocardial infarction, congestive heart failure, pneumonia, and surgical infection prevention; 20 measures are included in all. This is the result of the Hospital Quality Initiative, which represents a collaboration among many entities, including the Hospital Quality Alliance, the JCAHO, the NQF, and the Agency for Healthcare Research and Quality, among others. The data are housed at the Center for Medicare and Medicaid Services, which publicly releases performance on the measures on a website called *Hospital Compare*. These data are voluntarily reported and are available for a very high proportion of the nation's hospitals; they were first released in April 2006. Early analyses demonstrate that there is substantial regional variation in quality and that there are important differences among hospitals. Analyses by the Joint Commission for very similar indicators demonstrate that performance on measures by hospitals did improve over time, and that, as might be hoped, lower performers improved more than higher performers. Analogous national data for ambulatory care are not yet available, but a group called the Ambulatory care Quality Alliance (AQA) has been formed and is developing an analogous set of measures.

Public Reporting Overall, public reporting of quality data is becoming increasingly common. There are now commercial websites that have quality-related data for most regions of the country that can be accessed for a fee. Similarly, national data for hospitals are available. The evidence to date is that patients have not used such data very much, but that such data have had an important effect on provider and organization behavior. Instead, patients have relied on provider reputation to make choices. Part of the reason for this choice basis is that until very recently little information was available, and it was not necessarily represented in ways that were easy for patients to access. Many believe that as more information about quality becomes available, it will become increasingly central to patient choices about where to access care.

Pay-for-Performance Currently, providers in the United States get paid exactly the same amount for a specific service regardless of what quality care is delivered. The theory of pay-for-performance suggests that if providers are paid more for higher-quality care, they will invest in strategies that enable them to deliver that care. The current key issues in the pay-for-performance debate relate to (1) how effective it is, (2) what levels of incentives are needed, and (3) what perverse consequences are produced. The evidence about effectiveness is fairly limited to date, although a number of studies are ongoing. With respect to levels, most performance incentives around quality have accounted for merely 1–2% of total payment in this country to date, but in the United Kingdom, 40% of general practitioners' salaries have recently been placed at risk based on performance across a wide array of parameters. This has been associated with large improvements in reported quality performance, although it is still unclear as to what extent this represents better performance versus better reporting. The potential for perverse consequences exists with any incentive scheme. One problem is that if incentives are tied to outcomes, this introduces the incentive to transfer the sickest patients to other providers and systems. Another concern is that providers will pay too much attention to quality measures with incentives, and ignore the rest of the quality picture. The validity of these concerns remains to be determined.

CONCLUSIONS

The safety and quality of care in the United States could be improved substantially. A number of interventions are available today that have been demonstrated to improve the safety of care and should be used more widely; others are undergoing evaluation or will be evaluated. Quality could also be dramatically better, and the science of quality improvement is increasingly mature. Implementation of pay-for-performance should make it much easier for organizations to justify investments in improving these parameters, including health informa-

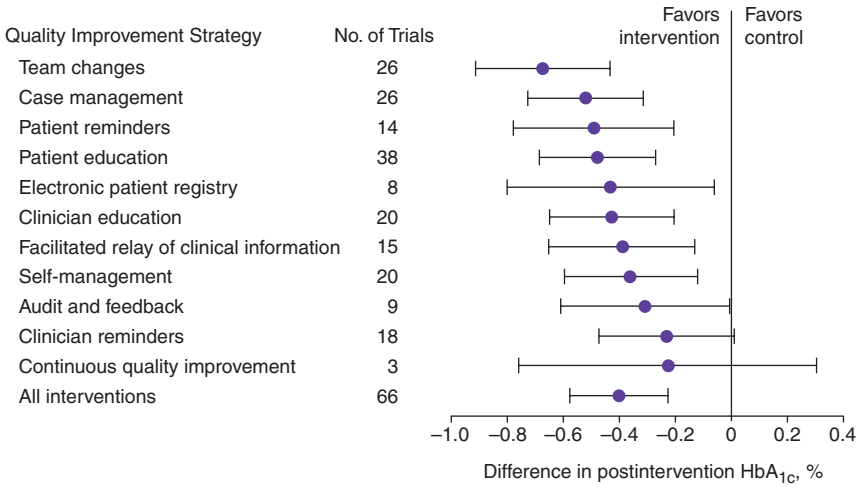

FIGURE e1-4 The efficacy of various strategies for improving diabetes care in outpatients. Shojania et al. performed a meta-analysis of evaluating the efficacy of strategies for reducing hemoglobin A_{1c} (HbA_{1c}) in diabetic outpatients; they found that team changes and case management had the largest impact on HbA_{1c}, although there was a trend toward improvement for many strategies. Interventions in which nurse or pharmacist case managers can make medication adjustments without awaiting physician authorization resulted in the largest reductions. *(From Shojania et al: JAMA 296:427, 2006.)*

tion technology; however, many will also require changing the structure of care, e.g., moving to a more team-oriented approach, and ensuring that the patients are more involved in their own care. The measures of safety are still relatively immature and could be made much more robust; it would be particularly useful if organizations had measures that they could use in routine operations to assess safety at reasonable cost. While the quality measures available are more robust than those for safety, they still cover a relatively small proportion of the entire domain of quality, and more need to be developed. The public and payers are now demanding better information about safety and quality, as well as better performance in these areas. The clear implication is that these domains will need to be addressed directly by providers.

e2 Economic Considerations in the Practice of Medicine

David Meltzer

The enormous and continuing growth of health care spending in the United States and many other countries over recent decades has focused attention on the causes, consequences, and possible responses to rising expenditures on health care. A variety of strategies to control costs have been developed that have made it increasingly important that physicians and other health care professionals understand a wide range of economic considerations in the practice of medicine.

HEALTH CARE COSTS

Between 1960 and 2005, health care spending in the United States increased from about $27 billion to $2.1 trillion. This growth in spending was about 2–3% higher per year than growth in the overall economy, causing health care spending to rise from 6% of gross domestic product to >16%. This increase in spending has produced enormous challenges for everyone who pays for health care. For government, these challenges include rising federal, state, and local government health care budgets, which have required increases in taxes. For firms and their workers, the biggest challenge is the high cost of insuring workers, which causes employers to drop (or reduce) health insurance coverage, to move jobs overseas, or to reduce wages. The rising cost of insurance coverage that is passed on to workers also increases rates of uninsurance, because some workers choose to forego insurance even when it is available or take jobs that do not offer insurance coverage. The increasing cost of medical care also raises the cost of any attempts through public policy to provide insurance coverage to the >45 million Americans who now lack health insurance. Increased out-of-pocket costs for patients are also a common outgrowth of rising health care expenditures. Overall, about 15–20% of health care costs are now paid out of pocket by consumers. Because some persons consume no health care, the fraction of health care costs paid out of pocket by persons who actually use health care is even higher, ~35% of their total health care costs.

The combination of rising costs and high rates of uninsurance, along with the knowledge that many other developed countries spend only about half as much on health care yet are able to provide universal coverage and have health outcomes that are as good as or better than those in the United States, has understandably created widespread concern that the U.S. health care system is neither as efficient nor as effective as it could be. This, in turn, has produced many efforts to understand the causes of increased costs and to improve the delivery and financing of health care in the United States.

Causes of Rising Costs Many causes of the rise in health care costs have been suggested. An aging population is commonly cited but has actually contributed rather little to recent increases in per capita spending. One reason for this is that, unlike the large cohort of baby boomers who will reach old age in the coming years, the cohort of persons born during the Depression Era of the 1930s who have reached retirement age in recent years is relatively small, because birth rates were low during that depression. Another reason that aging has not contributed so greatly to increasing expenditures is that improving health during old age has tended to delay the onset of serious illness and high health care expenditures. Another commonly suggested cause of rising expenditures has been medical malpractice and resulting defensive medicine, but evidence suggests that this is not a large contributor to health care costs in the United States. Administrative costs have also have been suggested to play an important role and are probably at least 10–15% of total costs for private insurance.

Despite the significant and rising number of persons who lack insurance in the United States, one possible cause of rising health care costs since 1960 for which there is strong evidence is the increasing insurance coverage of health care and resulting increases in demand for health care. Some scholars date the growth in health insurance coverage to the beginning of World War II when an Internal Revenue Service ruling established that employer-provided health insurance would be exempt from personal income tax. Today, employer-sponsored health insurance provides insurance coverage for ~60% of Americans. The growth of Blue Cross and Blue Shield insurance plans dates from this period of the establishment of employer-sponsored health insurance, and these plans formed a model for private health insurance in the United States. This was followed in the 1960s by the creation of Medicare and then Medicaid and a series of subsequent expansion of these programs. Nevertheless, based on data from the effects of health insurance coverage on the demand for health care, experts have estimated that these increases in insurance coverage account for only about one-quarter of the increase in health care spending since 1960.

Instead, most health economists now believe that the primary cause of increasing spending on health care is the development of new technologies that, on average, offer improvements in health that are of substantial value to patients. An illustrative example of this is the cost of treating an acute myocardial infarction, which grew at ~5% annually in real terms over the mid-1980s and -1990s. This occurred at the same time that the cost of the individual major treatments for acute myocardial infarction—medical management, fibrinolysis, percutaneous coronary intervention, and coronary bypass surgery—either fell or increased minimally. The change in the overall cost occurred because the more expensive treatment options (e.g., revascularization) were increasingly used over the less expensive ones (e.g., medical management). Most economists have concluded that similar increases in the use of new technologies explain most of the increase in health care spending over this period. Estimates of the value of these increases in spending in terms of health indicate that on average they have yielded benefits far in excess of their costs, suggesting that these changes are the result of expanding opportunities to produce increases in health that are valued well above the cost of producing them. However, a broad body of evidence also indicates that many new technologies are not worth their costs, and it has been suggested that the broad expansion of insurance coverage has increased the incentives to develop costly medical technologies, even when they are not worth their cost. These conclusions suggest that efforts to control the cost of health care must consider both immediate and longer-term effects and be acutely aware of the value of health that is produced.

THE DEMAND FOR AND SUPPLY OF HEALTH CARE

Demand and supply are the fundamental tools that economists use to analyze health care markets and the spending within them. The demand for health care derives ultimately from the desire of individuals to be healthy. Health economists think of health as a capital good ("health capital") in the sense that it tends to be durable, so that health today contributes positively to health tomorrow. A logical consequence of this is that rational decisions about health involve thinking about benefits and costs both in the present and in the future. Although individuals cannot buy health, they can buy health care that they hope will improve their health. Because health care costs can be high and variable, health insurance is desirable to protect against the risk of catastrophic costs that could otherwise lead to bankruptcy and/or to limit access to health care.

Insurance can produce incentives to consume more medical care than individuals would purchase if they faced the true cost of care, but such inefficiencies need to be balanced against the financial and health risks of lacking insurance. Contractual limits on what insurance will cover are a strategy to address this tendency for excessive consumption but are often sources of controversy and patient dissatisfaction. One reason for this is that health care spending tends to be highly concentrated, with ~5% of the population accounting for 50% of total spending. This concentration of spending makes it difficult to use cost-sharing to control health care without having these costs fall heavily on a small fraction of individuals.

Because simple across-the-board cost-sharing can produce unacceptable financial risk, health care insurance is better constructed by

Copyright © 2008 by McGraw-Hill Company. All rights reserved.

designing a package of benefits that provides variable subsidies for access to different medical technologies that can improve health while leaving an acceptable level of financial risk and an affordable annual premium. These tradeoffs are increasingly being put in the hands of consumers as they choose among health plans. This has the advantage of allowing consumer choice but can also result in adverse selection in which people choose insurance plans based on their personal needs but, in so doing, undermine the ability of insurance to spread costs and risk among patient groups. An example of adverse selection would be if a low-cost plan were chosen only by healthy individuals, leaving sicker persons alone in the high-cost plan, which might then become unaffordable. These types of concerns greatly complicate the creation of successful insurance markets.

Medicare and Medicaid Medicare provides health insurance for almost all Americans age 65 and older. Established in 1965, Medicare covers both hospital care (part A) and physician fees (part B). In 2006 Medicare also began offering a prescription drug benefit (part D). Insurance coverage within Medicare has some idiosyncrasies that, in part, reflect its origins in being modeled based on private health insurance in the 1960s. These include lifetime caps on benefits and copayment rates that are sometimes lower for low-use patients than for higher-use patients. Medicare beneficiaries who can afford them can purchase supplemental Medicare (Medigap) policies that can sometimes fill these gaps in coverage. Medicare also interfaces with the Medicaid program to address the needs of lower income older persons, as discussed below.

The Part D program in Medicare addresses a long-standing need to provide older persons with better access to pharmaceuticals. This program has a complicated benefit structure, with varying copayment rates depending on an individual's prescription drug expenditures within the year. There are also significant variations in the coverage provided by different plans, but online tools are available at *www.medicare.gov* to help patients and their families to make informed decisions. Medicare Advantage is a program developed by Medicare to provide managed care options for Medicare beneficiaries. Patients in these programs generally give up flexibility in the providers they can see without paying for visits themselves but benefit from lower copayments for covered services or coverage for certain benefits that traditional Medicare may not cover. Medicare also has a special program that provides health insurance coverage for persons with end-stage renal disease.

Medicaid is an important source of insurance coverage for patients who lack private health insurance or Medicare and who cannot afford to purchase insurance on their own. Medicaid currently provides coverage to about 14% of the U.S. population. Like Medicare, Medicaid is managed by the Centers for Medicare and Medicaid services (CMS). However, unlike Medicare, Medicaid is a federal-state partnership with funding that is shared, and there is a great deal of variation across states as to who is eligible and what benefits are provided. In general, Medicaid tends to have lower copayments than other types of health insurance, which is important because of the limited income of the recipients of Medicaid. Older persons whose incomes and assets are low enough to qualify may be eligible for both Medicare and Medicaid ("dual-eligible"). One aspect of Medicaid coverage that is especially important for older persons and their families is that it pays for nursing home coverage for those whose income and assets are sufficiently low. For patients and their families for whom high health care costs and insurance coverage are major concerns, referral to a social worker, patient advocate, or another expert in health care costs is among the most valuable things a physician can do to help protect the family from unnecessary economic hardship.

SUPPLY OF HEALTH CARE

Physicians, nurses and other health professionals, hospitals, manufacturers of pharmaceuticals and devices, and researchers all provide key inputs into the health care system.

Health Professionals The economics of medical practice are shaped by the high level of investment in tuition and time (foregone earnings) that physicians must make during their training. Typically, longer training periods are associated with higher earnings. Nevertheless, some specialties with the longest training periods still offer exceptionally high returns on investment. In a competitive market with free entry, one might expect the returns on investment to equalize across specialties as high earnings encourage more entrants into a field and lowers average earnings. This tends not to happen because entry into medical specialties is often tightly controlled by a variety of accrediting agencies in collaboration with medical specialty societies. In addition, the large role of government as a payer in health care makes physician reimbursement a political issue in which lobbying and other strategies for specialty influence play a role.

In the past, physicians usually owned their own practices, but this is increasingly less common in the United States as physicians more often work as part of large groups or for health plans. These models sometimes pay doctors fixed salaries, although incentives to see more patients are common. Incentives for physicians to provide services can lead to concerns about "demand inducement," in which physicians provide more care than is desirable because of the financial returns they receive from providing that care, but the evidence for this being common is not compelling. Legal constraints exist to prevent physicians from gaining economically from referring patients for the services of other providers.

Nurses and other health professionals also have complex labor market issues. Often the boundaries of practice between different forms of training (e.g., ophthalmologists and optometrists or nurse practitioners and physician assistants) are not clear, and so there can be intense competition between, as well as within, specialty areas.

Hospitals These are complex organizations that require expensive capital investments, a large and complex staff, and close ties with physicians. Most hospitals are not-for-profit (NFP), meaning that any surplus left at the end of each year must be reinvested in the hospital or the health of the community it serves. This contrasts with a for-profit (FP) hospital, which can return profits to shareholders and is not required to provide benefits to its community in the same way as NFP hospitals are required to. NFP hospitals are exempt from many taxes, but there is active debate about whether NFP hospitals provide as much community benefit as would be expected based on the subsidies that they receive. Hospital management in NFP hospitals is supervised by a board of directors that typically includes community, staff, and physician participation. In contrast, FP hospitals are managed by a corporate structure. However, managers in both NFP and FP hospitals use similar tools to analyze and improve the cost and quality of care they provide. Increasingly, management tools such as process mapping, human factors analysis, and continuous quality improvement approaches (e.g., plan-do-study-act cycles) are becoming essential tools of a modern physician leader.

The Pharmaceutical and Device Industries The pharmaceutical industry and its close cousin, the medical device industry, are among the most important aspects of the modern health care system and supply many of the products most responsible for improvements in public health, such as medications to treat hypertension, immunizations, and devices such as joint replacements and artificial lenses that allow the removal of cataracts. Concerns about the rising cost of pharmaceuticals, safety, direct-to-consumer advertising, and inappropriate marketing strategies have made the pharmaceutical industry and its regulators [e.g., the U.S. Food and Drug Administration (FDA)] the subject of a great deal of recent scrutiny. Another major concern is the rising costs of developing new drugs, which has recently been estimated to be in the vicinity of $1 billion per new chemical entity brought to market. The rising cost of prescription drugs and concern that prices charged in the United States are above those charged in other countries have led to calls for efforts to control drug pricing in the United States. Attempts to bring down the costs of prescription drugs both in the United States and internationally must balance their short-term effects on the cost of health care with longer-term effects on the incen-

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

tives to produce innovative new drugs and effects on access to patients within and across countries with varying incomes and ability to pay.

Innovation Medical innovation is also produced by academia and government, often in close collaboration. The National Institutes of Health (NIH) is the source of the vast majority of federal funding for health research, with the Centers for Disease Control and Prevention (CDC) a distant second and the Agency for Healthcare Research Quality (AHRQ) and a variety of other federal agencies further behind. NIH, CDC, and AHRQ support basic, translational, and clinical research as well as a wide range of programs to support the training and ongoing career development of researchers. There are also loan repayment programs to encourage entry into research careers. The federal government also supports academic medicine through extra payments to academic medical centers through Medicare. Teaching hospitals have traditionally made profits on their clinical care that have allowed them to subsidize their educational and research activities, but the increasingly competitive health care market place is making this progressively more difficult. Therefore, it is more important that research activities be supported by government, private foundations, philanthropy, or industry.

Practice Variation Another major concern about health care spending is the large degree of variation in spending across small geographic areas around the United States. These variations in spending are due to variations in the rate at which expensive care is provided and yet do not appear to result in improved outcomes, suggesting that much of the excess utilization in high-cost areas is of little value. The causes of this excess utilization of services does not appear to result primarily from patient level factors or from differences in insurance coverage. Some have hypothesized that increased utilization of services results from increased capacity in some areas ("if you build it, they will come"). However, other experts have argued that variations in use across small areas may reflect differences in physician beliefs about appropriate practice patterns that are shaped by the influence of peers in their local area.

COST-CONTROL STRATEGIES

The rapid rise in health care costs over the past three decades has led to a variety of strategies to control costs. Some early programs focused on direct regulation of health care, such as the requirement that a "certificate of need" be issued by a local health authority before construction of a new medical facility can proceed. Other strategies have included direct regulation of payments through publicly established fee schedules for Medicare or Medicaid that often influence private payment rates. Sometimes fee schedules have been created with multiple policy goals. One example is the resource-based relative value scale (RBRVS), which was developed with the intent to realign incentives to encourage physicians to enter needed medical specialties (such as primary care) and be rewarded based on the effort and complexity of the work they do.

Prospective Payment This is probably the most important cost-control strategy that has been adopted in the United States. Under a prospective payment system, a health care provider is provided a fixed amount of money to provide care for a patient over a specified episode of care. This contrasts with a retrospective reimbursement system, in which a provider is paid based on the amount of care they provide. The most important example of such a system has been the Medicare Prospective Payment system. This was established in 1983 and replaced the prior system, in which Medicare reimbursed hospitals based on the specific services they provided with a system that provided a fixed payment for a hospital stay for any given diagnosis, classified according to one of several hundred diagnosis-related groups, or DRGs. This provided strong incentives to decrease hospital length of stay and costs and had large effects on hospital cost growth for several years. It was also coupled with the creation of Professional Review Organizations (PROs) that, among other things, sought to ensure that hospitals were acting appropriately in admitting patients according to the criteria for each DRG, and providing quality care within that diagnosis. This linkage of quality improvement and payment policy was an important move in the history of Medicare, from serving merely as a payer to acting as an increasingly active manager of care.

Pay for Performance Today's interest in pay for performance, in which providers receive higher reimbursement rates for care that meets specified quality indicators is an extension of this. Prospective payment is a key idea underlying the use of managed care organizations to control costs by providing a fixed payment for providing care for a patient over a given period of time. Because managed care organizations are responsible for all of the care of the patient over this time period, they may have more incentives and ability to provide integrated care. Health maintenance organizations (HMOs) and other managed care organizations may emphasize prevention as a key aspect of their strategy for managing care and controlling costs. However, the high rate at which individuals switch health care plans and the long period of time it takes for many preventive therapies (such as control of hypertension or diabetes) to exert their major benefits suggest that economic incentives for at least some forms of prevention are unlikely to be strong, even in HMOs. This is one motivation for the use of report cards for health plans, which often report on the rate at which various preventive care goals are met. As with prospective payment of hospitals, successful implementation of managed care requires the ability to adjust payments to reflect the underlying cost of care so that providers are not systematically penalized for caring for certain classes of patients. Likewise, development of tools to measure and reward the quality of care provided by managed care organization has arisen as a major priority for the field of health outcomes research.

Competition This has been another important strategy used to attempt to control costs. Competitive bidding for contracts in which only the low-price bidders are able to provide services, often called *selective contracting*, is now common in medical care and provides a powerful strategy to encourage providers to lower their prices and, accordingly, costs. Competition does not always lower costs, however. For example, when hospital reimbursement was retrospective, competition between hospitals tended to increase costs as hospitals provided more and more services to attract patients and were well reimbursed for them. In the era of prospective payment, competition has the opposite effect of lowering costs because hospitals can no longer charge insurers for added costs and because, with a fixed reimbursement, hospitals can be more profitable only if they lower their costs. The combination of competition and prospective payment may be particularly powerful in reducing costs but can also create incentives to decrease the amount of care provided to the sickest patients within a given category, the costs of whose care may often exceed reimbursement. For this reason, it is especially important that quality-of-care measures not neglect the special needs of the sickest patients.

Consumer-Driven Care Another cost-containment strategy that has recently received increasing attention is the idea of consumer-driven care, in which patients select an insurance plan tailored to their personal needs, but often with more limited coverage of certain services. Given the evidence on the effect of health insurance on the demand for medical care, consumer-driven health care will likely have only a modest effect on overall health care demand over the short run. Nevertheless, it is possible that there could be much larger effects over time if greater consumer sensitivity to cost leads to changes in the way new technologies are developed and their use diffuses. It is also possible—though still unproven—that the development of novel new insurance mechanisms, such as health savings accounts paired with high-deductible health insurance coverage for catastrophic care, could induce far more price sensitivity and cost control than was possible with traditional insurance arrangements.

Cost-Effectiveness Analyses In making medical decisions, especially in making decisions when costs are a concern, cost-effectiveness analy-

Copyright © 2008 by McGraw-Hill Company. All rights reserved.

sis and other approaches to technology assessment are an important source of evidence for decisions about when a medical technology is likely to be worthwhile. In cost-effectiveness analysis, the health benefits and costs of a medical intervention are compared to one or more other options by calculating a ratio of costs (*C*) to effectiveness (*E*), where the *C*/*E* ratio = change in health benefits/change in costs. Often benefits will be measured using a metric of *quality-adjusted life years*, or QALYs, which is a measure of life expectancy in which each year of life is weighted with a number between 0 (death) and 1 (perfect health) reflecting quality of life in that health state. In general, cost-effectiveness theory suggests that interventions that cost less than some threshold value per QALY (often $50,000/QALY or $100,000/QALY) would be considered cost-effective, though the appropriate threshold remains highly controversial.

In countries (such as the United Kingdom) where cost-effectiveness analysis is used to inform coverage policy, it is most commonly used as part of a broader process of technology assessment that may incorporate other forms of evidence, including expert judgment and political concerns emanating from patient and providers, and from producers of new technologies. It is generally agreed that cost-effectiveness analysis take a societal perspective, accounting for all costs and benefits of a medical intervention regardless of to whom they accrue. There is also a strong case to be made for considering multiple perspectives in a cost-effectiveness analysis. For example, a cost-effectiveness analysis done from the perspective of an HMO might find that intensive therapy for diabetes, for which most benefits are far in the future, is not cost-effective from a business perspective, even if it is cost-effective from a societal perspective. In such a case, knowing that the business case for this valuable intervention is not strong might help target attention to developing quality indicators to ensure that plans are making good efforts to encourage intensive therapy for the appropriate patients. Cost-effectiveness analysis can also sometimes be used to assess when it would be valuable to do more research on a technology in order to better characterize how it should be used.

Evidence-Based Medicine and Physician Practice Patterns To the extent that variation in practice patterns is an important contributor to higher health care costs, it becomes important to control practice variations by improving alignment of practice patterns using evidence on the costs and benefits of care. The scientific literature provides important data for such evidence-based practice. Nevertheless, it is well established that there are large gaps between the time evidence becomes available and the time it is incorporated into practice. As a result, a great deal of effort has gone into approaches that may be used to change physician behavior and to create systems-level changes that can support the better use of evidence in clinical care. Health information systems provide a variety of tools, and their increasing use has already begun to show promise in addressing practice variations to improve meaningfully both the cost and effectiveness of care.

Costs and the Clinician Economic concerns arise in clinical care on a daily basis. They range from patient–oriented concerns (such as out-of-pocket costs or insurance purchase decisions) to system-oriented concerns (such as hospital or health plan management) to physician-oriented concerns (practice management and personal earnings). To be fully effective, physicians need to develop and maintain an understanding of these economic considerations in the practice of medicine and to reflect them in their professional behavior.

e3 Racial and Ethnic Disparities in Health Care

Joseph R. Betancourt, David Blumenthal

Over the course of its history, the United States has experienced dramatic improvements in overall health and life expectancy due largely to initiatives in public health, health promotion, disease prevention, and chronic care management. Our ability to prevent, detect, and treat diseases in their early stages has allowed us to target and reduce morbidity and mortality. Despite interventions that have improved the overall health of the majority of Americans, racial and ethnic minorities (Blacks, Hispanics/Latinos, Native Americans/Alaska Natives, Asian/Pacific Islanders) have benefited less from these advances and suffer poorer health outcomes than whites from many major diseases (e.g., cardiovascular disease, cancer, diabetes) in the United States. Research has highlighted that minorities may receive lower quality of care than whites in the health care setting, even when confounders such as stage of presentation and comorbidities are controlled for and they have the same level of health insurance. These differences in quality are called *racial and ethnic disparities in health care.* This chapter will provide an overview of racial and ethnic disparities in health and health care, identify root causes, and provide key recommendations to address them at both the health system and clinical level.

NATURE AND EXTENT OF RACIAL AND ETHNIC DISPARITIES IN HEALTH AND HEALTH CARE

Minority Americans have poorer health outcomes (compared with whites) from preventable and treatable conditions such as cardiovascular disease, diabetes, asthma, cancer, and HIV/AIDS, among others (Fig. e3-1). Multiple factors contribute to these racial and ethnic disparities in health. First and foremost, there is little doubt that social determinants—such as lower levels of education, overall lower socioeconomic status, inadequate and unsafe housing, racism, and living in close proximity to environmental hazards—disproportionately impact minority populations and thus contribute to poorer health outcomes. For example, three of the five largest landfills in the country are found in African-American and Latino communities; these environmental hazards have contributed to some of the highest rates of pediatric asthma among these populations. Second, lack of access to care also takes a significant toll, as uninsured individuals are less likely to have a regular source of care, are more likely to report delaying seeking care, and are more likely to report that they have not received needed care—all resulting in avoidable hospitalizations, emergency hospital care, and adverse health outcomes.

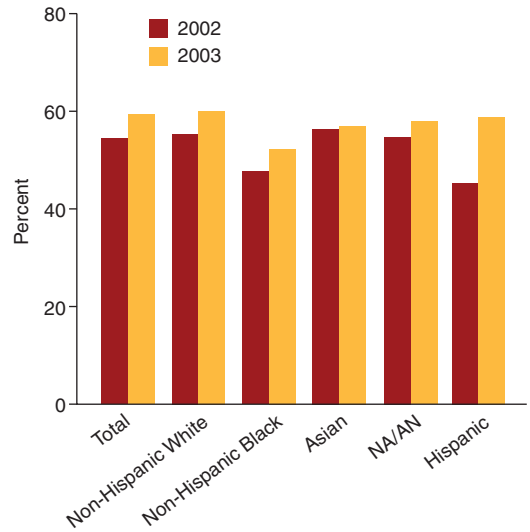

FIGURE e3-2 Recommended hospital care received by Medicare patients with pneumonia, by race/ethnicity, 2002–2003. Reference population is Medicare beneficiaries with pneumonia who are hospitalized. Composite is calculated by averaging the percentage of the population that received each of the five incorporated components of care. NA/AN, Native American or Alaska Native. *(Adapted from Agency for Health Care Research and Quality: The 2005 National Health Care Disparities Report.)*

In addition to the existence of racial and ethnic disparities in *health,* there are racial/ethnic disparities in the *quality of care* for those with access to the health care system. For instance, disparities have been found in the treatment of pneumonia (Fig. e3-2) and congestive heart failure (African Americans receiving less optimal care than whites when hospitalized for these conditions) and referral to renal transplantation (African Americans with end-stage renal disease being referred less often to the transplant list than whites) (Fig. e3-3). Disparities have also been found in the utilization of cardiac diagnostic and therapeutic procedures (African Americans being referred less than whites for cardiac catheterization and bypass grafting), prescription of analgesia for pain control (African Americans and Latinos receiving less pain medication than whites for long bone fractures and cancer), and surgical treatment of lung cancer (African Americans re-

ceiving less curative surgery than whites for non-small cell lung cancer), among others. Again, many of these disparities occurred even when variations in factors such as insurance status, income, age, comorbid conditions, and symptom expression are taken into account.

Little progress has been made in addressing racial/ethnic disparities in cardiovascular procedures and other advanced surgical procedures, while some progress has been made in eliminating disparities in primary care process measures. Data from the National Registry of Myocardial Infarction found no evidence that the racial differences in rates of reperfusion therapy, coronary angiography, and in-hospital death after myocardial infarction have narrowed between 1994 and 2002 (Fig. e3-4). Black women fared worst of all groups, while white men were significantly more likely to receive more aggressive interventions. Using Medicare data from 1992–2001 on annual rates of receipt of nine surgical procedures (such as coronary artery bypass surgery and total hip replacement) previously shown to have disparities, the difference between the rates among whites and blacks increased significantly for five of the nine procedures, remained unchanged for three procedures, and narrowed significantly for only one procedure (Fig. e3-5). Overall, there were no meaningful or consistent reductions in the gaps in care between black and white Medicare enrollees. Using data from enrollees in Medicare managed care plans, there is evidence for a narrowing in racial disparities between 1997 and 2003 in several "report card" preventive care measures such as mammography and glucose and cholesterol testing. However, racial disparities in more complex items such as glucose control in diabetics and cholesterol levels in patients after a heart attack had actually worsened.

The second National Healthcare Disparities Report (NHDR), released by the Agency for Healthcare Research and Quality in January 2006, found that in comparison to the previous year, disparities for blacks are improving in some areas, but disparities for Hispanic/Latino populations appear to be widening. For example, for disparities measured between blacks and whites, 58% are narrowing, while 42% are widening. For disparities measures between Hispanics/Latinos and whites, 41% are narrowing while 59% are widening. For both populations, significant disparities persist, yet for Hispanics/Latinos, the situation seems to be getting worse, not better. Ultimately, in none of the measured areas have disparities been eliminated.

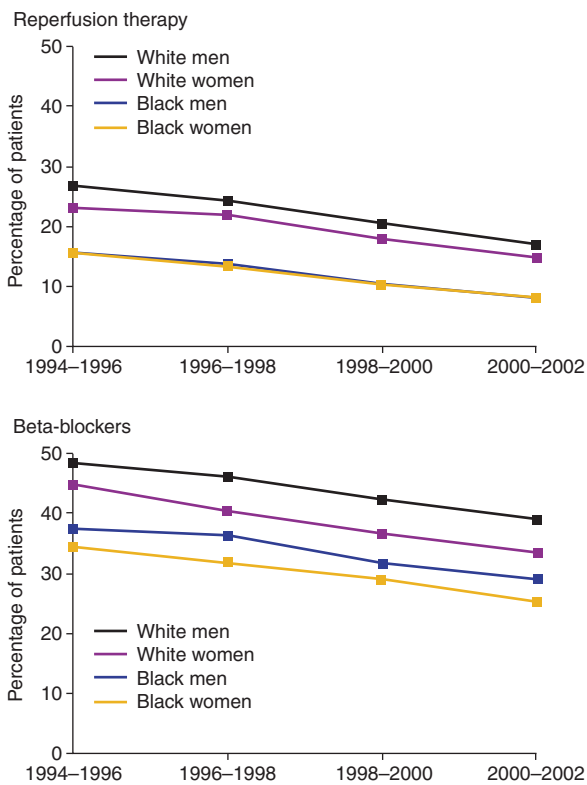

FIGURE e3-4 Sex and racial differences in the management of acute myocardial infarction, 1994–2002. ROOT CAUSES FOR RACIAL/ETHNIC DISPARITIES IN HEALTH CARE

The Institute of Medicine (IOM) report *Unequal Treatment*, released in March 2002, remains the preeminent study of the issue of racial and ethnic disparities in health care in the United States. The IOM was charged to assess the extent of racial/ethnic differences in health care that are not otherwise attributable to known factors such as access to care. To provide recommendations regarding interventions to eliminate health care disparities, the IOM studied health system, provider, and patient factors. The report found the following:

- Racial and ethnic disparities in health care exist and, because they are associated with worse health outcomes, are unacceptable.
- Racial and ethnic disparities in health care occur in the context of (1) broader historic and contemporary social and economic inequality and (2) evidence of persistent racial and ethnic discrimination in many sectors of American life.
- Many sources—including health systems, health care providers, patients, and utilization managers—may contribute to racial and ethnic disparities in health care.
- Bias, stereotyping, prejudice, and clinical uncertainty on the part of health care providers may contribute to racial and ethnic disparities in health care.
- A small number of studies suggest that certain patients may be more likely to refuse treatments, yet these refusal rates are generally small and do not fully explain health care disparities.

Unequal Treatment went on to identify a set of root causes that included the following, among others:

- Health system factors: These include issues related to the complexity of the health care system, the difficulty that minority patients may have in navigating this complex health system, and the lack of availability of interpreter services to assist patients with limited English proficiency.
- Provider-level factors: These include issues related to the health care provider, including stereotyping, the impact of race/ethnicity on clinical decision-making, and clinical uncertainty due to poor communication.
- Patient-level factors: These include patient's refusal of services, poor adherence to treatment, and delay in seeking care.

A more detailed analysis of these root causes is presented here.

Health System Factors • ***HEALTH SYSTEM COMPLEXITY*** Even among those who are insured and educated, and who have a high degree of health literacy, navigating the health care system can be complicated and confusing. Some individuals, however, may be at higher risk for receiving substandard care because of their difficulty navigating the complexities of the U.S. health care system. These individuals may include those from cultures unfamiliar with the Western model of health care delivery, those with limited English proficiency, those with low health literacy, and those who are mistrustful of the health care system. People from these backgrounds may have difficulty knowing how and where to go for a referral to a specialist; how to prepare for a procedure, such as a colonoscopy; or how to follow up on an abnormal test, such as a mammogram, for example. Since people of color in the United States tend to be overrepresented among the groups listed above, the inherent complexity of navigating our health care system has been seen as a root cause for racial/ethnic disparities in health care.

Provider-Level Factors • ***PROVIDER-PATIENT COMMUNICATION*** Significant evidence highlights the impact of sociocultural factors, race, ethnicity, and limited English proficiency on health and clinical care. Health care professionals frequently care for diverse patient populations who present varied perspectives, values, beliefs, and behaviors regarding health and well-being. These include variations in recognition of symptoms, thresholds for seeking care, comprehension of management strategies, expectations of care (including preferences for or against diagnostic and therapeutic procedures), and adherence to preventive measures and medications. In addition, sociocultural differences between patient and provider influence communication and clinical decision-making and are especially pertinent given evidence that clearly links provider-patient communication to improved patient satisfaction, adherence, and, subsequently, better health outcomes (Fig. e3-6). Thus, when sociocultural differences between patient and provider aren't appreciated, explored, understood, or communicated effectively in the medical encounter, patient dissatisfaction, poor adherence, poorer health outcomes, and racial/ethnic disparities in care may result.

A survey of 6722 Americans age 18 and older is particularly relevant given the important link between provider-patient communication and health outcomes. Whites, African Americans, Hispanics/Latinos, and Asian Americans who had a medical visit in the last 2 years were asked whether they had trouble understanding their doctor; whether they felt the doctor did not listen; and whether they had medical questions they were afraid to ask. The survey found that 19% of all patients experienced one or more of these problems, yet whites experienced them 16% of the time, compared with 23% of the time for African Americans, 33% for Hispanics/Latinos, and 27% for Asian Americans (Fig. e3-7).

In addition, provider-patient communication without an interpreter, in the setting of even a minimal language barrier, is recognized as a major challenge to effective health care delivery. Spanish-speaking patients discharged from the emergency room are less likely than their English-speaking counterparts to understand their diagnosis, prescribed medications, special instructions, and plans for follow-up care; less likely to be satisfied with their care or willing to return if they have a problem; more likely to report problems with their care; and less satisfied with the patient-provider relationship. In addition, physicians who have access to trained interpreters report a significantly higher quality of patient-physician communication than physicians who used other methods. Hispanic patients with language-discordant physicians are more likely to omit medication, miss office appointments, and visit the emergency department for care. Communication issues related to discordant language disproportionately affect minorities and others with limited English proficiency and likely contribute to racial/ethnic disparities in health care.

Base: Adults with health care visit in past two years
*Problems include understanding doctor, feeling doctor listened, had questions but did not ask.

FIGURE e3-7 Communication difficulties with physicians, by race/ethnicity. Reference population is 6722 Americans age 18 and older who had had a medical visit in the last 2 years and were asked whether they had trouble understanding their doctor, whether they felt the doctor did not listen, and whether they had medical questions they were afraid to ask. *(From Commonwealth Fund Health Care Quality Survey, 2001.)*

CLINICAL DECISION-MAKING Theory and research on clinical decision-making suggest that physicians' understanding and interpretations of information obtained from patients, as well as assumptions about patients themselves, may contribute to racial and ethnic disparities in health care. Two factors are central to this process: clinical uncertainty and stereotyping. A doctor's decision-making process is nested in clinical uncertainty—in sum, doctors must depend on inferences about severity based on what they understand about illness, and the information they obtain from the patient. If the doctor is caring for a patient for whom they have difficulty understanding the symptoms and are less sure of the "signal"—the set of clues and indications that physicians rely on to make clinical decisions—their decisions may not be the same for two patients who present with the exact same condition. Given that the expression of symptoms may differ among and between cultural and racial groups, doctors—the overwhelming majority of whom are white—may understand symptoms best from patients of their own racial group. The consequence is that white patients may be treated differently from minority patients. Differences in clinical decisions from this mechanism can arise when the doctor has the same regard for each patient (i.e., no prejudice).

Stereotyping can be defined as the process by which people use social categories (e.g., race, gender) in acquiring, processing, and recalling information about others. The literature on social cognitive theory highlights the ways in which natural tendencies to stereotype may influence clinical decision-making. Faced with enormous information loads and the need to make many decisions, people subconsciously simplify the decision-making process and lessen cognitive effort by us-

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

ing "categories" or "stereotypes" that group information and decisions into groups or types that can be more quickly processed and executed. Sometimes, those stereotypes are applied to individuals who are lumped together into groups to which certain beliefs and expectations are attached. Interestingly, people may not be aware of their attitudes or they may consciously endorse stereotyping. Nevertheless, when people assign someone to a particular class or group, they tend to make a "snap judgment" in which they subconsciously and automatically assign the group's characteristics to that individual. Although functional, stereotyping can be systematically biased as people are automatically classified into social categories relating to dimensions such as *race*, *gender*, and *age*. These biases may exist in overt forms, as represented by outward racism or bigotry. However, because of their origins in virtually universal social categorization processes, they may also exist, often subconsciously, among people who strongly endorse egalitarian principles and truly believe they are not prejudiced. Moreover, this social categorization enhances perceptions of similarities within groups and differences between groups (particularly with respect to one's own group), which emphasizes social difference and group distinctiveness. In the process of categorizing people into two different groups, people typically classify themselves into one of the social categories and out of the other. Upon categorization of individuals into in-groups and out-groups, people experience more positive feelings toward the in-group, as well as favor them in terms of evaluation and resource allocation. Although stereotyping may be a normal cognitive process, the cues that lead to particular stereotypes are also strongly influenced by the messages presented consciously and subconsciously in society. For instance, if the media constantly present images of minorities as being less educated, violent, and nonadherent to health care recommendations, these impressions may generate stereotypes that unnaturally and unjustly impact clinical decision-making. Thus, as signs of racism, classism, gender bias, and ageism are experienced—consciously or unconsciously in our society—stereotypes may be created that impact the way doctors manage patients from these groups. In addition, based on training or practice location, doctors may develop certain perceptions about race/ethnicity, culture, and class that may evolve into stereotypes. For example, many medical students and residents are often trained—and minorities cared for—in academic health centers or public hospitals located in socioeconomically disadvantaged areas. As a result, doctors may begin to equate certain races and ethnicities with specific health beliefs and behaviors (e.g., "these patients" engage in risky behaviors, or "those patients" tend to be noncompliant) that are more associated with the social environment (e.g., poverty) than a patient's racial/ethnic background or cultural traditions. This "conditioning" phenomenon may also occur if doctors are faced with certain racial/ethnic patient groups who don't frequently choose aggressive forms of diagnostic or therapeutic interventions. The result over time may be that doctors begin to believe that "these patients" don't like invasive procedures, and thus they may not offer them as options very ardently, if at all.

In addition, doctors are commonly taught that their own personal characteristics (race, ethnicity, socioeconomic status), as well as personal characteristics of the patient and the clinical setting, should be excluded from consideration in the formulation of clinical decisions. Many nonmedical factors, however, ranging from the patient's physical appearance to the organizational setting in which medical care is delivered, may have as much influence on clinical decisions as the actual signs and symptoms of disease. These nonmedical factors include characteristics of the patient (including patient age, gender, socioeconomic status, race/ethnicity, language proficiency, and insurance status), characteristics of the doctor (including the specialty, level of training, clinical experience, age, gender, and race/ethnicity), and features of the practice setting (including location, organization of practice, form of compensation, performance expectations, and incentives). This may furthermore contribute to unconscious stereotyping.

It is important to differentiate stereotyping from prejudice and discrimination, both conscious processes. Prejudice is a conscious, knowledgeable prejudgment of individuals that may lead to disparate treatment, and discrimination is conscious and intentional disparate treatment. All individuals stereotype subconsciously, despite the best intentions to treat every patient equitably. The challenge is that if left unchecked, stereotyping (especially based on stereotypes derived abnormally from conscious and subconscious societal cues, such as those related to race) may lead to lower quality of care for certain groups—such as minorities—who may be deemed less worthy of diagnostic or therapeutic procedures or resources. What is particularly salient is that stereotypes tend to be activated most in environments where the individual is stressed, multitasking, and under the time pressure—the hallmarks of the clinical encounter.

Patient-Level Factors • ***MISTRUST*** Lack of trust has become a major concern for many health care institutions today. For example, an Institute of Medicine Report, *To Err Is Human: Building a Safer Health System,* documented alarming rates of medical errors and made patients feel vulnerable and less trustful of the U.S. health care system. The increased media and academic attention to problems of quality of care (and even disparities themselves) have clearly diminished trust in doctors and nurses.

Trust is a crucial element in the therapeutic alliance between patient and health care provider. It facilitates open communication and is directly correlated with adherence to physician recommendations and patient satisfaction. Patients who mistrust their health care providers are less satisfied with the care they receive, and mistrust of the health care system greatly affects patients' use of services. This lack of confidence in physicians also results in inconsistent care, doctor-shopping, self-medicating, and an increased demand for referrals and diagnostic tests by patients.

Based on historic factors of discrimination, segregation, and medical experimentation, African Americans may be especially mistrustful of providers. The exploitation of African Americans by the U.S. Public Health Service during the Tuskegee study left a legacy of mistrust that persists even today among this population. A national survey by the Kaiser Family Foundation found that there is significant mistrust of the health care system among minority populations. Of the 3884 individuals surveyed, 36% of Hispanics and 35% of African Americans (compared with 15% of whites) felt they were treated unfairly in the health care system in the past based on their race and ethnicity. Perhaps even more alarming, 65% of African Americans and 58% of Hispanics (compared with 22% of whites) were afraid of being treated unfairly in the future based on their race/ethnicity (Fig. e3-8).

This mistrust may contribute to wariness in accepting or following recommendations, undergoing invasive procedures, or participating in clinical research. This in turn may lead doctors to misunderstand

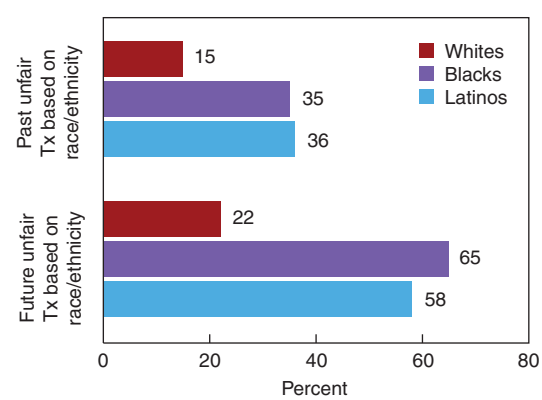

FIGURE e3-8 Patient perspectives regarding how fairly they have been treated in the health care system, by race/ethnicity. Reference population is 3884 individuals surveyed about how fairly they have been treated in the health care system in the past, and how fairly they feel they will be treated in the future based on their race/ethnicity. *(From Race, Ethnicity & Medical Care: A Survey of Public Perceptions and Experiences. Kaiser Family Foundation, 2005.)*

why African-American populations seem less adherent to or less interested in aggressive treatments.

KEY RECOMMENDATIONS TO ADDRESS RACIAL/ETHNIC DISPARITIES IN HEALTH CARE

The publication *Unequal Treatment* provides a series of recommendations to address racial and ethnic disparities in health care, focusing on a broad set of stakeholders. These include *health systems interventions*, *provider interventions*, and *patient interventions*, as well as *general recommendations.* These recommendations are described in more detail below.

Health System Interventions 1. *Collect and report health care access and utilization data by patient's race/ethnicity*

Unequal Treatment found that the appropriate systems to track and monitor racial and ethnic disparities in health care are lacking, and there is less known about the disparities for minority groups (Hispanics, Asian Americans, Pacific Islanders, Native Americans, and Alaska Natives) other than African Americans. For instance, only in the mid-1980s did the Medicare database begin to collect data on patient groups outside the standard categories of "white," "black," and "other." Federal, private, and state-supported data collection efforts are scattered and unsystematic, and many health care systems and hospitals, with a few notable exceptions, do not collect data on the race, ethnicity, or primary language of patients or enrollees. A Robert Wood Johnson Foundation survey found that 51% of health plans either ask members to provide their race voluntarily on enrollment and other forms, or use indirect methods to obtain aggregate data on race. Any effort to identify and address disparities must begin with the collection of race/ethnicity data and the stratification of quality measures by these groupings.

2. *Encourage the use of evidence-based guidelines and quality improvement*

Unequal Treatment highlights the subjectivity of clinical decision-making as a potential cause of racial and ethnic disparities in health care by describing how clinicians may offer different diagnostic and treatment options to different patients (consciously and unconsciously) based on their race or ethnicity, even in the presence of well-delineated practice guidelines. Therefore, the adoption and implementation of evidence-based guidelines broadly is a major recommendation to eliminate disparities. For instance, there now exist evidence-based guidelines for the management of diabetes, HIV/AIDS, cardiovascular diseases, cancer screening and management, and asthma—all areas where significant disparities exist. As part of ongoing quality improvement efforts, particular attention should be paid to the implementation of evidence-based guidelines for all patients, regardless of their race and ethnicity.

3. *Support the use of language interpretation services in the clinical setting*

As described previously, health care systems that lack interpreter services can lead to patient dissatisfaction, poor comprehension and compliance, and ineffective/lower-quality care for patients with limited English proficiency. *Unequal Treatment*'s recommendation to support the use of interpretation services has clear implications for delivery of quality health care by improving doctors' ability to communicate effectively with patients with limited English proficiency.

4. *Increase the proportion of underrepresented minorities in the health care workforce*

Recent data from the American Medical Association indicate that of the 70.5% of U.S. physicians whose race and ethnicity is known, Hispanics make up 3.5%, African Americans 2.6%, and American Indian and Alaska Natives less than 0.5% percent. Data regarding the racial/ethnic composition of medical school faculty are no different, with minorities composing only 4.2% nationally. It should further be noted that approximately 20% of these faculty teach at the four historically black medical schools and the three Liaison Committee on Medical Education (LCME)-accredited medical schools in Puerto Rico. Despite composing 30% of the population, minority students accounted for approximately 10% of medical school graduates in 2001. It will be difficult to develop a diverse health care workforce that can meet the needs of an increasingly diverse population without dramatic change in the racial and ethnic composition of medical student bodies.

Provider Interventions ***Integrate Cross-Cultural Education into the Training of All Health Care Professionals*** The goal of cross-cultural education is to improve providers' ability to understand, communicate with, and care for patients from diverse backgrounds; such education focuses on enhancing awareness of sociocultural influences on health beliefs and behaviors, and on providing skills to understand and manage these factors in the medical encounter. Cross-cultural education includes curricula on health care disparities, how to use an interpreter, and how to effectively communicate and negotiate across cultures. These curricula can be incorporated into health professions training in medical schools and nursing schools, and as part of continuing education. Despite the importance of this area of education, as well as the attention it has attracted from medical education accreditation bodies, a national survey of resident physicians by Weissman and colleagues found that more than one in five felt unprepared to deal with cross-cultural issues, including caring for patients who have religious beliefs that may affect treatment, patients who use complementary medicine, patients with health beliefs at odds with Western medicine, patients with mistrust of the health care system, and new immigrants. Efforts to incorporate cross-cultural education into undergraduate and graduate medical education will contribute to improving doctor-patient communication and to better quality of care.

Incorporate Teaching on the Impact of Race, Ethnicity, and Culture on Clinical Decision-Making *Unequal Treatment* found that stereotyping by health care providers might lead to disparate treatment based on a patient's race or ethnicity. The LCME—the body that accredits medical schools—now has a directive that medical education should teach how a patient's race, ethnicity, and culture might subconsciously impact on communication and clinical decision-making.

Patient Interventions ***Educate Patients on How to Navigate the Health Care System and How to Be More Active in the Medical Encounter*** Difficulty navigating the health care system and obtaining access to care can be a hindrance to all populations, particularly to minorities. Similarly, lack of empowerment or involvement in the medical encounter by minorities can be a barrier to care as well. Interventions should be used to increase patients' knowledge of how to best access care and participate in treatment decisions.

General Recommendations ***Increase Awareness of Racial/Ethnic Disparities in Health Care*** Recent surveys have shown that both physicians and the public tend to be unaware of the extent and severity of racial and ethnic disparities in health care in the United States. For example, a Kaiser Family Foundation survey of 2608 physicians whose primary activity is patient care found that the majority of respondents (mainly white) said that the health care system "never" (14%) or "rarely" (55%) treats people differently based on race/ethnicity. In 2003, shortly after the release of *Unequal Treatment*, a national survey was conducted in which individuals were asked "Do all Americans receive the same quality of health care?" Most thought so, and the majority of physicians felt patients were treated equally regardless of their race or ethnicity. These beliefs were held despite a large body of published research to the contrary. A poll in 2005 showed that the majority of Americans were actually unaware that racial and ethnic minorities receive poorer care than whites, with the lack of awareness being greatest among whites. Despite this lack of awareness, most believed that all Americans deserve quality care, regardless of their background. Increasing awareness of racial and ethnic disparities among health care professionals and the public is an important first step in addressing disparities in health care. The ultimate goal is to generate discourse and mobilize action to address disparities in multiple areas, including at the level of health policy, health systems, and the community.

Conduct Further Research to Identify Sources of Disparities and Promising Interventions While the literature that formed the basis of the findings and recommendations of *Unequal Treatment* provided significant evidence for racial and ethnic disparities, additional research is needed

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

in several areas. First, most of the literature on disparities focuses on black-versus-white differences; much less is known about the experiences of other minority groups. Improving the ability to collect racial and ethnic patient data should facilitate this process, but in instances where those systems are not yet in place, racial and ethnic patient data may be collected prospectively in the setting of clinical or health services research to better understand disparities for other populations. Second, much of the literature on disparities to date has focused on defining areas where they exist, but much less has been done to identify the multiple factors that contribute to disparities, and very little has been done to test interventions to address them. There is clearly a need for a research agenda that identifies promising practices and solutions to disparities.

IMPLICATIONS FOR CLINICAL PRACTICE

Individual health care providers can do several things in the clinical encounter to address racial and ethnic disparities in health care. These approaches are discussed here.

Be Aware That Disparities Exist Increasing awareness of racial and ethnic disparities among health care professionals is an important first step in addressing disparities in health care. Only then can they be attuned to monitoring their behavior and clinical practice so as to ensure that all patients receive the highest quality of care, regardless of their race, ethnicity, or culture.

Practice Culturally Competent Care Many have thought of "cultural competence" as simply the skills necessary for addressing language barriers in the clinical encounter, or learning as much as you can about patients from specific cultures. While the former is important and remains a key component of cultural competence, the latter is an area in evolution. Previous efforts in cultural competence have aimed to teach clinicians about the attitudes, values, beliefs, and behaviors of certain cultural groups—the key practice "do's and don'ts" for caring for "the Hispanic patient," for example. In certain situations, learning about a particular local community or cultural group can be helpful (following the principles of community-oriented primary care), but, when broadly and uncritically applied, this approach can also lead to stereotyping and oversimplification of culture without respect for its complexity.

Cultural competence has thus evolved from learning information and making assumptions about patients based on their background to focusing on the development of skills that follow the principles of patient-centered care. Patient-centeredness encompasses the qualities of compassion, empathy, and responsiveness to the needs, values, and expressed preferences of the individual patient. Cultural competence aims to take this a step further, by expanding the repertoire of knowledge and skills classically defined as patient-centered to include those that are especially useful in cross-cultural interactions (but remain vital to all clinical encounters). This includes eliciting the patient's understanding of his or her condition, identifying and negotiating different styles of communication, assessing decision-making preferences and the role of family, determining the patient's perception of biomedicine and complementary and alternative medicine, recognizing sexual and gender issues, and being aware of mistrust, prejudice, and racism, among others. For example, while it is important to understand all patients' health beliefs, it may be particularly crucial to understand the health beliefs of those who come from a different culture or have a different health care experience. With the individual patient as teacher, one can adjust their practice style accordingly to meet their specific needs.

Avoid Stereotyping Several strategies can allow us to counteract, both systemically and individually, our normal tendency to stereotype. For example, when racially/ethnically/culturally/socially diverse teams are assembled (in which each member is given equal power) and are tasked to achieve a common goal, a sense of camaraderie develops and prevents the future development of stereotypes based on race/ethnicity, gender, culture, or class. Thus, we should aim to gain experiences working with, and learning from, a diverse set of colleagues. In addition, simply being aware of the operation of social cognitive factors allows one to actively "check" or "monitor" behavior. For instance, physicians can constantly ensure that they are offering the same things, in the same ways, to all patients. Understanding how we are susceptible to stereotyping—and how this may lead to disparities—is essential if we are to provide equitable, high-quality care to all patients.

Work to Build Trust Patient mistrust of the health care system and health care providers impacts multiple facets of the medical encounter, from decreased patient satisfaction to the delay of care. Although the historic legacy of discrimination can never be erased, several steps can be taken to build trust with patients and address disparities. First, providers must be aware that mistrust exists and may be more prevalent among minority populations given this nation's history. Second, providers must reassure patients that they come first, and that we will do everything in our power to ensure that they always get the best care possible, and that we will serve as their advocates. Third, interpersonal skills and communication techniques that demonstrate honesty, openness, compassion, and respect on the part of the health care provider are essential tools in dismantling mistrust. Finally, patients indicate that trust is built when there is shared, participatory decision-making and the provider makes a concerted effort to understand the patient's background. By reframing the doctor-patient relationship as one of solidarity, the patient's sense of vulnerability can be transformed into one of trust. For the process of eliminating disparities to be successful, we must utilize trust-building interventions and strengthen the doctor-patient relationship.

New Areas for Exploration • ***DISPARITIES AND QUALITY IMPROVEMENT*** A major advance is that key health care stakeholders have begun to understand that disparities are an inequality in quality. Health plans and hospitals, for example, have begun to consider the importance of stratifying their quality data by race/ethnicity so as to identify disparities and develop interventions to address them. The emergence of targeting disparities through quality improvement has gained significant traction nationally, especially given the fact that the IOM report *Crossing the Quality Chasm* highlighted among its six pillars of quality the concept of equity—the principle that health outcomes should not vary based on personal characteristics such as race, ethnicity, and gender. There is no doubt that the quality approach to address disparities has great promise.

GEOGRAPHIC VARIATIONS IN CARE Where a patient lives can itself have a large impact on the level and quality of health care. Since black or Hispanic populations tend to live in different areas from non-Hispanic white populations, location likely matters in the measurement and interpretation of health (and health care) disparities. There is preliminary evidence to suggest wide variation in racial disparities across geographic lines: some areas have substantial disparities, while others have equal treatment. The problem of differences in quality of care across regions remains an important area of study and should remain a target of policy makers, as reducing quality disparities would play a major role in improving the health care received by all Americans and by minority Americans in particular.

CONCLUSION

The issue of racial and ethnic disparities in health care has gained national prominence, both with the release of the IOM report *Unequal Treatment* and with the many recent articles that have confirmed their persistence. Furthermore, another influential IOM report, *Crossing the Quality Chasm,* highlights the importance of equity—that there be no variations in quality of care by personal characteristics including race and ethnicity—as a central principle of quality. There are many obvious opportunities for interventions to eliminate racial and ethnic disparities in health care. Greater attention to addressing the root causes

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

of disparities will improve the care provided to all patients, not just those who are racial and ethnic minorities.

e4 Ethical Issues in Clinical Medicine

Bernard Lo

Physicians frequently confront ethical issues in clinical practice that are perplexing, time-consuming, and emotionally draining. Experience, common sense, and simply being a good person do not guarantee that physicians can identify or resolve ethical dilemmas. Knowledge about common ethical dilemmas is also essential.

FUNDAMENTAL ETHICAL GUIDELINES

Physicians should follow two fundamental but frequently conflicting ethical guidelines: respecting patient autonomy and acting in the patient's best interests.

RESPECTING PATIENT AUTONOMY

Treating patients with respect requires doctors to accept the medical decisions of persons who are informed and acting freely. Individuals place different values on health, medical care, and risk. In most clinical settings different goals and approaches are possible, outcomes are uncertain, and an intervention may cause both benefits and harms. Thus competent, informed patients may refuse recommended interventions and choose among reasonable alternatives.

Informed Consent For patients to make informed decisions, physicians need to discuss with them the nature of the proposed care, the alternatives, the risks and benefits of each, and the likely consequences, and to obtain the patient's agreement to care. Informed consent involves more than obtaining signatures on consent forms. Physicians need to educate patients, answer questions, make recommendations, and help them deliberate. Patients can be overwhelmed with medical jargon, needlessly complicated explanations, or too much information at once.

Nondisclosure of Information Physicians may consider withholding a serious diagnosis, misrepresenting it, or limiting discussions of prognosis or risks because they fear that a patient will develop severe anxiety or depression or refuse needed care. Generally, physicians should provide relevant information, while adjusting the pace of disclosure, offering empathy and hope, and helping patients cope with bad news.

In many cultures, patients traditionally are not told of a diagnosis of cancer or of other serious illness. In these cultures, disclosure of a grave diagnosis is believed to cause patients to suffer, while withholding information promotes serenity, security, and hope. Patients should not be forced to receive information against their will, even in the name of promoting informed decisions. However, many individuals in these groups want to know their diagnosis and prognosis, even if they are terminally ill. Health care providers therefore should ask patients how they want decisions to be made, saying that they usually provide information and make decisions together with patients, while offering patients the option not to receive information or to turn over decision-making to someone else.

Emergency Care Informed consent is not required when patients cannot give consent and when delay of treatment would place their lives or health in peril. People are presumed to want such emergency care, unless they have previously indicated otherwise.

Futile Interventions Autonomy does not entitle patients to insist on whatever care they want. Physicians are not obligated to provide futile interventions that have no physiologic rationale or have already failed. For example, cardiopulmonary resuscitation would be futile in a patient with progressive hypotension despite maximal therapy. But physicians should be wary of using the term "futile" in looser senses to justify unilateral decisions to forego interventions when they believe that the probability of success is too low, no worthwhile goals can be achieved, the patient's quality of life is unacceptable, or the costs are too high. Such looser usages of the term are problematic because they may be inconsistent and mask important value judgments.

Maintaining Confidentiality Confidentiality respects patients' autonomy and privacy, encourages them to seek treatment and discuss their problems candidly, and prevents discrimination. However, maintaining confidentiality is not an absolute rule. Confidentiality may be overridden in certain situations to prevent serious harm to third parties or to the patient. The law may require physicians to override confidentiality in order to protect third parties. For example, public health laws require reporting of tuberculosis and syphilis. In other situations, medical providers have a legal duty to report victims of elder abuse, child abuse, and domestic violence. These exceptions to confidentiality are justified because the risk is serious and probable, there are no less-restrictive measures to avert risk, the adverse effects of overriding confidentiality are minimized, and these adverse effects are deemed acceptable by society.

The recent HIPAA (Health Insurance Portability and Accountability Act) health privacy regulations have heightened awareness of the importance of confidentiality. These regulations are not meant to inhibit transmission of information needed for patient treatment: disclosure of patient information to other health care providers for the purposes of treatment without having the patient sign an authorization form is permissible.

Avoiding Deception Health care providers sometimes consider using lies or deception in order to protect the patient from bad news or to obtain benefits for the patient. Lying refers to statements that the speaker knows are false and that are intended to mislead the listener. Deception, which is broader, may be defined as statements and actions that are intended to mislead the listener, whether or not they are literally true. For example, the health care provider may tell a patient that she has a "small growth" so that she does not think she has cancer. Or the provider may complete and sign a form for a patient to get a bus pass, even though he does not meet the criteria for physical disability. Although such deception may be motivated by a desire to help the patient, it is ethically problematic. The person who is deceived cannot make informed decisions if they receive misleading information. Furthermore, deception undermines physicians' credibility and trustworthiness.

ACTING IN THE BEST INTERESTS OF PATIENTS

The guideline of beneficence requires physicians to act for the patient's benefit. Laypeople do not possess medical expertise and may be vulnerable because of their illness. They justifiably rely on physicians to provide sound advice and to promote their well-being. Physicians encourage such trust. Hence, physicians have a fiduciary duty to act in the best interests of their patients. The interests of the patient should prevail over physicians' self-interest or the interests of third parties, such as hospitals or insurers. These fiduciary obligations of physicians contrast sharply with business relationships, which are characterized by "let the buyer beware," not by trust and reliance. The guideline of "do no harm" forbids physicians from providing ineffective interventions or acting without due care. This precept, while often cited, provides only limited guidance, because many beneficial interventions also have serious risks.

CONFLICTS BETWEEN BENEFICENCE AND AUTONOMY

Patients' refusals of care may thwart their own goals or cause them serious harm. For example, a young man with asthma may refuse mechanical ventilation for reversible respiratory failure. Simply to accept such refusals, in the name of respecting autonomy, seems morally constricted. Physicians can elicit patients' expectations and concerns, correct misunderstandings, and try to persuade them to accept beneficial therapies. If disagreements persist after discussions, the patient's informed choices and view of his or her best interests should prevail. While refusing recommended care does not render a patient incompe-

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

tent, it may lead the physician to probe further to ensure that the patient is able to make informed decisions.

JUSTICE

The term *justice* is used in a general sense to mean fairness: people should receive what they deserve. In addition, it is important to act consistently in cases that are similar in ethically relevant ways. Otherwise, decisions would be arbitrary, biased, and unfair. Justice forbids discrimination in health care based on race, religion, or gender and supports a moral right to health care, with access based on medical need rather than ability to pay.

PATIENTS WHO LACK DECISION-MAKING CAPACITY

Patients may not be able to make informed decisions because of unconsciousness, dementia, delirium, or other conditions. Physicians should ask two questions regarding such patients: Who is the appropriate surrogate? What would the patient want done?

ASSESSING CAPACITY TO MAKE MEDICAL DECISIONS

All adults are considered legally competent unless declared incompetent by a court. In practice, physicians usually determine that patients lack the capacity to make health care decisions and arrange for surrogates to make them, without involving the courts. By definition, competent patients can express a choice and appreciate the medical situation; the nature of the proposed care; the alternatives; and the risks, benefits, and consequences of each. Their choices should be consistent with their values and should not result from delusions or hallucinations. Psychiatrists may help in difficult cases because they are skilled at interviewing mentally impaired patients and can identify treatable depression or psychosis. When impairments are fluctuating or reversible, decisions should be postponed if possible until the patient recovers decision-making capacity.

CHOICE OF SURROGATE

If a patient lacks decision-making capacity, physicians routinely ask family members to serve as surrogates. Most patients want their family members to be surrogates, and family members generally know the patient's preferences and have the patient's best interests at heart. Patients may designate a particular individual to serve as proxy; such choices should be respected. Some states have established a prioritized list of which relative may serve as surrogate if the patient has not designated a proxy.

STANDARDS FOR SURROGATE DECISION-MAKING

Advance Directives These are statements by competent patients to direct care if they lose decision-making capacity. They may indicate (1) what interventions they would refuse or accept, or (2) who should serve as surrogate. Following the patient's advance directives, the surrogate respects the patient's autonomy.

Oral conversations are the most frequent form of advance directives. While such conversations are customarily followed in clinical practice, casual or vague comments may not be trustworthy. Living wills direct physicians to forego or provide life-sustaining interventions if the patient develops a terminal condition or persistent vegetative state. Generally patients may refuse only interventions that "merely prolong the process of dying."

A health care proxy is someone appointed by the patient to make health care decisions if he or she loses decision-making capacity. It is more flexible and comprehensive than the living will, applying whenever the patient is unable to make decisions.

Physicians can encourage patients to provide advance directives, to indicate both what they would want and who should be the surrogate, and to discuss their preferences with surrogates. In discussions with patients, physicians can ensure that advance directives are informed, up-to-date, and address likely clinical scenarios. Such discussions are best carried out in the ambulatory setting. The federal Patient Self-Determination Act requires hospitals and health maintenance organizations to inform patients of their right to make health care decisions and to provide advance directives.

Substituted Judgment In the absence of clear advance directives, surrogates and physicians should try to decide as the patient would under the circumstances, using all information that they know about the patient. While such substituted judgments try to respect the patient's values, they may be speculative or inaccurate. A surrogate may be mistaken about the patient's preferences, particularly when they have not been discussed explicitly.

Best Interests When the patient's preferences are unclear or unknown, decisions should be based on the patient's best interests. Patients generally take into account the quality of life as well as the duration of life when making decisions for themselves. It is understandable that surrogates would also consider quality of life of patients who lack decision-making capacity. Judgments about quality of life are appropriate if they reflect the patient's own values. Bias or discrimination may occur, however, if others project their values onto the patient or weigh the perceived social worth of the patient. Most patients with chronic illness rate their quality of life higher than their family members and physicians do.

Legal Issues Physicians need to know pertinent state laws regarding patients who lack decision-making capacity. A few state courts allow doctors to forego life-sustaining interventions only if patients have provided written advance directives or very specific oral ones.

Disagreements Disagreements may occur among potential surrogates or between the physician and surrogate. Physicians can remind everyone to base decisions on what the patient would want, not what they would want for themselves. Consultation with the hospital ethics committee or with another physician often helps resolve disputes. Such consultation is also helpful when patients have no surrogate and no advance directives. The courts should be used only as a last resort when disagreements cannot be resolved in the clinical setting.

DECISIONS ABOUT LIFE-SUSTAINING INTERVENTIONS

Although medical technology can save lives, it can also prolong the process of dying. Competent, informed patients may refuse life-sustaining interventions. When patients lack decision-making capacity, such interventions may also be withheld on the basis of advance directives or decisions by appropriate surrogates. Courts have ruled that foregoing life-sustaining interventions is neither suicide nor murder.

MISLEADING DISTINCTIONS

People commonly draw distinctions that are intuitively plausible but prove untenable on closer analysis.

Extraordinary and Ordinary Care Some physicians are willing to forego "extraordinary" or "heroic" interventions, such as surgery, mechanical ventilation, or renal dialysis but insist on providing "ordinary" ones, such as antibiotics, IV fluids, or feeding tubes. However, this distinction is not logical because all medical interventions have both risks and benefits. Any intervention may be withheld, if the burdens for the individual patient outweigh the benefits.

Withdrawing and Withholding Interventions Many health care providers find it more difficult to discontinue interventions than to withhold them in the first place. Although such emotions need to be acknowledged, there is no logical distinction between the two acts. Justifications for withholding interventions, such as refusal by patients or surrogates, are also justifications for withdrawing them. In addition, after an intervention has been started, new data may indicate that it is no longer appropriate. The intervention may prove unsuccessful, or it may be learned that the patient did not want the intervention. If interventions could never be discontinued, patients and surrogates might not even attempt treatments that might prove beneficial.

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

DO NOT RESUSCITATE (DNR) ORDERS

When a patient suffers a cardiopulmonary arrest, cardiopulmonary resuscitation (CPR) is initiated unless a DNR order has been made. Although CPR can restore people to vigorous health, it can also disrupt a peaceful death. After CPR is attempted on a general hospital service, only 14% of patients survive to discharge, and even fewer in certain subgroups. DNR orders are appropriate if the patient or surrogate requests them or if CPR would be futile. To prevent misunderstandings, physicians should write DNR orders and the reasons for them in the medical record. "Slow" or "show" codes that merely appear to provide CPR are deceptive and therefore unacceptable. Although a DNR order signifies only that CPR will be withheld, the reasons that justify DNR orders may lead to a reconsideration of other plans for care.

ASSISTED SUICIDE AND ACTIVE EUTHANASIA

Proponents of these controversial acts believe that competent, terminally ill patients should have control over the end of life and that physicians should relieve refractory suffering. Opponents assert that such actions violate the sanctity of life, that suffering can generally be relieved, that abuses are inevitable, and that such actions are outside the physician's proper role. These actions are illegal throughout the United States, except that physician-assisted suicide is legal in Oregon under restricted circumstances. Whatever their personal views, physicians should respond to patients' inquiries about these actions with compassion and concern. Physicians should elicit and address any underlying problems, such as physical symptoms, loss of control, or depression. Often, additional efforts to relieve distress are successful, and after this is done patients generally withdraw their requests for these acts.

CARE OF DYING PATIENTS

Patients often suffer unrelieved pain and other symptoms during their final days of life. Physicians may hesitate to order high doses of narcotics and sedatives, fearing they will hasten death. Relieving pain in terminal illness and alleviating dyspnea when patients forego mechanical ventilation enhances patient comfort and dignity. If lower doses of narcotics and sedatives have failed to relieve suffering, increasing the dose to levels that might suppress respiratory drive or lower blood pressure is ethically appropriate because the physician's intention is to relieve suffering, not hasten death. Such palliative sedation is distinguished ethically and legally from active euthanasia, which is administering a lethal dose with the intention of ending the patient's life. Physicians can also relieve suffering by spending time with dying patients, listening to them, and attending to their psychological distress.

CONFLICTS OF INTEREST

Acting in the patient's best interests may conflict with the physician's self-interest or the interests of third parties such as insurers or hospitals. The ethical ideal is to keep the patient's interests paramount. Even the appearance of a conflict of interest may undermine trust in the profession.

FINANCIAL INCENTIVES

In managed care systems, physicians may serve as gatekeepers or bear financial risk for expenditures. Although such incentives are intended to reduce inefficiency and waste, there is concern that physicians may withhold beneficial care in order to control costs. In contrast, physicians have incentives to provide more care than indicated when they receive fee-for-service reimbursement or when they refer patients to laboratory or imaging facilities in which they have invested. Regardless of financial incentives, physicians should recommend available care that is in the patient's best interests, no more and no less.

GIFTS FROM PHARMACEUTICAL COMPANIES

Physicians may be offered gifts ranging from pens and notepads to lavish entertainment. Critics contend that any gift from drug companies can impair objectivity, increase the cost of health care, and give the appearance of conflict of interest. A helpful rule of thumb is to consider whether patients would approve of the gift if they knew physicians had accepted it.

OCCUPATIONAL RISKS

Some health care workers, fearing fatal occupational infections, refuse to care for persons with HIV infection or multidrug-resistant tuberculosis. Such fears about personal safety need to be acknowledged, and health care institutions should reduce occupational risk by providing proper training, protective equipment, and supervision. To fulfill their mission of helping patients, physicians should provide appropriate care within their clinical expertise, despite some personal risk.

MEDICAL ERRORS

Errors are inevitable in clinical medicine. They may cause serious harm to patients or result in substantial changes in management. Physicians and students may fear that disclosing such errors could damage their careers. Without disclosure, however, patients cannot understand their clinical situation or make informed choices about subsequent care. Furthermore, patients are often outraged when physicians do not acknowledge errors. Similarly, unless attending physicians are informed of trainees' errors, they cannot provide optimal care and help trainees learn from mistakes.

LEARNING CLINICAL SKILLS

Learning clinical medicine, particularly learning to perform invasive procedures, may present inconvenience or risk to patients. To ensure patient cooperation, students may be introduced as physicians or patients may not be told that trainees will be performing procedures. Such misrepresentation undermines trust, may lead to more elaborate deception, and makes it difficult for patients to make informed choices about their care. Patients should be told who is providing care, what benefits and burdens can be attributed to trainees, and how trainees are supervised. Most patients, when informed, allow trainees to play an active role in their care.

IMPAIRED PHYSICIANS

Physicians may hesitate to intervene when colleagues impaired by alcohol abuse, drug abuse, or psychiatric or medical illness place patients at risk. However, society relies on physicians to regulate themselves. If colleagues of an impaired physician do not take steps to protect patients, no one else may be in a position to do so.

CONFLICTS FOR TRAINEES

Medical students and residents may fear that they will receive poor grades or evaluations if they act on the patient's behalf by disclosing mistakes, avoiding misrepresentation of their role, and reporting impaired colleagues. Discussing such dilemmas with more senior physicians can help trainees check their interpretation of the situation and obtain advice and assistance.

ALLOCATING RESOURCES JUSTLY

Patient access to needed care is a moral aspiration rather than established public policy in the United States. Physicians caring for underserved populations must act ethically in a health care system that has serious ethical shortcomings in access to and quality of care. Some patients with a clear need for medical care cannot pay for medications, tests, or hospitalizations, or the insurer may deny coverage. If this occurs, physicians should advocate for patients, trying to help them obtain essential care. Doctors might consider, or patients might request, using lying or deception to help them gain such benefits. While physicians understandably want to help patients, such misrepresentation undermines physicians' credibility and trustworthiness. Avoiding deception is a basic ethical guideline that sets limits on advocating for patients. Allocation of health care resources is unavoidable because re-

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

sources are limited. Ideally, allocation decisions should be made as public policy, with physician input. Allocation of resources at the bedside is problematic because it may be inconsistent, unfair, and ineffective. At the bedside, physicians generally should act as patient advocates within constraints set by society, reasonable insurance coverage, and evidence-based practice. For example, a patient's insurer may have a higher co-payment for non-formulary drugs. It is reasonable for physicians to advocate for non-formulary drugs only if there are compelling reasons for an exception, as when the formulary drugs are ineffective or not tolerated.

ASSISTANCE WITH ETHICAL ISSUES

Discussing perplexing ethical issues with other members of the health care team, colleagues, or the hospital ethics committee often clarifies issues and suggests ways to improve communication and to deal with strong emotions. When struggling with difficult ethical issues, physicians may need to reevaluate their basic convictions, tolerate uncertainty, and maintain their integrity while respecting the opinions of others.

12 Pain: Pathophysiology and Management

Howard L. Fields, Joseph B. Martin

The task of medicine is to preserve and restore health and to relieve suffering. Understanding pain is essential to both these goals. Because pain is universally understood as a signal of disease, it is the most common symptom that brings a patient to a physician's attention. The function of the pain sensory system is to protect the body and maintain homeostasis. It does this by detecting, localizing, and identifying tissue-damaging processes. Since different diseases produce characteristic patterns of tissue damage, the quality, time course, and location of a patient's pain complaint and the location of tenderness provide important diagnostic clues and are used to evaluate the response to treatment. Once this information is obtained, it is the obligation of the physician to provide rapid and effective pain relief.

THE PAIN SENSORY SYSTEM

Pain is an unpleasant sensation localized to a part of the body. It is often described in terms of a penetrating or tissue-destructive process (e.g., stabbing, burning, twisting, tearing, squeezing) and/or of a bodily or emotional reaction (e.g., terrifying, nauseating, sickening). Furthermore, any pain of moderate or higher intensity is accompanied by anxiety and the urge to escape or terminate the feeling. These properties illustrate the duality of pain: it is both sensation and emotion. When acute, pain is characteristically associated with behavioral arousal and a stress response consisting of increased blood pressure, heart rate, pupil diameter, and plasma cortisol levels. In addition, local muscle contraction (e.g., limb flexion, abdominal wall rigidity) is often present.

PERIPHERAL MECHANISMS

The Primary Afferent Nociceptor A peripheral nerve consists of the axons of three different types of neurons: primary sensory afferents, motor neurons, and sympathetic postganglionic neurons (Fig. 12-1). The cell bodies of primary sensory afferents are located in the dorsal root ganglia in the vertebral foramina. The primary afferent axon bifurcates to send one process into the spinal cord and the other to innervate tissues. Primary afferents are classified by their diameter, degree of myelination, and conduction velocity. The largest-diameter fibers, A-beta (Aβ), respond maximally to light touch and/or moving stimuli; they are present primarily in nerves that innervate the skin. In normal individuals, the activity of these fibers does not produce pain. There are two other classes of primary afferents: the small-diameter myelinated A-delta (Aδ) and the unmyelinated (C fiber) axons (Fig. 12-1). These fibers are present in nerves to the skin and to deep somatic and visceral structures. Some tissues, such as the cornea, are innervated only by Aδ and C afferents. Most Aδ and C afferents respond maximally only to intense (painful) stimuli and produce the subjective experience of pain when they are electrically stimulated; this defines them as *primary afferent nociceptors* (*pain receptors*). The ability to detect painful stimuli is completely abolished when Aδ and C axons are blocked.

Individual primary afferent nociceptors can respond to several different types of noxious stimuli. For example, most nociceptors respond to heating, intense cold, intense mechanical stimuli such as a pinch, and application of irritating chemicals including ATP, serotonin, bradykinin and histamine.

Sensitization When intense, repeated, or prolonged stimuli are applied to damaged or inflamed tissues, the threshold for activating primary afferent nociceptors is lowered and the frequency of firing is higher for all stimulus intensities. Inflammatory mediators such as bradykinin, nerve growth factor, some prostaglandins, and leukotrienes contribute to this process, which is called *sensitization*. In sensitized tissues, normally innocuous stimuli can produce pain. Sensitization is a clinically important process that contributes to tenderness, soreness, and hyperalgesia. A striking example of sensitization is sunburned skin, in which severe pain can be produced by a gentle slap on the back or a warm shower.

Sensitization is of particular importance for pain and tenderness in deep tissues. Viscera are normally relatively insensitive to noxious mechanical and thermal stimuli, although hollow viscera do generate significant discomfort when distended. In contrast, when affected by a disease process with an inflammatory component, deep structures such as joints or hollow viscera characteristically become exquisitely sensitive to mechanical stimulation.

A large proportion of Aδ and C afferents innervating viscera are completely insensitive in normal noninjured, noninflamed tissue. That is, they cannot be activated by known mechanical or thermal stimuli and are not spontaneously active. However, in the presence of inflammatory mediators, these afferents become sensitive to mechanical stimuli. Such afferents have been termed *silent nociceptors*, and

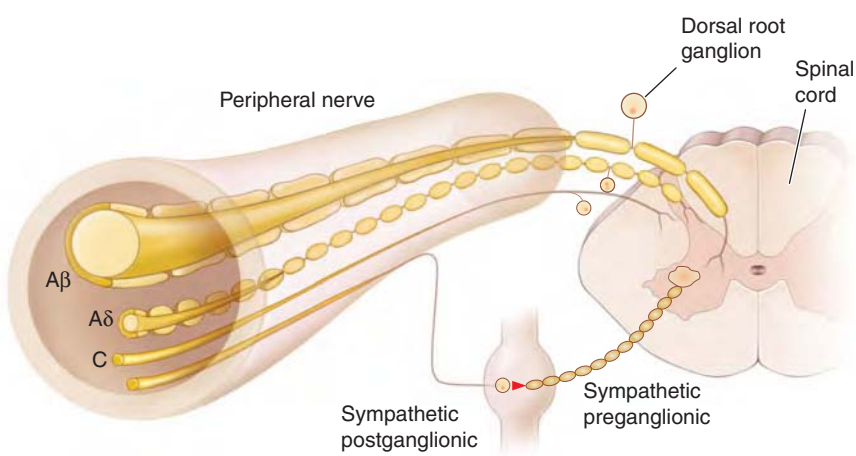

FIGURE 12-1 Components of a typical cutaneous nerve. There are two distinct functional categories of axons: primary afferents with cell bodies in the dorsal root ganglion, and sympathetic postganglionic fibers with cell bodies in the sympathetic ganglion. Primary afferents include those with large-diameter myelinated (Aβ), small-diameter myelinated (Aδ), and unmyelinated (C) axons. All sympathetic postganglionic fibers are unmyelinated.

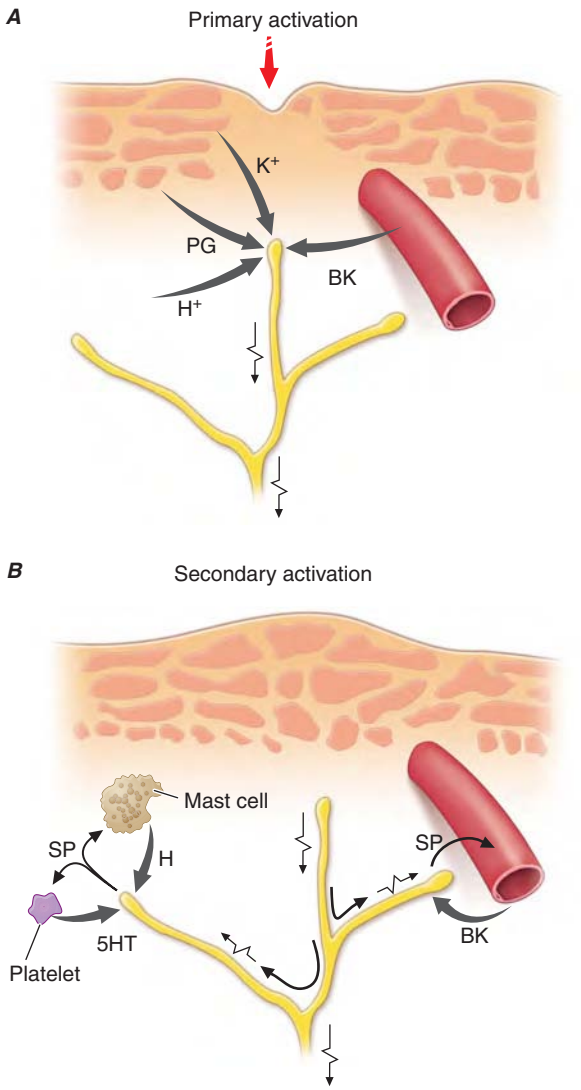

FIGURE 12-2 Events leading to activation, sensitization, and spread of sensitization of primary afferent nociceptor terminals. ***A.*** Direct activation by intense pressure and consequent cell damage. Cell damage induces lower pH (H^+) and leads to release of potassium (K^+) and to synthesis of prostaglandins (PG) and bradykinin (BK). Prostaglandins increase the sensitivity of the terminal to bradykinin and other pain-producing substances. ***B.*** Secondary activation. Impulses generated in the stimulated terminal propagate not only to the spinal cord but also into other terminal branches where they induce the release of peptides, including substance P (SP). Substance P causes vasodilation and neurogenic edema with further accumulation of bradykinin. Substance P also causes the release of histamine (H) from mast cells and serotonin (5HT) from platelets.

their characteristic properties may explain how under pathologic conditions the relatively insensitive deep structures can become the source of severe and debilitating pain and tenderness. Low pH, prostaglandins, leukotrienes, and other inflammatory mediators such as bradykinin play a significant role in sensitization.

Nociceptor-Induced Inflammation Primary afferent nociceptors also have a neuroeffector function. Most nociceptors contain polypeptide mediators that are released from their peripheral terminals when they are activated (Fig. 12-2). An example is substance P, an 11-amino-acid peptide. Substance P is released from primary afferent nociceptors and has multiple biologic activities. It is a potent vasodilator, degranulates mast cells, is a chemoattractant for leukocytes, and increases the production and release of inflammatory mediators. Interestingly, depletion of substance P from joints reduces the severity of experimental arthritis. Primary afferent nociceptors are not simply passive messengers of threats to tissue injury but also play an active role in tissue protection through these neuroeffector functions.

CENTRAL MECHANISMS

The Spinal Cord and Referred Pain The axons of primary afferent nociceptors enter the spinal cord via the dorsal root. They terminate in the dorsal horn of the spinal gray matter (Fig. 12-3). The terminals of primary afferent axons contact spinal neurons that transmit the pain signal to brain sites involved in pain perception. When primary afferents are activated by noxious stimuli, they release neurotransmitters from their terminals that excite the spinal cord neurons. The major neurotransmitter they release is glutamate, which rapidly excites dorsal horn neurons. Primary afferent nociceptor terminals also release peptides, including substance P and calcitonin gene-related peptide, which produce a slower and longer-lasting excitation of the dorsal horn neurons. The axon of each primary afferent contacts many spinal neurons, and each spinal neuron receives convergent inputs from many primary afferents.

The convergence of sensory inputs to a single spinal pain-transmission neuron is of great importance because it underlies the phenomenon of referred pain. All spinal neurons that receive input from the viscera and deep musculoskeletal structures also receive input from the skin. The convergence patterns are determined by the spinal segment of the dorsal root ganglion that supplies the afferent innervation of a structure. For example, the afferents that supply the central diaphragm are derived from the third and fourth cervical dorsal root ganglia. Primary afferents with cell bodies in these same ganglia supply the skin of the shoulder and lower neck. Thus, sensory inputs from both the shoulder skin and the central diaphragm converge on pain-transmission neurons in the third and fourth cervical spinal segments. *Because of this convergence and the fact that the spinal neurons are most often activated by inputs from the skin, activity evoked in spinal neurons by input from deep structures is mislocalized by the patient to a place that is roughly coextensive with the region of skin innervated by the same spinal segment.* Thus, inflammation near the central diaphragm is usually reported as discomfort near the shoulder. This spatial displacement of pain sensation from the site of the injury that produces it is known as *referred pain*.

Ascending Pathways for Pain A majority of spinal neurons contacted by primary afferent nociceptors send their axons to the contralateral thalamus. These axons form the contralateral spinothalamic tract, which lies in the anterolateral white matter of the spinal cord, the lateral edge of the medulla, and the lateral pons and midbrain. The spinothalamic pathway is crucial for pain sensation in humans. Interruption of this pathway produces permanent deficits in pain and temperature discrimination.

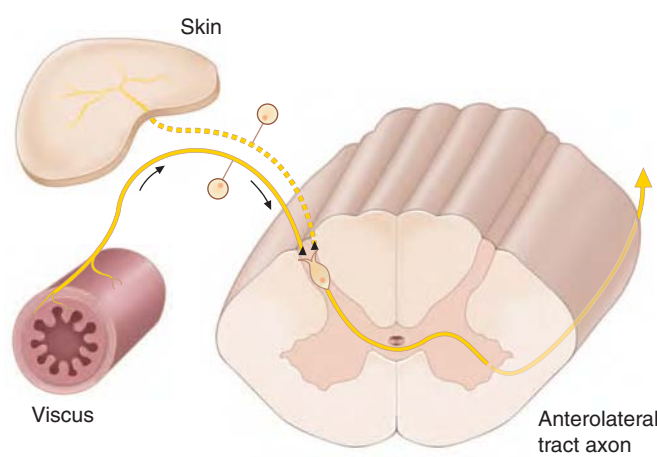

FIGURE 12-3 The convergence-projection hypothesis of referred pain. According to this hypothesis, visceral afferent nociceptors converge on the same pain-projection neurons as the afferents from the somatic structures in which the pain is perceived. The brain has no way of knowing the actual source of input and mistakenly "projects" the sensation to the somatic structure.

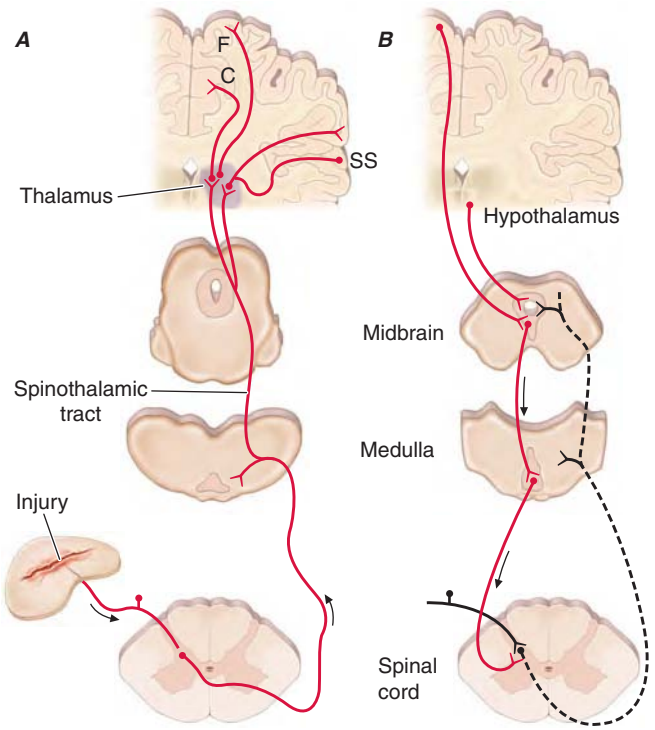

FIGURE 12-4 Pain transmission and modulatory pathways. *A.* Transmission system for nociceptive messages. Noxious stimuli activate the sensitive peripheral ending of the primary afferent nociceptor by the process of transduction. The message is then transmitted over the peripheral nerve to the spinal cord, where it synapses with cells of origin of the major ascending pain pathway, the spinothalamic tract. The message is relayed in the thalamus to the anterior cingulate (C), frontal insular (F), and somatosensory cortex (SS). ***B.*** Pain-modulation network. Inputs from frontal cortex and hypothalamus activate cells in the midbrain that control spinal pain-transmission cells via cells in the medulla.

Spinothalamic tract axons ascend to several regions of the thalamus. There is tremendous divergence of the pain signal from these thalamic sites to broad areas of the cerebral cortex that subserve different aspects of the pain experience (Fig. 12-4). One of the thalamic projections is to the somatosensory cortex. This projection mediates the purely sensory aspects of pain, i.e., its location, intensity, and quality. Other thalamic neurons project to cortical regions that are linked to emotional responses, such as the cingulate gyrus and other areas of the frontal lobes, including the insular cortex. These pathways to the frontal cortex subserve the affective or unpleasant emotional dimension of pain. This affective dimension of pain produces suffering and exerts potent control of behavior. Because of this dimension, fear is a constant companion of pain.

PAIN MODULATION

The pain produced by injuries of similar magnitude is remarkably variable in different situations and in different individuals. For example, athletes have been known to sustain serious fractures with only minor pain, and Beecher's classic World War II survey revealed that many soldiers in battle were unbothered by injuries that would have produced agonizing pain in civilian patients. Furthermore, even the suggestion of relief can have a significant analgesic effect (placebo). On the other hand, many patients find even minor injuries (such as venipuncture) frightening and unbearable, and the expectation of pain has been demonstrated to induce pain without a noxious stimulus.

The powerful effect of expectation and other psychological variables on the perceived intensity of pain implies the existence of brain circuits that can modulate the activity of the pain-transmission pathways. One of these circuits has links in the hypothalamus, midbrain, and medulla, and it selectively controls spinal pain-transmission neurons through a descending pathway (Fig. 12-4).

Human brain imaging studies have implicated this pain-modulating circuit in the pain-relieving effect of attention, suggestion, and opioid analgesic medications. Furthermore, each of the component structures of the pathway contains opioid receptors and is sensitive to the direct application of opioid drugs. In animals, lesions of the system reduce the analgesic effect of systemically administered opioids such as morphine. Along with the opioid receptor, the component nuclei of this pain-modulating circuit contain endogenous opioid peptides such as the enkephalins and β-endorphin.

The most reliable way to activate this endogenous opioid-mediated modulating system is by prolonged pain and/or fear. There is evidence that pain-relieving endogenous opioids are released following surgical procedures and in patients given a placebo for pain relief.

Pain-modulating circuits can enhance as well as suppress pain. Both pain-inhibiting and pain-facilitating neurons in the medulla project to and control spinal pain-transmission neurons. Since pain-transmission neurons can be activated by modulatory neurons, it is theoretically possible to generate a pain signal with no peripheral noxious stimulus. In fact, human functional imaging studies have demonstrated increased activity in this circuit during migraine headache. A central circuit that facilitates pain could account for the finding that pain can be induced by suggestion or enhanced by expectation, and it could provide a framework for understanding how psychological factors can contribute to chronic pain.

NEUROPATHIC PAIN

Lesions of the peripheral or central nervous pathways for pain typically result in a loss or impairment of pain sensation. Paradoxically, damage to or dysfunction of these pathways can produce pain. For example, damage to peripheral nerves, as occurs in diabetic neuropathy, or to primary afferents, as in herpes zoster, can result in pain that is referred to the body region innervated by the damaged nerves. Though rare, pain may also be produced by damage to the central nervous system, particularly the spinothalamic pathway or thalamus. Such neuropathic pains are often severe and are notoriously intractable to standard treatments for pain.

Neuropathic pains typically have an unusual burning, tingling, or electric shock–like quality and may be triggered by very light touch. These features are rare in other types of pain. On examination, a sensory deficit is characteristically present in the area of the patient's pain. Hyperpathia is also characteristic of neuropathic pain; patients often complain that the very lightest moving stimuli evoke exquisite pain (allodynia). In this regard it is of clinical interest that a topical preparation of 5% lidocaine in patch form is effective for patients with postherpetic neuralgia who have prominent allodynia.

A variety of mechanisms contribute to neuropathic pain. As with sensitized primary afferent nociceptors, damaged primary afferents, including nociceptors, become highly sensitive to mechanical stimulation and begin to generate impulses in the absence of stimulation. There is evidence that this increased sensitivity and spontaneous activity is due to an increased concentration of sodium channels. Damaged primary afferents may also develop sensitivity to norepinephrine. Interestingly, spinal cord pain-transmission neurons cut off from their normal input may also become spontaneously active. Thus, both central and peripheral nervous system hyperactivity contribute to neuropathic pain.

Sympathetically Maintained Pain Patients with peripheral nerve injury can develop a severe burning pain (causalgia) in the region innervated by the nerve. The pain typically begins after a delay of hours to days or even weeks. The pain is accompanied by swelling of the extremity, periarticular osteoporosis, and arthritic changes in the distal joints. The pain is dramatically and immediately relieved by blocking the sympathetic innervation of the affected extremity. Damaged primary afferent nociceptors acquire adrenergic sensitivity and can be activated by stimulation of the sympathetic outflow. A similar syndrome called *reflex sympathetic dystrophy* can be produced without obvious nerve damage by a variety of injuries, including fractures of bone, soft tissue trauma, myocardial infarction, and stroke (Chap. 370). Although the pathophysiology of this condition is poorly understood, the pain and the signs of inflammation are rapidly relieved by blocking the sympathetic nervous

TABLE 12-1 DRUGS FOR RELIEF OF PAIN

Generic Name	Dose, mg	Interval	Comments
Nonnarcotic Analgesics: Usual Doses and Intervals			
Acetylsalicylic acid	650 PO	q 4 h	Enteric-coated preparations available
Acetaminophen	650 PO	q 4 h	Side effects uncommon
Ibuprofen	400 PO	q 4–6 h	Available without prescription
Naproxen	250–500 PO	q 12 h	Delayed effects may be due to long half-life
Fenoprofen	200 PO	q 4–6 h	Contraindicated in renal disease
Indomethacin	25–50 PO	q 8 h	Gastrointestinal side effects common
Ketorolac	15–60 IM/IV	q 4–6 h	Available for parenteral use
Celecoxib	100–200 PO	q 12–24 h	Useful for arthritis
Valdecoxib	10–20 PO	q12–24 h	Removed from U.S. market in 2005

Generic Name	Parenteral Dose, mg	PO Dose, mg	Comments
Narcotic Analgesics: Usual Doses and Intervals			
Codeine	30–60 q 4 h	30–60 q 4 h	Nausea common
Oxycodone	—	5–10 q 4–6 h	Usually available with acetaminophen or aspirin
Morphine	10 q 4 h	60 q 4 h	
Morphine sustained release	—	30–200 bid to tid	Oral slow-release preparation
Hydromorphone	1–2 q 4 h	2–4 q 4 h	Shorter acting than morphine sulfate
Levorphanol	2 q 6–8 h	4 q 6–8 h	Longer acting than morphine sulfate; absorbed well PO
Methadone	10 q 6–8 h	20 q 6–8 h	Delayed sedation due to long half-life
Meperidine	75–100 q 3–4 h	300 q 4 h	Poorly absorbed PO; normeperidine a toxic metabolite
Butorphanol	—	1–2 q 4 h	Intranasal spray
Fentanyl	25–100 μg/h	—	72 h Transdermal patch
Tramadol	—	50–100 q 4–6 h	Mixed opioid/adrenergic action

Generic Name	Uptake Blockade 5-HT	Uptake Blockade NE	Sedative Potency	Anticholinergic Potency	Orthostatic Hypotension	Cardiac Arrhythmia	Ave. Dose, mg/d	Range, mg/d
Antidepressants[a]								
Doxepin	++	+	High	Moderate	Moderate	Less	200	75–400
Amitriptyline	++++	++	High	Highest	Moderate	Yes	150	25–300
Imipramine	++++	++	Moderate	Moderate	High	Yes	200	75–400
Nortriptyline	+++	++	Moderate	Moderate	Low	Yes	100	40–150
Desipramine	+++	++++	Low	Low	Low	Yes	150	50–300
Venlafaxine	+++	++	Low	None	None	No	150	75–400
Duloxetine	+++	+++	Low	None	None	No	40	30–60

Generic Name	PO Dose, mg	Interval	Generic Name	PO Dose, mg	Interval
Anticonvulsants and Antiarrhythmics[a]					
Phenytoin	300	daily/qhs	Clonazepam	1	q 6 h
Carbamazepine	200–300	q 6 h	Gabapentin[b]	600–1200	q 8 h
Oxcarbazine	300	bid	Pregabalin	150–600	bid

[a]Antidepressants, anticonvulsants, and antiarrhythmics have not been approved by the U.S. Food and Drug Administration (FDA) for the treatment of pain.

[b]Gabapentin in doses up to 1800 mg/d is FDA approved for postherpetic neuralgia.

Note: 5-HT, serotonin; NE, norepinephrine.

system. This implies that sympathetic activity can activate undamaged nociceptors when inflammation is present. Signs of sympathetic hyperactivity should be sought in patients with posttraumatic pain and inflammation and no other obvious explanation.

℞ ACUTE PAIN

The ideal treatment for any pain is to remove the cause; thus, diagnosis should always precede treatment planning. Sometimes treating the underlying condition does not immediately relieve pain. Furthermore, some conditions are so painful that rapid and effective analgesia is essential (e.g., the postoperative state, burns, trauma, cancer, sickle cell crisis). Analgesic medications are a first line of treatment in these cases, and all practitioners should be familiar with their use.

ASPIRIN, ACETAMINOPHEN, AND NONSTEROIDAL ANTI-INFLAMMATORY AGENTS (NSAIDS) These drugs are considered together because they are used for similar problems and may have a similar mechanism of action **(Table 12-1)**. All these compounds inhibit cyclooxygenase (COX), and, except for acetaminophen, all have anti-inflammatory actions, especially at higher dosages. They are particularly effective for mild to moderate headache and for pain of musculoskeletal origin.

Since they are effective for these common types of pain and are available without prescription, COX inhibitors are by far the most commonly used analgesics. They are absorbed well from the gastrointestinal tract and, with occasional use, have only minimal side effects. With chronic use, gastric irritation is a common side effect of aspirin and NSAIDs and is the problem that most frequently limits the dose that can be given. Gastric irritation is most severe with aspirin, which may cause erosion and ulceration of the gastric mucosa leading to bleeding or perforation. Because aspirin irreversibly acetylates platelets and thereby interferes with coagulation of the blood, gastrointestinal bleeding is a particular risk. Increased age and history of gastrointestinal disease increase the risks of aspirin and NSAIDs. In addition to NSAIDs' well-known gastrointestinal toxicity, nephrotoxicity is a significant problem for patients using them on a chronic basis, and patients at risk for renal insufficiency should be monitored closely. NSAIDs also cause an increase in blood pressure in a significant number of individuals. Long-term treatment with NSAIDs requires regular blood pressure monitoring and treatment if necessary. Although toxic to the liver when taken in a high dose, acetaminophen rarely produces gastric irritation and does not interfere with platelet function.

The introduction of a parenteral form of NSAID, ketorolac, extends the usefulness of this class of compounds in the management of acute severe pain. Ketorolac is sufficiently potent and rapid in onset to supplant opioids for many patients with acute severe headache and musculoskeletal pain.

There are two major classes of COX: COX-1 is constitutively expressed, and COX-2 is induced in the inflammatory state. COX-2–selective drugs have moderate analgesic potency and produce less gastric irritation than the nonselective COX inhibitors. It is not yet clear whether the use of COX-2–selec-

tive drugs is associated with a lower risk of nephrotoxicity compared to nonselective NSAIDs. On the other hand, COX-2–selective drugs offer a significant benefit in the management of acute postoperative pain because they do not affect blood coagulation. This is a situation in which the nonselective COX inhibitors would be contraindicated because they impair platelet-mediated blood clotting and are thus associated with increased bleeding at the operative site. COX-2 inhibitors, including celecoxib (Celebrex), and valdecoxib (Bextra), are associated with increased cardiovascular risk. It is possible that this is a class effect of NSAIDs, excluding aspirin. These drugs are contraindicated in patients in the immediate period after coronary artery bypass surgery and should be used with caution in patients having a history of or significant risk factors for cardiovascular disease.

OPIOID ANALGESICS Opioids are the most potent pain-relieving drugs currently available. Furthermore, of all analgesics, they have the broadest range of efficacy, providing the most reliable and effective method for rapid pain relief. Although side effects are common, they are usually not serious except for respiratory depression and can be reversed rapidly with the narcotic antagonist naloxone. The physician should not hesitate to use opioid analgesics in patients with acute severe pain. **Table 12-1** lists the most commonly used opioid analgesics.

Opioids produce analgesia by actions in the central nervous system. They activate pain-inhibitory neurons and directly inhibit pain-transmission neurons. Most of the commercially available opioid analgesics act at the same opioid receptor (μ-receptor), differing mainly in potency, speed of onset, duration of action, and optimal route of administration. Although the dose-related side effects (sedation, respiratory depression, pruritus, constipation) are similar among the different opioids, some side effects are due to accumulation of nonopioid metabolites that are unique to individual drugs. One striking example of this is normeperidine, a metabolite of meperidine. Normeperidine produces hyperexcitability and seizures that are not reversible with naloxone. Normeperidine accumulation is increased in patients with renal failure.

The most rapid relief with opioids is obtained by intravenous administration; relief with oral administration is significantly slower. Common side effects include nausea, vomiting, constipation, and sedation. The most serious side effect is respiratory depression. Patients with any form of respiratory compromise must be kept under close observation following opioid administration; an oxygen saturation monitor may be useful. The opioid antagonist naloxone should be readily available. Opioid effects are dose-related, and there is great variability among patients in the doses that relieve pain and produce side effects. Because of this, initiation of therapy requires titration to optimal dose and interval. The most important principle is to provide adequate pain relief. This requires determining whether the drug has adequately relieved the pain and the duration of the relief. *The most common error made by physicians in managing severe pain with opioids is to prescribe an inadequate dose. Since many patients are reluctant to complain, this practice leads to needless suffering*. In the absence of sedation at the expected time of peak effect, a physician should not hesitate to repeat the initial dose to achieve satisfactory pain relief.

An innovative approach to the problem of achieving adequate pain relief is the use of patient-controlled analgesia (PCA). PCA requires a device that can deliver a baseline continuous dose of an opioid drug, as well as preprogrammed additional doses whenever the patient pushes a button. The patient can then titrate the dose to the optimal level. This approach is used most extensively for the management of postoperative pain, but there is no reason why it should not be used for any hospitalized patient with persistent severe pain. PCA is also used for short-term home care of patients with intractable pain, such as that caused by metastatic cancer.

Because of patient variability in analgesia requirement, intravenous PCA is generally begun after the patient's pain has been controlled. The bolus dose of the drug (typically 1 mg morphine or 40 μg fentanyl) can then be delivered repeatedly as needed. To prevent overdosing, PCA devices are programmed with a lockout period after each demand dose is delivered (5–10 min) and a limit on the total dose delivered per hour. While some have advocated the use of a simultaneous background infusion of the PCA drug, this increases the risk of respiratory depression and has not been shown to increase the overall efficacy of the technique.

Many physicians, nurses, and patients have a certain trepidation about using opioids that is based on an exaggerated fear of addiction. In fact, there is a vanishingly small chance of patients becoming addicted to narcotics as a result of their appropriate medical use.

The availability of new routes of administration has extended the usefulness of opioid analgesics. Most important is the availability of spinal administration. Opioids can be infused through a spinal catheter placed either intrathecally or epidurally. By applying opioids directly to the spinal cord, regional analgesia can be obtained using a relatively low total dose. In this way, such side effects as sedation, nausea, and respiratory depression can be minimized. This approach has been used extensively in obstetric procedures and for lower-body postoperative pain. Opioids can also be given intranasally (butorphanol), rectally, and transdermally (fentanyl), thus avoiding the discomfort of frequent injections in patients who cannot be given oral medication. The fentanyl transdermal patch has the advantage of providing fairly steady plasma levels, which maximizes patient comfort.

Opioid and COX Inhibitor Combinations When used in combination, opioids and COX inhibitors have additive effects. Because a lower dose of each can be used to achieve the same degree of pain relief, and their side effects are nonadditive, such combinations can be used to lower the severity of dose-related side effects. Fixed-ratio combinations of an opioid with acetaminophen carry a special risk. Dose escalation as a result of increased severity of pain or decreased opioid effect as a result of tolerance may lead to levels of acetaminophen that are toxic to the liver.

CHRONIC PAIN

Managing patients with chronic pain is intellectually and emotionally challenging. The patient's problem is often difficult to diagnose; such patients are demanding of the physician's time and often appear emotionally distraught. The traditional medical approach of seeking an obscure organic pathology is usually unhelpful. On the other hand, psychological evaluation and behaviorally based treatment paradigms are frequently helpful, particularly in the setting of a multidisciplinary pain-management center.

There are several factors that can cause, perpetuate, or exacerbate chronic pain. First, of course, the patient may simply have a disease that is characteristically painful for which there is presently no cure. Arthritis, cancer, migraine headaches, fibromyalgia, and diabetic neuropathy are examples of this. Second, there may be secondary perpetuating factors that are initiated by disease and persist after that disease has resolved. Examples include damaged sensory nerves, sympathetic efferent activity, and painful reflex muscle contraction. Finally, a variety of psychological conditions can exacerbate or even cause pain.

There are certain areas to which special attention should be paid in the medical history. Because depression is the most common emotional disturbance in patients with chronic pain, patients should be questioned about their mood, appetite, sleep patterns, and daily activity. A simple standardized questionnaire, such as the Beck Depression Inventory, can be a useful screening device. It is important to remember that major depression is a common, treatable, and potentially fatal illness.

Other clues that a significant emotional disturbance is contributing to a patient's chronic pain complaint include: pain that occurs in multiple unrelated sites; a pattern of recurrent, but separate, pain problems beginning in childhood or adolescence; pain beginning at a time of emotional trauma, such as the loss of a parent or spouse; a history of physical or sexual abuse; and past or present substance abuse.

On examination, special attention should be paid to whether the patient guards the painful area and whether certain movements or postures are avoided because of pain. Discovering a mechanical component to the pain can be useful both diagnostically and therapeutically. Painful areas should be examined for deep tenderness, noting whether this is localized to muscle, ligamentous structures, or joints. Chronic myofascial pain is very common, and in these patients deep palpation may reveal highly localized trigger points that are firm bands or knots in muscle. Relief of the pain following injection of local anesthetic into these trigger points supports the diagnosis. A neuropathic component to the pain is indicated by evidence of nerve damage, such as sensory impairment, exquisitely sensitive skin, weakness and muscle atrophy, or loss of deep tendon reflexes. Evidence suggesting sympathetic nervous system involvement includes the presence of diffuse swelling, changes in skin color and temperature, and hypersensitive skin and joint tenderness compared with the normal side. Relief of the pain with a sympathetic block is diagnostic.

A guiding principle in evaluating patients with chronic pain is to assess both emotional and organic factors before initiating therapy. Addressing these issues together, rather than waiting to address emotional issues after organic causes of pain have been ruled out, improves compliance in part because it assures patients that a psychological evaluation does not mean that the physician is questioning the validity of their complaint. Even when an organic cause for a patient's pain can be found, it is still wise to look for other factors. For example, a cancer patient with painful bony metastases may have additional pain due to nerve damage and may also be depressed. Optimal therapy requires that each of these factors be looked for and treated.

CHRONIC PAIN

Once the evaluation process has been completed and the likely causative and exacerbating factors identified, an explicit treatment plan should be developed. An important part of this process is to identify specific and realistic functional goals for therapy, such as getting a good night's sleep, being able to go shopping, or returning to work. A multidisciplinary approach that utilizes medications, counseling, physical therapy, nerve blocks, and even surgery may be required to improve the patient's quality of life. There are also some newer, relatively invasive procedures that can be helpful for some patients with intractable pain. These procedures include implanting intraspinal cannulae to deliver morphine or intraspinal electrodes for spinal stimulation. There are no set criteria for predicting which patients will respond to these procedures. They are generally reserved for patients who have not responded to conventional pharmacologic approaches. Referral to a multidisciplinary pain clinic for a full evaluation should precede any invasive procedures. Such referrals are clearly not necessary for all chronic pain patients. For some, pharmacologic management alone can provide adequate relief.

ANTIDEPRESSANT MEDICATIONS The tricyclic antidepressants [amitriptyline, imipramine, nortriptyline, desipramine (TCAs; Table 12-1)] are extremely useful for the management of patients with chronic pain. Although developed for the treatment of depression, the tricyclics have a spectrum of dose-related biologic activities that include the production of analgesia in a variety of clinical conditions. Although the mechanism is unknown, the analgesic effect of TCAs has a more rapid onset and occurs at a lower dose than is typically required for the treatment of depression. Furthermore, patients with chronic pain who are not depressed obtain pain relief with antidepressants. There is evidence that tricyclic drugs potentiate opioid analgesia, so they may be useful adjuncts for the treatment of severe persistent pain such as occurs with malignant tumors. **Table 12-2** lists some of the painful conditions that respond to tricyclics. TCAs are of particular value in the management of neuropathic pain such as occurs in diabetic neuropathy and postherpetic neuralgia, for which there are few other therapeutic options.

The TCAs that have been shown to relieve pain have significant side effects (Table 12-1; Chap. 386). Some of these side effects, such as orthostatic hypotension, drowsiness, cardiac conduction delay, memory impairment, constipation, and urinary retention, are particularly problematic in elderly patients, and several are additive to the side effects of opioid analgesics. The serotonin-selective reuptake inhibitors such as fluoxetine (Prozac) have fewer and less serious side effects than TCAs, but they are much less effective for relieving pain. It is of interest that venlafaxine (Effexor) and duloxetine (Cymbalta), which are nontricyclic antidepressants that block both serotonin and norepinephrine reuptake, appear to retain most of the pain-relieving effect of TCAs with a side-effect profile more like that of the serotonin-selective reuptake inhibitors. These drugs may be particularly useful in patients who cannot tolerate the side effects of tricyclics.

TABLE 12-2 PAINFUL CONDITIONS THAT RESPOND TO TRICYCLIC ANTIDEPRESSANTS

Postherpetic neuralgia[a]
Diabetic neuropathy[a]
Tension headache[a]
Migraine headache[a]
Rheumatoid arthritis[a,b]
Chronic low back pain[b]
Cancer
Central post-stroke pain

[a]Controlled trials demonstrate analgesia.
[b]Controlled studies indicate benefit but not analgesia.

ANTICONVULSANTS AND ANTIARRHYTHMICS These drugs are useful primarily for patients with neuropathic pain. Phenytoin (Dilantin) and carbamazepine (Tegretol) were first shown to relieve the pain of trigeminal neuralgia. This pain has a characteristic brief, shooting, electric shock–like quality. In fact, anticonvulsants seem to be helpful largely for pains that have such a lancinating quality. Newer anticonvulsants, gabapentin (Neurontin) and pregabalin (Lyrica), are effective for a broad range of neuropathic pains.

Antiarrhythmic drugs such as low-dose lidocaine and mexiletine (Mexitil) can also be effective for neuropathic pain. These drugs block the spontaneous activity of damaged primary afferent nociceptors.

CHRONIC OPIOID MEDICATION The long-term use of opioids is accepted for patients with pain due to malignant disease. Although opioid use for chronic pain of nonmalignant origin is controversial, it is clear that for many such patients opioid analgesics are the best available option. This is understandable since opioids are the most potent and have the broadest range of efficacy of any analgesic medications. Although addiction is rare in patients who first use opioids for pain relief, some degree of tolerance and physical dependence are likely with long-term use. Therefore, before embarking on opioid therapy, other options should be explored, and the limitations and risks of opioids should be explained to the patient. It is also important to point out that some opioid analgesic medications have mixed agonist-antagonist properties (e.g., pentazocine and butorphanol). From a practical standpoint, this means that they may worsen pain by inducing an abstinence syndrome in patients who are physically dependent on other opioid analgesics.

With long-term outpatient use of orally administered opioids, it is desirable to use long-acting compounds such as levorphanol, methadone, or sustained-release morphine (Table 12-1). Transdermal fentanyl is another excellent option. The pharmacokinetic profile of these drug preparations enables prolonged pain relief, minimizes side effects such as sedation that are associated with high peak plasma levels, and reduces the likelihood of rebound pain associated with a rapid fall in plasma opioid concentration. Constipation is a virtually universal side effect of opioid use and should be treated expectantly.

TREATMENT OF NEUROPATHIC PAIN It is important to individualize treatment for patients with neuropathic pain. Several general principles should guide therapy: the first is to move quickly to provide relief; a second is to minimize drug side effects. For example, in patients with postherpetic neuralgia and significant cutaneous hypersensitivity, topical lidocaine (Lidoderm patches) can provide immediate relief without side effects. Anticonvulsants (gabapentin or pregabalin, see above) or antidepressants can be used as first-line drugs for patients with neuropathic pain. Antiarrhythmic drugs such as lidocaine and mexiletene can be effective (see above). There is no consensus on which class of drug should be used as a first-line treatment for any chronically painful condition. However, because relatively high doses of anticonvulsants are required for pain relief, sedation is very common. Sedation is also a problem with the tricyclic antidepressants but is much less of a problem with serotonin/norepinephrine reuptake inhibitors (SNRIs, e.g., venlafaxine and duloxetine). Thus, in the elderly or in those patients whose daily activities require high-level mental activity, these drugs should be considered as the first line. In contrast, opioid medications should be used as a second- or third-line drug class. While highly effective for many painful conditions, opioids are sedating, and their effect tends to lessen over time, leading to dose escalation and, occasionally, a worsening of pain due to physical dependence. Drugs of different classes can be used in combination to optimize pain control.

It is worth emphasizing that many patients, especially those with chronic pain, seek medical attention primarily because they are suffering and because only physicians can provide the medications required for pain relief. A primary responsibility of all physicians is to minimize the physical and emotional discomfort of their patients. Familiarity with pain mechanisms and analgesic medications is an important step toward accomplishing this aim.

13 Chest Discomfort

Thomas H. Lee

Chest discomfort is one of the most common challenges for clinicians in the office or emergency department. The differential diagnosis includes conditions affecting organs throughout the thorax and abdomen, with prognostic implications that vary from benign to life-threatening (Table 13-1). Failure to recognize potentially serious conditions such as acute ischemic heart disease, aortic dissection, tension pneumothorax, or pulmonary embolism can lead to serious complications, including death. Conversely, overly conservative management of low-risk patients leads to unnecessary hospital admissions, tests, procedures, and anxiety.

CAUSES OF CHEST DISCOMFORT

Myocardial Ischemia and Injury Myocardial ischemia occurs when the oxygen supply to the heart is not sufficient to meet metabolic needs. This mismatch can result from a decrease in oxygen supply, a rise in demand, or both. The most common underlying cause of myocardial ischemia is obstruction of coronary arteries by atherosclerosis; in the presence of such obstruction, transient ischemic episodes are usually precipitated by an increase in oxygen demand as a result of physical exertion. However, ischemia can also result from psychological stress, fever, or large meals or from compromised oxygen delivery due to anemia, hypoxia, or hypotension. Ventricular hypertrophy due to valvular heart disease, hypertrophic cardiomyopathy, or hypertension can predispose the myocardium to ischemia because of impaired penetration of blood flow from epicardial coronary arteries to the endocardium.

ANGINA PECTORIS (See also Chap. 237) The chest discomfort of myocardial ischemia is a visceral discomfort that is usually described as a heaviness, pressure, or squeezing (Table 13-2). Other common adjectives for anginal pain are burning and aching. Some patients deny any "pain" but may admit to dyspnea or a vague sense of anxiety. The word "sharp" is sometimes used by patients to describe intensity rather than quality.

The location of angina pectoris is usually retrosternal; most patients do not localize the pain to any small area. The discomfort may radiate to the neck, jaw, teeth, arms, or shoulders, reflecting the common origin in the posterior horn of the spinal cord of sensory neurons supplying the heart and these areas. Some patients present with aching in sites of radiated pain as their only symptoms of ischemia. Occasional patients report epigastric distress with ischemic episodes. Less common is radiation to below the umbilicus or to the back.

Stable angina pectoris usually develops gradually with exertion, emotional excitement, or after heavy meals. Rest or treatment with sublingual nitroglycerin typically leads to relief within several minutes. In contrast, pain that is fleeting (lasting only a few seconds) is rarely ischemic in origin. Similarly, pain that lasts for several hours is unlikely to represent angina, particularly if the patient's electrocardiogram (ECG) does not show evidence of ischemia.

Anginal episodes can be precipitated by any physiologic or psychological stress that induces tachycardia. Most myocardial perfusion occurs during diastole, when there is minimal pressure opposing coronary artery flow from within the left ventricle. Since tachycardia decreases the percentage of the time in which the heart is in diastole, it decreases myocardial perfusion.

TABLE 13-1 DIFFERENTIAL DIAGNOSES OF PATIENTS ADMITTED TO HOSPITAL WITH ACUTE CHEST DISCOMFORT RULED NOT MYOCARDIAL INFARCTION

Diagnosis	Percent
Gastroesophageal disease[a]	42
Gastroesophageal reflux	
Esophageal motility disorders	
Peptic ulcer	
Gallstones	
Ischemic heart disease	31
Chest wall syndromes	28
Pericarditis	4
Pleuritis/pneumonia	2
Pulmonary embolism	2
Lung cancer	1.5
Aortic aneurysm	1
Aortic stenosis	1
Herpes zoster	1

UNSTABLE ANGINA AND MYOCARDIAL INFARCTION (See also Chaps. 238 and 239) Patients with these acute ischemic syndromes usually complain of symptoms similar in quality to angina pectoris, but more prolonged and severe. The onset of these syndromes may occur with the patient at rest, or awakened from sleep, and sublingual nitroglycerin may lead to transient or no relief. Accompanying symptoms may include diaphoresis, dyspnea, nausea, and light-headedness.

The physical examination may be completely normal in patients with chest discomfort due to ischemic heart disease. Careful auscultation during ischemic episodes may reveal a third or fourth heart sound, reflecting myocardial systolic or diastolic dysfunction. A transient murmur of mitral regurgitation suggests ischemic papillary muscle dysfunction. Severe episodes of ischemia can lead to pulmonary congestion and even pulmonary edema.

OTHER CARDIAC CAUSES Myocardial ischemia caused by hypertrophic cardiomyopathy or aortic stenosis leads to angina pectoris similar to that caused by coronary atherosclerosis. In such cases, a loud systolic murmur or other findings usually suggest that abnormalities other than coronary atherosclerosis may be contributing to the patient's symptoms. Some patients with chest pain and normal coronary angiograms have functional abnormalities of the coronary circulation, ranging from coronary spasm visible on coronary angiography to abnormal vasodilator responses and heightened vasoconstrictor responses. The term "cardiac syndrome X" is used to describe patients with angina-like chest pain and ischemic-appearing ST-segment depression during stress despite normal coronary arteriograms. Some data indicate that many such patients have limited changes in coronary flow in response to pacing stress or coronary vasodilators. Despite the possibility that chest pain may be due to myocardial ischemia in such patients, their prognosis is excellent.

Pericarditis (See also Chap. 232) The pain in pericarditis is believed to be due to inflammation of the adjacent parietal pleura, since most of the pericardium is believed to be insensitive to pain. Thus, infectious pericarditis, which usually involves adjoining pleural surfaces, tends to be associated with pain, while conditions that cause only local inflammation (e.g., myocardial infarction or uremia) and cardiac tamponade tend to result in mild or no chest pain.

TABLE 13-2 TYPICAL CLINICAL FEATURES OF MAJOR CAUSES OF ACUTE CHEST DISCOMFORT

Condition	Duration	Quality	Location	Associated Features
Angina	More than 2 and less than 10 min	Pressure, tightness, squeezing, heaviness, burning	Retrosternal, often with radiation to or isolated discomfort in neck, jaw, shoulders, or arms—frequently on left	Precipitated by exertion, exposure to cold, psychologic stress S_4 gallop or mitral regurgitation murmur during pain
Unstable angina	10–20 min	Similar to angina but often more severe	Similar to angina	Similar to angina, but occurs with low levels of exertion or even at rest
Acute myocardial infarction	Variable; often more than 30 min	Similar to angina but often more severe	Similar to angina	Unrelieved by nitroglycerin May be associated with evidence of heart failure or arrhythmia
Aortic stenosis	Recurrent episodes as described for angina	As described for angina	As described for angina	Late-peaking systolic murmur radiating to carotid arteries
Pericarditis	Hours to days; may be episodic	Sharp	Retrosternal or toward cardiac apex; may radiate to left shoulder	May be relieved by sitting up and leaning forward Pericardial friction rub
Aortic dissection	Abrupt onset of unrelenting pain	Tearing or ripping sensation; knifelike	Anterior chest, often radiating to back, between shoulder blades	Associated with hypertension and/or underlying connective tissue disorder, e.g., Marfan syndrome Murmur of aortic insufficiency, pericardial rub, pericardial tamponade, or loss of peripheral pulses
Pulmonary embolism	Abrupt onset; several minutes to a few hours	Pleuritic	Often lateral, on the side of the embolism	Dyspnea, tachypnea, tachycardia, and hypotension
Pulmonary hypertension	Variable	Pressure	Substernal	Dyspnea, signs of increased venous pressure including edema and jugular venous distention
Pneumonia or pleuritis	Variable	Pleuritic	Unilateral, often localized	Dyspnea, cough, fever, rales, occasional rub
Spontaneous pneumothorax	Sudden onset; several hours	Pleuritic	Lateral to side of pneumothorax	Dyspnea, decreased breath sounds on side of pneumothorax
Esophageal reflux	10–60 min	Burning	Substernal, epigastric	Worsened by postprandial recumbency Relieved by antacids
Esophageal spasm	2–30 min	Pressure, tightness, burning	Retrosternal	Can closely mimic angina
Peptic ulcer	Prolonged	Burning	Epigastric, substernal	Relieved with food or antacids
Gallbladder disease	Prolonged	Burning, pressure	Epigastric, right upper quadrant, substernal	May follow meal
Musculoskeletal disease	Variable	Aching	Variable	Aggravated by movement May be reproduced by localized pressure on examination
Herpes zoster	Variable	Sharp or burning	Dermatomal distribution	Vesicular rash in area of discomfort
Emotional and psychiatric conditions	Variable; may be fleeting	Variable	Variable; may be retrosternal	Situational factors may precipitate symptoms Anxiety or depression often detectable with careful history

The adjacent parietal pleura receives its sensory supply from several sources, so the pain of pericarditis can be experienced in areas ranging from the shoulder and neck to the abdomen and back. Most typically, the pain is retrosternal and is aggravated by coughing, deep breaths, or changes in position—all of which lead to movements of pleural surfaces. The pain is often worse in the supine position and relieved by sitting upright and leaning forward. Less common is a steady aching discomfort that mimics acute myocardial infarction.

Diseases of the Aorta (See also Chap. 242) *Aortic dissection* is a potentially catastrophic condition that is due to spread of a subintimal hematoma within the wall of the aorta. The hematoma may begin with a tear in the intima of the aorta or with rupture of the vasa vasorum within the aortic media. This syndrome can occur with trauma to the aorta, including motor vehicle accidents or medical procedures in which catheters or intraaortic balloon pumps damage the intima of the aorta. Nontraumatic aortic dissections are rare in the absence of hypertension and/or conditions associated with deterioration of the elastic or muscular components of the media within the aorta's wall. Cystic medial degeneration is a feature of several inherited connective tissue diseases, including Marfan and Ehlers-Danlos syndromes. About half of all aortic dissections in women under 40 years of age occur during pregnancy.

Almost all patients with acute dissections present with severe chest pain, although some patients with chronic dissections are identified without associated symptoms. Unlike the pain of ischemic heart disease, symptoms of aortic dissection tend to reach peak severity immediately, often causing the patient to collapse from its intensity. The classic teaching is that the adjectives used to describe the pain reflect the process occurring within the wall of the aorta—"ripping" and "tearing"—but more recent data suggest that the most common presenting complaint is sudden onset of severe, sharp pain. The location often correlates with the site and extent of the dissection. Thus, dissections that begin in the ascending aorta and extend to the descending aorta tend to cause pain in the front of the chest that extends into the back, between the shoulder blades.

Physical findings may also reflect extension of the aortic dissection that compromises flow into arteries branching off the aorta. Thus, loss of a pulse in one or both arms, cerebrovascular accident, or paraplegia can all be catastrophic consequences of aortic dissection. Hematomas that extend proximally and undermine the coronary arteries or aortic valve apparatus may lead to acute myocardial infarction or acute aortic insufficiency. Rupture of the hematoma into the pericardial space leads to pericardial tamponade.

Another abnormality of the aorta that can cause chest pain is a *thoracic aortic aneurysm*. Aortic aneurysms are frequently asymptomatic but can cause chest pain and other symptoms by compressing adjacent structures. This pain tends to be steady, deep, and sometimes severe.

Pulmonary Embolism (See also Chap. 256) Chest pain due to pulmonary embolism is believed to be due to distention of the pulmonary artery or infarction of a segment of the lung adjacent to the pleura. Massive pulmonary emboli may lead to substernal pain that is suggestive of acute myocardial infarction. More commonly, smaller emboli lead to focal pulmonary infarctions that cause pain that is lateral and pleuritic. Associated symptoms include dyspnea and, occasionally, hemoptysis. Tachycardia is usually present. Although not always present, certain characteristic ECG changes can support the diagnosis.

Pneumothorax (See also Chap. 257) Sudden onset of pleuritic chest pain and respiratory distress should lead to consideration of spontaneous pneumothorax, as well as pulmonary embolism. Such events may occur without a precipitating event in persons without lung disease, or as a consequence of underlying lung disorders.

Pneumonia or Pleuritis (See also Chaps. 251 and 257) Lung diseases that damage and cause inflammation of the pleura of the lung usually cause a sharp, knifelike pain that is aggravated by inspiration or coughing.

Gastrointestinal Conditions (See also Chap. 286) Esophageal pain from acid reflux from the stomach, spasm, obstruction, or injury can be difficult to discern from myocardial syndromes. Acid reflux typically causes a deep burning discomfort that may be exacerbated by alcohol, aspirin, or some foods; this discomfort is often relieved by antacid or other acid-reducing therapies. Acid reflux tends to be exacerbated by lying down and may be worse in early morning when the stomach is empty of food that might otherwise absorb gastric acid.

Esophageal spasm may occur in the presence or absence of acid reflux and leads to a squeezing pain indistinguishable from angina. Prompt relief of esophageal spasm is often provided by antianginal therapies such as sublingual nifedipine, further promoting confusion between these syndromes. Chest pain can also result from injury to the esophagus, such as a Mallory-Weiss tear caused by severe vomiting.

Chest pain can result from diseases of the gastrointestinal tract below the diaphragm, including *peptic ulcer disease*, *biliary disease*, and *pancreatitis*. These conditions usually cause abdominal pain as well as chest discomfort; symptoms are not likely to be associated with exertion. The pain of ulcer disease typically occurs 60 to 90 min after meals, when postprandial acid production is no longer neutralized by food in the stomach. Cholecystitis usually causes a pain that is described as aching, occurring an hour or more after meals.

Neuromusculoskeletal Conditions *Cervical disk disease* can cause chest pain by compression of nerve roots. Pain in a dermatomal distribution can also be caused by *intercostal muscle cramps* or by *herpes zoster*. Chest pain symptoms due to herpes zoster may occur before skin lesions are apparent.

Costochondral and *chondrosternal syndromes* are the most common causes of anterior chest musculoskeletal pain. Only occasionally are physical signs of costochondritis such as swelling, redness, and warmth (Tietze's syndrome) present. The pain of such syndromes is usually fleeting and sharp, but some patients experience a dull ache that lasts for hours. Direct pressure on the chondrosternal and costochondral junctions may reproduce the pain from these and other musculoskeletal syndromes. Arthritis of the shoulder and spine and bursitis may also cause chest pain. Some patients who have these conditions and myocardial ischemia blur and confuse symptoms of these syndromes.

Emotional and Psychiatric Conditions As many as 10% of patients who present to emergency departments with acute chest discomfort have panic disorder or other emotional conditions. The symptoms in these populations are highly variable, but frequently the discomfort is described as visceral tightness or aching that lasts more than 30 min. Some patients offer other atypical descriptions, such as pain that is fleeting, sharp, and/or localized to a small region. The ECG in patients with emotional conditions may be difficult to interpret if hyperventilation causes ST-T-wave abnormalities. A careful history may elicit clues of depression, prior panic attacks, somatization, agoraphobia, or other phobias.

APPROACH TO THE PATIENT: Chest Discomfort

The evaluation of the patient with chest discomfort must accommodate two goals—determining the diagnosis and assessing the safety of the immediate management plan. The latter issue is often dominant when the patient has acute chest discomfort, such as patients seen in the emergency department. In such settings, the clinician must focus first on identifying patients who require aggressive interventions to diagnose or manage potentially life-threatening conditions, including acute ischemic heart disease, acute aortic dissection, pulmonary embolism, and tension pneumothorax. If such conditions are unlikely, the clinician must address questions such as the safety of discharge to home, admission to a non-coronary care unit facility, or immediate exercise testing. Table 13-3 displays a sequence of questions that can be used in the evaluation of the patient with chest discomfort, with the diagnostic entities that are most important for consideration at each stage of the evaluation.

TABLE 13-3 CONSIDERATIONS IN THE ASSESSMENT OF THE PATIENT WITH CHEST DISCOMFORT

1. Could the chest discomfort be due to an acute, potentially life-threatening condition that warrants immediate hospitalization and aggressive evaluation?
   - Acute ischemic heart disease
   - Aortic dissection
   - Pulmonary embolism
   - Spontaneous pneumothorax
2. If not, could the discomfort be due to a chronic condition likely to lead to serious complications?
   - Stable angina
   - Aortic stenosis
   - Pulmonary hypertension
3. If not, could the discomfort be due to an acute condition that warrants specific treatment?
   - Pericarditis
   - Pneumonia/pleuritis
   - Herpes zoster
4. If not, could the discomfort be due to another treatable chronic condition?
   - Esophageal reflux
   - Esophageal spasm
   - Peptic ulcer disease
   - Gallbladder disease
   - Other gastrointestinal conditions
   - Cervical disk disease
   - Arthritis of the shoulder or spine
   - Costochondritis
   - Other musculoskeletal disorders
   - Anxiety state

ACUTE CHEST DISCOMFORT In patients with acute chest discomfort, the clinician must first assess the patient's respiratory and hemodynamic status. If either is compromised, initial management should focus on stabilizing the patient before the diagnostic evaluation is pursued. If, however, the patient does not require emergent interventions, then a focused history, physical examination, and laboratory evaluation should be performed to assess the patient's risk of life-threatening conditions.

Clinicians who are seeing patients in the office setting should not assume that they do not have acute ischemic heart disease, even if the prevalence may be lower. Malpractice litigation related to myocardial infarctions that were missed during office evaluations is becoming increasingly common, and ECGs were not performed in many such cases. The prevalence of high-risk patients seen in office settings may be increasing due to congestion in emergency departments.

In either setting, the *history* should include questions about the quality and location of the chest discomfort (Table 13-2). The patient should also be asked about the nature of onset of the pain and its duration. Myocardial ischemia is usually associated with a gradual intensification of symptoms over a period of minutes. Pain that is fleeting or that lasts hours without being associated with electrocardiographic changes is not likely to be ischemic in origin. Although the presence of risk factors for coronary artery disease may heighten concern for this diagnosis, the absence of such risk factors does not lower the risk for myocardial ischemia enough to be used to justify a decision to discharge a patient.

Wide radiation of chest pain increases probability that pain is due to myocardial infarction. Radiation of chest pain to the left arm is common with acute ischemic heart disease, but radiation to the right arm is also highly consistent with this diagnosis. Figure 13-1 shows estimates derived from several studies of the impact of various clinical features from the history on the probability that a patient has an acute myocardial infarction.

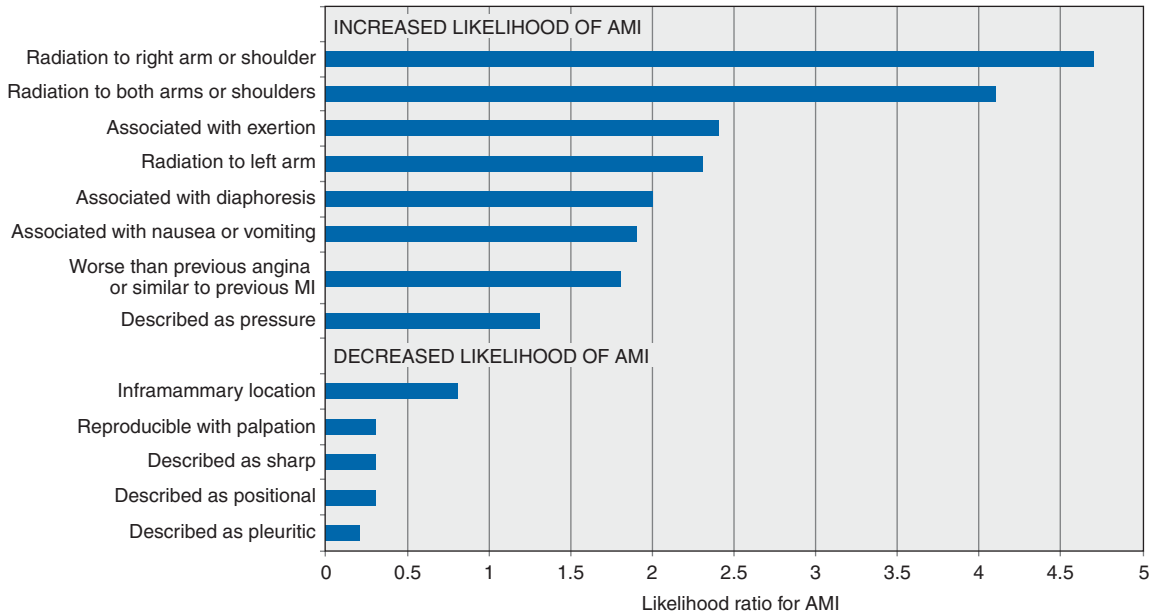

FIGURE 13-1 Impact of chest pain characteristics on odds of acute myocardial infarction (AMI). *(Figure prepared from data in Swap and Nagurney.)*

Right shoulder pain is also common with acute cholecystitis, but this syndrome is usually accompanied by pain that is located in the abdomen rather than chest. Chest pain that radiates between the scapulae raises the question of aortic dissection.

The *physical examination* should include evaluation of blood pressure in both arms and of pulses in both legs. Poor perfusion of a limb may be due to an aortic dissection that has compromised flow to an artery branching from the aorta. Chest auscultation may reveal diminished breath sounds; a pleural rub; or evidence of pneumothorax, pulmonary embolism, pneumonia, or pleurisy. Tension pneumothorax may lead to a shift in the trachea from the midline, away from the side of the pneumothorax. The cardiac examination should seek pericardial rubs, systolic and diastolic murmurs, and third or fourth heart sounds. Pressure on the chest wall may reproduce symptoms in patients with musculoskeletal causes of chest pain; it is important that the clinician ask the patient if the chest pain syndrome is being completely reproduced before drawing too much reassurance that more serious underlying conditions are not present.

An *ECG* is an essential test for adults with chest discomfort that is not due to an obvious traumatic cause. In such patients, the presence of electrocardiographic changes consistent with ischemia or infarction (Chap. 221) is associated with high risks of acute myocardial infarction or unstable angina (Table 13-4); such patients should be admitted to a unit with electrocardiographic monitoring and the capacity to respond to a cardiac arrest. The absence of such changes does not exclude acute ischemic heart disease, but the risk of life-threatening complications is low for patients with normal electrocardiograms or only nonspecific ST-T-wave changes. If these patients are not considered appropriate for immediate discharge, they are often candidates for early or immediate exercise testing.

Markers of myocardial injury are often obtained in the emergency department evaluation of acute chest discomfort. The most commonly used markers are creatine kinase (CK), CK-MB, and the cardiac troponins (I and T). Rapid bedside assays of the cardiac troponins have been developed and shown to be sufficiently accurate to predict prognosis and guide management. Some data support the use of other markers, such as serum myoglobin, C-reactive protein (CRP), placental growth factor, myeloperoxidase, and B-type natriuretic peptide (BNP); their roles are the subject of ongoing research. Single values of any of these markers do not have high sensitivity for acute myocardial infarction or for prediction of complications. Hence, decisions to discharge patients home should not be made on the basis of single negative values of these tests.

Provocative tests for coronary artery disease are not appropriate for patients with ongoing chest pain. In such patients, rest myocardial perfusion scans can be considered; a normal scan reduces the likelihood of coronary artery disease and can help avoid admission of low-risk patients to the hospital. Promising early results suggest that 64-slice CT and cardiac MRI may be of sufficient accuracy for diagnosis of coronary disease that these technologies may become widely used for patients with acute chest pain in whom the diagnosis is not clear.

Clinicians frequently employ therapeutic trials with sublingual nitroglycerin or antacids or, in the stable patient seen in the office setting, a proton pump inhibitor. A common error is to assume that a response to any of these interventions clarifies the diagnosis. While such information is often helpful, the patient's response may be due to the placebo effect. Hence, myocardial ischemia should never be considered excluded solely because of a response to antacid therapy. Similarly, failure of nitroglycerin to relieve pain does not exclude the diagnosis of coronary disease.

TABLE 13-4 PREVALENCE OF MYOCARDIAL INFARCTION AND UNSTABLE ANGINA AMONG SUBSETS OF PATIENTS WITH ACUTE CHEST DISCOMFORT IN THE EMERGENCY DEPARTMENT

Finding	Prevalence	
	Myocardial Infarction, %	Unstable Angina, %
ST elevation (≥1 mm) or Q waves on ECG not known to be old	79	12
Ischemia or strain on ECG not known to be old (ST depression ≥1 mm or ischemic T waves)	20	41
None of the preceding ECG changes but a prior history of angina or myocardial infarction (history of heart attack or nitroglycerin use)	4	51
None of the preceding ECG changes and no prior history of angina or myocardial infarction (history of heart attack or nitroglycerin use)	2	14

Note: ECG, electrocardiogram.
Unpublished data from Brigham and Women's Hospital Chest Pain Study, 1997–1999.

If the patient's history or examination is consistent with aortic dissection, imaging studies to evaluate the aorta must be pursued promptly because of the high risk of catastrophic complications with this condition. Appropriate tests include a chest CT scan with contrast, MRI, or transesophageal echocardiography.

Acute pulmonary embolism should be considered in patients with respiratory symptoms, pleuritic chest pain, hemoptysis, or a history of venous thromboembolism or coagulation abnormalities. Initial tests usually include CT angiography or a lung scan, which are sometimes combined with lower extremity venous ultrasound or D-dimer testing.

If patients with acute chest discomfort show no evidence of life-threatening conditions, the clinician should then focus on serious chronic conditions with the potential to cause major complications, the most common of which is stable angina. Early use of exercise electrocardiography, stress echocardiography, or stress perfusion imaging for such patients, whether in the office or the emergency department, is now an accepted management strategy for low-risk patients. Exercise testing is not appropriate, however, for patients who (1) report pain that is believed to be ischemic occurring at rest or (2) have electrocardiographic changes not known to be old that are consistent with ischemia.

Patients with sustained chest discomfort who do not have evidence for life-threatening conditions should be evaluated for evidence of conditions likely to benefit from acute treatment (Table 13-3). Pericarditis may be suggested by the history, physical examination, and ECG (Table 13-2). Clinicians should carefully assess blood pressure patterns and consider echocardiography in such patients to detect evidence of impending pericardial tamponade. Chest x-rays can be used to evaluate the possibility of pulmonary disease.

GUIDELINES AND CRITICAL PATHWAYS FOR ACUTE CHEST DISCOMFORT

Guidelines for the initial evaluation for patients with acute chest pain have been developed by the American College of Cardiology, American Heart Association, and other organizations. These guidelines recommend performance of an ECG for virtually all patients with chest pain who do not have an obvious noncardiac cause of their pain, and performance of a chest x-ray for patients with signs or symptoms consistent with congestive heart failure, valvular heart disease, pericardial disease, or aortic dissection or aneurysm.

The American College of Cardiology/American Heart Association guidelines on exercise testing support its use in low-risk patients presenting to the emergency department, as well as in selected intermediate-risk patients. However, these guidelines emphasize that exercise tests should be performed only after patients have been screened for high-risk features or other indicators for hospital admission.

Many medical centers have adopted critical pathways and other forms of guidelines to increase efficiency and to expedite the treatment of patients with high-risk acute ischemic heart disease syndromes. These guidelines emphasize the following strategies:

- Rapid identification and treatment of patients for whom emergent reperfusion therapy, either via percutaneous coronary interventions or thrombolytic agents, is likely to lead to improved outcomes.
- Triage to non-coronary care unit monitored facilities such as intermediate-care units or chest pain units of patients with a low risk for complications, such as patients without new ischemic changes on their ECGs and without ongoing chest pain. Such patients can usually be safely observed in non-coronary care unit settings, undergo early exercise testing, or be discharged home. Risk stratification can be assisted through use of prospectively validated multivariate algorithms that have been published for acute ischemic heart disease and its complications.
- Shortening lengths of stay in the coronary care unit and hospital. Recommendations regarding the minimum length of stay in a monitored bed for a patient who has no further symptoms have decreased in recent years to 12 h or less if exercise testing or other risk stratification technologies are available.

NONACUTE CHEST DISCOMFORT

The management of patients who do not require admission to the hospital or who no longer require inpatient observation should seek to identify the cause of the symptoms and the likelihood of major complications. Noninvasive tests for coronary disease serve both to diagnose this condition and to identify patients with high-risk forms of coronary disease who may benefit from revascularization. Gastrointestinal causes of chest pain can be evaluated via endoscopy or radiology studies, or with trials of medical therapy. Emotional and psychiatric conditions warrant appropriate evaluation and treatment; randomized trial data indicate that cognitive therapy and group interventions lead to decreases in symptoms for such patients.

14 Abdominal Pain

William Silen

The correct interpretation of acute abdominal pain is challenging. Since proper therapy may require urgent action, the unhurried approach suitable for the study of other conditions is sometimes denied. Few other clinical situations demand greater judgment, because the most catastrophic of events may be forecast by the subtlest of symptoms and signs. A meticulously executed, detailed history and physical examination are of great importance. The etiologic classification in Table 14-1, although not complete, forms a useful basis for the evaluation of patients with abdominal pain.

The diagnosis of "acute or surgical abdomen" is not an acceptable one because of its often misleading and erroneous connotation. The most obvious of "acute abdomens" may not require operative intervention, and the mildest of abdominal pains may herald an urgently correctable lesion. Any patient with abdominal pain of recent onset requires early and thorough evaluation and accurate diagnosis.

SOME MECHANISMS OF PAIN ORIGINATING IN THE ABDOMEN

Inflammation of the Parietal Peritoneum The pain of parietal peritoneal inflammation is steady and aching in character and is located directly over the inflamed area, its exact reference being possible because it is transmitted by somatic nerves supplying the parietal peritoneum. The intensity of the pain is dependent on the type and amount of material to which the peritoneal surfaces are exposed in a given time period. For example, the sudden release into the peritoneal cavity of a small quantity of *sterile* acid gastric juice causes much more pain than the same amount of grossly contaminated neutral feces. Enzymatically active pancreatic juice incites more pain and inflammation than does the same amount of sterile bile containing no potent enzymes. Blood and urine are often so bland as to go undetected if their contact with the peritoneum has not been sudden and massive. In the case of bacterial contamination, such as in pelvic inflammatory disease, the pain is frequently of low intensity early in the illness until bacterial multiplication has caused the elaboration of irritating substances.

The rate at which the irritating material is applied to the peritoneum is important. Perforated peptic ulcer may be associated with entirely different clinical pictures dependent only on the rapidity with which the gastric juice enters the peritoneal cavity.

The pain of peritoneal inflammation is invariably accentuated by pressure or changes in tension of the peritoneum, whether produced by palpation or by movement, as in coughing or sneezing. The patient with peritonitis lies quietly in bed, preferring to avoid motion, in contrast to the patient with colic, who may writhe incessantly.

Another characteristic feature of peritoneal irritation is tonic reflex spasm of the abdominal musculature, localized to the involved body segment. The intensity of the tonic muscle spasm accompanying peritoneal inflammation is dependent on the location of the inflammatory process, the rate at which it develops, and the integrity of the nervous system. Spasm over a perforated retrocecal appendix or perforated ulcer into the lesser peritoneal sac may be minimal or absent because of the protective effect of overlying viscera. A slowly developing process often greatly attenuates the degree of muscle spasm. Catastrophic abdominal emergencies such as a perforated ulcer may be associated with minimal or no detectable pain or muscle spasm in obtunded, seriously ill, debilitated elderly patients or in psychotic patients.

Obstruction of Hollow Viscera The pain of obstruction of hollow abdominal viscera is classically described as intermittent, or colicky. Yet the lack of a truly cramping character should not be misleading, because distention of a hollow viscus may produce steady pain with only very occasional exacerbations. It is not nearly as well localized as the pain of parietal peritoneal inflammation.

The colicky pain of obstruction of the small intestine is usually periumbilical or supraumbilical and is poorly localized. As the intestine becomes progressively dilated with loss of muscular tone, the colicky nature of the pain may diminish. With superimposed strangulating obstruction, pain may spread to the lower lumbar region if there is traction on the root of the mesentery. The colicky pain of colonic obstruction is of lesser intensity than that of the small intestine and is often located in the infraumbilical area. Lumbar radiation of pain is common in colonic obstruction.

Sudden distention of the biliary tree produces a steady rather than colicky type of pain; hence the term *biliary colic* is misleading. Acute distention of the gallbladder usually causes pain in the right upper quadrant with radiation to the right posterior region of the thorax or to the tip of the right scapula, and distention of the common bile duct is often associated with pain in the epigastrium radiating to the upper part of the lumbar region. Considerable variation is common, however, so that differentiation between these may be impossible. The typical subscapular pain or lumbar radiation is frequently absent. Gradual dilatation of the biliary tree, as in carcinoma of the head of the pancreas, may cause no pain or only a mild aching sensation in the epigastrium or right upper quadrant. The pain of distention of the pancreatic ducts is similar to that described for distention of the common bile duct but, in addition, is very frequently accentuated by recumbency and relieved by the upright position.

TABLE 14-1 SOME IMPORTANT CAUSES OF ABDOMINAL PAIN

Pain Originating in the Abdomen
Parietal peritoneal inflammation
Bacterial contamination
Perforated appendix or other perforated viscus
Pelvic inflammatory disease
Chemical irritation
Perforated ulcer
Pancreatitis
Mittelschmerz
Mechanical obstruction of hollow viscera
Obstruction of the small or large intestine
Obstruction of the biliary tree
Obstruction of the ureter
Vascular disturbances
Embolism or thrombosis
Vascular rupture
Pressure or torsional occlusion
Sickle cell anemia
Abdominal wall
Distortion or traction of mesentery
Trauma or infection of muscles
Distension of visceral surfaces, e.g. by hemorrhage
Hepatic or renal capsules
Inflammation of a viscus
Appendicitis
Typhoid fever
Typhlitis
Pain Referred from Extraabdominal Source
Cardiothoracic
Acute myocardial infarction
Myocarditis, endocarditis, pericarditis
Congestive heart failure
Pneumonia
Pulmonary embolus
Pleurodynia
Pneumothorax
Empyema
Esophageal disease, spasm, rupture, inflammation
Genitalia
Torsion of the testis
Metabolic Causes
Diabetes
Uremia
Hyperlipidemia
Hyperparathyroidism
Acute adrenal insufficiency
Familial Mediterranean fever
Porphyria
C'1 esterase inhibitor deficiency (angioneurotic edema)
Neurologic/Psychiatric Causes
Herpes zoster
Tabes dorsalis
Causalgia
Radiculitis from infection or arthritis
Spinal cord or nerve root compression
Functional disorders
Psychiatric disorders
Toxic Causes
Lead poisoning
Insect or animal envenomations
Black widow spiders
Snake bites
Uncertain Mechanisms
Narcotic withdrawal
Heat stroke

Obstruction of the urinary bladder results in dull suprapubic pain, usually low in intensity. Restlessness without specific complaint of pain may be the only sign of a distended bladder in an obtunded pa-

tient. In contrast, acute obstruction of the intravesicular portion of the ureter is characterized by severe suprapubic and flank pain that radiates to the penis, scrotum, or inner aspect of the upper thigh. Obstruction of the ureteropelvic junction is felt as pain in the costovertebral angle, whereas obstruction of the remainder of the ureter is associated with flank pain that often extends into the same side of the abdomen.

Vascular Disturbances A frequent misconception, despite abundant experience to the contrary, is that pain associated with intraabdominal vascular disturbances is sudden and catastrophic in nature. The pain of embolism or thrombosis of the superior mesenteric artery or that of impending rupture of an abdominal aortic aneurysm certainly may be severe and diffuse. Yet, just as frequently, the patient with occlusion of the superior mesenteric artery has only mild continuous diffuse pain for 2 or 3 days before vascular collapse or findings of peritoneal inflammation appear. The early, seemingly insignificant discomfort is caused by hyperperistalsis rather than peritoneal inflammation. Indeed, absence of tenderness and rigidity in the presence of continuous, diffuse pain in a patient likely to have vascular disease is quite characteristic of occlusion of the superior mesenteric artery. Abdominal pain with radiation to the sacral region, flank, or genitalia should always signal the possible presence of a rupturing abdominal aortic aneurysm. This pain may persist over a period of several days before rupture and collapse occur.

Abdominal Wall Pain arising from the abdominal wall is usually constant and aching. Movement, prolonged standing, and pressure accentuate the discomfort and muscle spasm. In the case of hematoma of the rectus sheath, now most frequently encountered in association with anticoagulant therapy, a mass may be present in the lower quadrants of the abdomen. Simultaneous involvement of muscles in other parts of the body usually serves to differentiate myositis of the abdominal wall from an intraabdominal process that might cause pain in the same region.

REFERRED PAIN IN ABDOMINAL DISEASES

Pain referred to the abdomen from the thorax, spine, or genitalia may prove a vexing diagnostic problem, because diseases of the upper part of the abdominal cavity such as acute cholecystitis or perforated ulcer are frequently associated with intrathoracic complications. A most important, yet often forgotten, dictum is that the possibility of intrathoracic disease must be considered in every patient with abdominal pain, especially if the pain is in the upper part of the abdomen. Systematic questioning and examination directed toward detecting myocardial or pulmonary infarction, pneumonia, pericarditis, or esophageal disease (the intrathoracic diseases that most often masquerade as abdominal emergencies) will often provide sufficient clues to establish the proper diagnosis. Diaphragmatic pleuritis resulting from pneumonia or pulmonary infarction may cause pain in the right upper quadrant and pain in the supraclavicular area, the latter radiation to be distinguished from the referred subscapular pain caused by acute distention of the extrahepatic biliary tree. The ultimate decision as to the origin of abdominal pain may require deliberate and planned observation over a period of several hours, during which repeated questioning and examination will provide the diagnosis or suggest the appropriate studies.

Referred pain of thoracic origin is often accompanied by splinting of the involved hemithorax with respiratory lag and decrease in excursion more marked than that seen in the presence of intraabdominal disease. In addition, apparent abdominal muscle spasm caused by referred pain will diminish during the inspiratory phase of respiration, whereas it is persistent throughout both respiratory phases if it is of abdominal origin. Palpation over the area of referred pain in the abdomen also does not usually accentuate the pain and in many instances actually seems to relieve it. Thoracic disease and abdominal disease frequently coexist and may be difficult or impossible to differentiate. For example, the patient with known biliary tract disease often has epigastric pain during myocardial infarction, or biliary colic may be referred to the precordium or left shoulder in a patient who has suffered previously from angina pectoris. **For an explanation of the radiation of pain to a previously diseased area, see Chap. 12.**

Referred pain from the spine, which usually involves compression or irritation of nerve roots, is characteristically intensified by certain motions such as cough, sneeze, or strain and is associated with hyperesthesia over the involved dermatomes. Pain referred to the abdomen from the testes or seminal vesicles is generally accentuated by the slightest pressure on either of these organs. The abdominal discomfort is of dull aching character and is poorly localized.

METABOLIC ABDOMINAL CRISES

Pain of metabolic origin may simulate almost any other type of intraabdominal disease. Several mechanisms may be at work. In certain instances, such as hyperlipidemia, the metabolic disease itself may be accompanied by an intraabdominal process such as pancreatitis, which can lead to unnecessary laparotomy unless recognized. C1 esterase deficiency associated with angioneurotic edema is often associated with episodes of severe abdominal pain. Whenever the cause of abdominal pain is obscure, a metabolic origin always must be considered. Abdominal pain is also the hallmark of familial Mediterranean fever (Chap. 323).

The problem of differential diagnosis is often not readily resolved. The pain of porphyria and of lead colic is usually difficult to distinguish from that of intestinal obstruction, because severe hyperperistalsis is a prominent feature of both. The pain of uremia or diabetes is nonspecific, and the pain and tenderness frequently shift in location and intensity. Diabetic acidosis may be precipitated by acute appendicitis or intestinal obstruction, so if prompt resolution of the abdominal pain does not result from correction of the metabolic abnormalities, an underlying organic problem should be suspected. Black widow spider bites produce intense pain and rigidity of the abdominal muscles and back, an area infrequently involved in intraabdominal disease.

NEUROGENIC CAUSES

Causalgic pain may occur in diseases that injure sensory nerves. It has a burning character and is usually limited to the distribution of a given peripheral nerve. Normal stimuli such as touch or change in temperature may be transformed into this type of pain, which is frequently present in a patient at rest. The demonstration of irregularly spaced cutaneous pain spots may be the only indication of an old nerve lesion underlying causalgic pain. Even though the pain may be precipitated by gentle palpation, rigidity of the abdominal muscles is absent, and the respirations are not disturbed. Distention of the abdomen is uncommon, and the pain has no relationship to the intake of food.

Pain arising from spinal nerves or roots comes and goes suddenly and is of a lancinating type (Chap. 16). It may be caused by herpes zoster, impingement by arthritis, tumors, herniated nucleus pulposus, diabetes, or syphilis. It is not associated with food intake, abdominal distention, or changes in respiration. Severe muscle spasm, as in the gastric crises of tabes dorsalis, is common but is either relieved or is not accentuated by abdominal palpation. The pain is made worse by movement of the spine and is usually confined to a few dermatomes. Hyperesthesia is very common.

Pain due to functional causes conforms to none of the aforementioned patterns. Mechanism is hard to define. Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder characterized by abdominal pain and altered bowel habits. The diagnosis is made on the basis of clinical criteria (Chap. 290) and after exclusion of demonstrable structural abnormalities. The episodes of abdominal pain are often brought on by stress, and the pain varies considerably in type and location. Nausea and vomiting are rare. Localized tenderness and muscle spasm are inconsistent or absent. The causes of IBS or related functional disorders are not known.

APPROACH TO THE PATIENT: Abdominal Pain

Few abdominal conditions require such urgent operative intervention that an orderly approach need be abandoned, no matter how ill the patient. Only those patients with exsanguinating intraab-

dominal hemorrhage (e.g., ruptured aneurysm) must be rushed to the operating room immediately, but in such instances only a few minutes are required to assess the critical nature of the problem. Under these circumstances, all obstacles must be swept aside, adequate venous access for fluid replacement obtained, and the operation begun. Many patients of this type have died in the radiology department or the emergency room while awaiting such unnecessary examinations as electrocardiograms or abdominal films. *There are no contraindications to operation when massive intraabdominal hemorrhage is present.* Fortunately, this situation is relatively rare. These comments do not pertain to gastrointestinal hemorrhage, which can often be managed by other means (Chap. 42).

Nothing will supplant an orderly, painstakingly *detailed history*, which is far more valuable than any laboratory or radiographic examination. This kind of history is laborious and time-consuming, making it not especially popular, even though a reasonably accurate diagnosis can be made on the basis of the history alone in the majority of cases. Computer-aided diagnosis of abdominal pain provides no advantage over clinical assessment alone. In cases of *acute* abdominal pain, a diagnosis is readily established in most instances, whereas success is not so frequent in patients with *chronic* pain. IBS is one of the most common causes of abdominal pain and must always be kept in mind (Chap. 290). The location of the pain can assist in narrowing the differential diagnosis (see Table 14-2); however, the *chronological sequence of events* in the patient's history is often more important than emphasis on the location of pain. If the examiner is sufficiently open-minded and unhurried, asks the proper questions, and listens, the patient will usually provide the diagnosis. Careful attention should be paid to the extraabdominal regions that may be responsible for abdominal pain. An accurate menstrual history in a female patient is essential. Narcotics or analgesics should *not* be withheld until a definitive diagnosis or a definitive plan has been formulated; obfuscation of the diagnosis by adequate analgesia is unlikely.

In the examination, simple critical inspection of the patient, e.g., of facies, position in bed, and respiratory activity, may provide valuable clues. The amount of information to be gleaned is directly proportional to the *gentleness* and thoroughness of the examiner. Once a patient with peritoneal inflammation has been examined brusquely, accurate assessment by the next examiner becomes almost impossible. Eliciting rebound tenderness by sudden release of a deeply palpating hand in a patient with suspected peritonitis is cruel and unnecessary. The same information can be obtained by gentle percussion of the abdomen (rebound tenderness on a miniature scale), a maneuver that can be far more precise and localizing. Asking the patient to cough will elicit true rebound tenderness without the need for placing a hand on the abdomen. Furthermore, the forceful demonstration of rebound tenderness will startle and induce protective spasm in a nervous or worried patient in whom true rebound tenderness is not present. A palpable gallbladder will be missed if palpation is so brusque that voluntary muscle spasm becomes superimposed on involuntary muscular rigidity.

As in history taking, sufficient time should be spent in the examination. Abdominal signs may be minimal but nevertheless, if accompanied by consistent symptoms, may be exceptionally meaningful. Abdominal signs may be virtually or totally absent in cases of pelvic peritonitis, so careful *pelvic and rectal examinations are mandatory in every patient with abdominal pain.* Tenderness on pelvic or rectal examination in the absence of other abdominal signs can be caused by operative indications such as perforated appendicitis, diverticulitis, twisted ovarian cyst, and many others.

Much attention has been paid to the presence or absence of peristaltic sounds, their quality, and their frequency. Auscultation of the abdomen is one of the least revealing aspects of the physical examination of a patient with abdominal pain. Catastrophes such as strangulating small intestinal obstruction or perforated appendicitis may occur in the presence of normal peristaltic sounds. Conversely, when the proximal part of the intestine above an obstruction becomes markedly distended and edematous, peristaltic sounds may lose the characteristics of borborygmi and become weak or absent, even when peritonitis is not present. It is usually the severe chemical peritonitis of sudden onset that is associated with the truly silent abdomen. Assessment of the patient's state of hydration is important.

Laboratory examinations may be of great value in assessment of the patient with abdominal pain, yet with few exceptions they rarely establish a diagnosis. Leukocytosis should never be the single deciding factor as to whether or not operation is indicated. A white blood cell count >20,000/μL may be observed with perforation of a viscus, but pancreatitis, acute cholecystitis, pelvic inflammatory disease, and intestinal infarction may be associated with marked leukocytosis. A normal white blood cell count is not rare in cases of perforation of abdominal viscera. The diagnosis of anemia may be more helpful than the white blood cell count, especially when combined with the history.

The urinalysis may reveal the state of hydration or rule out severe renal disease, diabetes, or urinary infection. Blood urea nitrogen, glucose, and serum bilirubin levels may be helpful. Serum amylase levels may be increased by many diseases other than pancreatitis, e.g., perforated ulcer, strangulating intestinal obstruction, and acute cholecystitis; thus, elevations of serum amylase do not rule out the need for an operation. The determination of the serum lipase may have greater accuracy than that of the serum amylase.

Plain and upright or lateral decubitus radiographs of the abdomen may be of value in cases of intestinal obstruction, perforated ulcer, and a variety of other conditions. They are usually unnecessary in patients with acute appendicitis or strangulated external hernias. In rare instances, barium or water-soluble contrast study of the upper part of the gastrointestinal tract may demonstrate partial intestinal obstruction that may elude diagnosis by other means. If there is any question of obstruction of the colon, oral administration of barium sulfate should be avoided. On the other hand, in cases of suspected colonic obstruction (without perforation), contrast enema may be diagnostic.

In the absence of trauma, peritoneal lavage has been replaced as a diagnostic tool by ultrasound, CT, and laparoscopy. Ultrasonog-

TABLE 14-2 DIFFERENTIAL DIAGNOSES OF ABDOMINAL PAIN BY LOCATION

Right Upper Quadrant	Epigastric	Left Upper Quadrant
Cholecystitis	Peptic ulcer disease	Splenic infarct
Cholangitis	Gastritis	Splenic rupture
Pancreatitis	GERD	Splenic abscess
Pneumonia/empyema	Pancreatitis	Gastritis
Pleurisy/pleurodynia	Myocardial infarction	Gastric ulcer
Subdiaphragmatic abscess	Pericarditis	Pancreatitis
Hepatitis	Ruptured aortic aneurysm	Subdiaphragmatic abscess
Budd-Chiari syndrome	Esophagitis	
Right Lower Quadrant	**Periumbilical**	**Left Lower Quadrant**
Appendicitis	Early appendicitis	Diverticulitis
Salpingitis	Gastroenteritis	Salpingitis
Inguinal hernia	Bowel obstruction	Inguinal hernia
Ectopic pregnancy	Ruptured aortic aneurysm	Ectopic pregnancy
Nephrolithiasis		Nephrolithiasis
Inflammatory bowel disease		Irritable bowel syndrome
Mesenteric lymphadenitis		Inflammatory bowel disease
Typhlitis		

Diffuse Nonlocalized Pain

Gastroenteritis	Diabetes
Mesenteric ischemia	Malaria
Bowel obstruction	Familial Mediterranean fever
Irritable bowel syndrome	Metabolic diseases
Peritonitis	Psychiatric disease

raphy has proved to be useful in detecting an enlarged gallbladder or pancreas, the presence of gallstones, an enlarged ovary, or a tubal pregnancy. Laparoscopy is especially helpful in diagnosing pelvic conditions, such as ovarian cysts, tubal pregnancies, salpingitis, and acute appendicitis. Radioisotopic scans (HIDA) may help differentiate acute cholecystitis from acute pancreatitis. A CT scan may demonstrate an enlarged pancreas, ruptured spleen, or thickened colonic or appendiceal wall and streaking of the mesocolon or mesoappendix characteristic of diverticulitis or appendicitis.

Sometimes, even under the best circumstances with all available aids and with the greatest of clinical skill, a definitive diagnosis cannot be established at the time of the initial examination. Nevertheless, despite lack of a clear anatomic diagnosis, it may be abundantly clear to an experienced and thoughtful physician and surgeon that on clinical grounds alone operation is indicated. Should that decision be questionable, watchful waiting with repeated questioning and examination will often elucidate the true nature of the illness and indicate the proper course of action.

15 Headache

Peter J. Goadsby, Neil H. Raskin

Headache is among the most common reasons that patients seek medical attention. Diagnosis and management is based on a careful clinical approach that is augmented by an understanding of the anatomy, physiology, and pharmacology of the nervous system pathways that mediate the various headache syndromes.

GENERAL PRINCIPLES

A classification system developed by the International Headache Society characterizes headache as primary or secondary (Table 15-1). *Primary headaches* are those in which headache and its associated features are the disorder in itself, whereas *secondary headaches* are those caused by exogenous disorders. Primary headache often results in considerable disability and a decrease in the patient's quality of life. Mild secondary headache, such as that seen in association with upper respiratory tract infections, is common but rarely worrisome. Life-threatening headache is relatively uncommon, but vigilance is required in order to recognize and appropriately treat patients with this category of head pain.

ANATOMY AND PHYSIOLOGY OF HEADACHE

Pain usually occurs when peripheral nociceptors are stimulated in response to tissue injury, visceral distension, or other factors (Chap. 12). In such situations, pain perception is a normal physiologic response mediated by a healthy nervous system. Pain can also result when pain-producing pathways of the peripheral or central nervous system (CNS) are damaged or activated inappropriately. Headache may originate from either or both mechanisms. Relatively few cranial structures are pain-producing; these include the scalp, middle meningeal artery, dural sinuses, falx cerebri, and proximal segments of the large pial arteries. The ventricular ependyma, choroid plexus, pial veins, and much of the brain parenchyma are not pain-producing.

TABLE 15-1 COMMON CAUSES OF HEADACHE

Primary Headache		Secondary Headache	
Type	**%**	**Type**	**%**
Migraine	16	Systemic infection	63
Tension-type	69	Head injury	4
Cluster	0.1	Vascular disorders	1
Idiopathic stabbing	2	Subarachnoid hemorrhage	<1
Exertional	1	Brain tumor	0.1

Source: After J Olesen et al: *The Headaches*. Philadelphia, Lippincott, Williams & Wilkins, 2005.

The key structures involved in primary headache appear to be

- the large intracranial vessels and dura mater
- the peripheral terminals of the trigeminal nerve that innervate these structures
- the caudal portion of the trigeminal nucleus, which extends into the dorsal horns of the upper cervical spinal cord and receives input from the first and second cervical nerve roots (the trigeminocervical complex)
- the pain modulatory systems in the brain that receive input from trigeminal nociceptors

The innervation of the large intracranial vessels and dura mater by the trigeminal nerve is known as the *trigeminovascular system*. Autonomic symptoms, such as *lacrimation* and *nasal congestion*, are prominent in the trigeminal autonomic cephalalgias, including cluster headache and paroxysmal hemicrania, and may also be seen in migraine. These autonomic symptoms reflect activation of cranial parasympathetic pathways, and functional imaging studies indicate that vascular changes in migraine and cluster headache, when present, are similarly driven by these cranial autonomic systems. Migraine and other primary headache types are not "vascular headaches"; these disorders do not reliably manifest vascular changes, and treatment outcomes cannot be predicted by vascular effects.

CLINICAL EVALUATION OF ACUTE, NEW-ONSET HEADACHE

The patient who presents with a new, severe headache has a differential diagnosis that is quite different from the patient with recurrent headaches over many years. In new-onset and severe headache, the probability of finding a potentially serious cause is considerably greater than in recurrent headache. Patients with recent onset of pain require prompt evaluation and often treatment. Serious causes to be considered include meningitis, subarachnoid hemorrhage, epidural or subdural hematoma, glaucoma, and purulent sinusitis. When worrisome symptoms and signs are present (Table 15-2), rapid diagnosis and management is critical.

TABLE 15-2 HEADACHE SYMPTOMS THAT SUGGEST A SERIOUS UNDERLYING DISORDER

"Worst" headache ever
First severe headache
Subacute worsening over days or weeks
Abnormal neurologic examination
Fever or unexplained systemic signs
Vomiting that precedes headache
Pain induced by bending, lifting, cough
Pain that disturbs sleep or presents immediately upon awakening
Known systemic illness
Onset after age 55
Pain associated with local tenderness, e.g., region of temporal artery

A complete neurologic examination is an essential first step in the evaluation. In most cases, patients with an abnormal examination or a history of recent-onset headache should be evaluated by a CT or MRI study. As an initial screening procedure for intracranial pathology in this setting, CT and MRI methods appear to be equally sensitive. In some circumstances a lumbar puncture (LP) is also required, unless a benign etiology can be otherwise established. A general evaluation of acute headache might include the investigation of cardiovascular and renal status by blood pressure monitoring and urine examination; eyes by fundoscopy, intraocular pressure measurement, and refraction; cranial arteries by palpation; and cervical spine by the effect of passive movement of the head and by imaging.

The psychological state of the patient should also be evaluated since a relationship exists between head pain and depression. Many patients in chronic daily pain cycles become depressed, although depression itself is rarely a cause of headache. Drugs with antidepressant actions are also effective in the prophylactic treatment of both tension-type headache and migraine.

Underlying recurrent headache disorders may be activated by pain that follows otologic or endodontic surgical procedures. Thus, pain about the head as the result of diseased tissue or trauma may reawaken an otherwise quiescent migrainous syndrome. Treatment of the headache is largely ineffective until the cause of the primary problem is addressed.

Serious underlying conditions that are associated with headache are described below. Brain tumor is a rare cause of headache and even less commonly a cause of severe pain. The vast majority of patients presenting with severe headache have a benign cause.

SECONDARY HEADACHE

The management of secondary headache focuses on diagnosis and treatment of the underlying condition.

MENINGITIS

Acute, severe headache with stiff neck and fever suggests meningitis. LP is mandatory. Often there is striking accentuation of pain with eye movement. Meningitis can be easily mistaken for migraine in that the cardinal symptoms of pounding headache, photophobia, nausea, and vomiting are present. **Meningitis is discussed in Chaps. 376 and 377.**

INTRACRANIAL HEMORRHAGE

Acute, severe headache with stiff neck but without fever suggests subarachnoid hemorrhage. A ruptured aneurysm, arteriovenous malformation, or intraparenchymal hemorrhage may also present with headache alone. Rarely, if the hemorrhage is small or below the foramen magnum, the head CT scan can be normal. Therefore, LP may be required to definitively diagnose subarachnoid hemorrhage. **Intracranial hemorrhage is discussed in Chap. 269.**

BRAIN TUMOR

Approximately 30% of patients with brain tumors consider headache to be their chief complaint. The head pain is usually nondescript—an intermittent deep, dull aching of moderate intensity, which may worsen with exertion or change in position and may be associated with nausea and vomiting. This pattern of symptoms results from migraine far more often than from brain tumor. The headache of brain tumor disturbs sleep in about 10% of patients. Vomiting that precedes the appearance of headache by weeks is highly characteristic of posterior fossa brain tumors. A history of amenorrhea or galactorrhea should lead one to question whether a prolactin-secreting pituitary adenoma (or the polycystic ovary syndrome) is the source of headache. Headache arising de novo in a patient with known malignancy suggests either cerebral metastases or carcinomatous meningitis, or both. Head pain appearing abruptly after bending, lifting, or coughing can be due to a posterior fossa mass (or a Chiari malformation). **Brain tumors are discussed in Chap. 374.**

TEMPORAL ARTERITIS

(See also Chaps. 29 and 319) Temporal (giant cell) arteritis is an inflammatory disorder of arteries that frequently involves the extracranial carotid circulation. It is a common disorder of the elderly; its annual incidence is 77 per 100,000 individuals ages 50 and older. The average age of onset is 70 years, and women account for 65% of cases. About half of patients with untreated temporal arteritis develop blindness due to involvement of the ophthalmic artery and its branches; indeed, the ischemic optic neuropathy induced by giant cell arteritis is the major cause of rapidly developing bilateral blindness in patients >60 years. Because treatment with glucocorticoids is effective in preventing this complication, prompt recognition of the disorder is important.

Typical presenting symptoms include headache, polymyalgia rheumatica (Chap. 319), jaw claudication, fever, and weight loss. Headache is the dominant symptom and often appears in association with malaise and muscle aches. Head pain may be unilateral or bilateral and is located temporally in 50% of patients but may involve any and all aspects of the cranium. Pain usually appears gradually over a few hours before peak intensity is reached; occasionally, it is explosive in onset. The quality of pain is only seldom throbbing; it is almost invariably described as dull and boring, with superimposed episodic stabbing pains similar to the sharp pains that appear in migraine. Most patients can recognize that the origin of their head pain is superficial, external to the skull, rather than originating deep within the cranium (the pain site for migraineurs). Scalp tenderness is present, often to a marked degree; brushing the hair or resting the head on a pillow may be impossible because of pain. Headache is usually worse at night and often aggravated by exposure to cold. Additional findings may include reddened, tender nodules or red streaking of the skin overlying the temporal arteries, and tenderness of the temporal or, less commonly, the occipital arteries.

The erythrocyte sedimentation rate (ESR) is often, though not always, elevated; a normal ESR does not exclude giant cell arteritis. A temporal artery biopsy followed by treatment with prednisone 80 mg daily for the first 4–6 weeks should be initiated when clinical suspicion is high. The prevalence of migraine among the elderly is substantial, considerably higher than that of giant cell arteritis. Migraineurs often report amelioration of their headaches with prednisone; thus, caution must be used when interpreting the therapeutic response.

GLAUCOMA

Glaucoma may present with a prostrating headache associated with nausea and vomiting. The headache often starts with severe eye pain. On physical examination, the eye is often red with a fixed, moderately dilated pupil. **Glaucoma is discussed in Chap. 29.**

PRIMARY HEADACHE SYNDROMES

Primary headaches are disorders in which headache and associated features occur in the absence of any exogenous cause (Table 15-1). The most common are migraine, tension-type headache, and cluster headache.

MIGRAINE HEADACHE

Migraine, the second most common cause of headache, afflicts approximately 15% of women and 6% of men. It is usually an episodic headache that is associated with certain features such as sensitivity to light, sound, or movement; nausea and vomiting often accompany the headache. A useful description of migraine is a benign and recurring syndrome of headache associated with other symptoms of neurologic dysfunction in varying admixtures **(Table 15-3)**. Migraine can often be recognized by its activators, referred to as *triggers*.

The brain of the migraineur is particularly sensitive to environmental and sensory stimuli; migraine-prone patients do not habituate easily to sensory stimuli. This sensitivity is amplified in females during the menstrual cycle. Headache can be initiated or amplified by various triggers, including glare, bright lights, sounds, or other afferent stimulation; hunger; excess stress; physical exertion; stormy weather or barometric pressure changes; hormonal fluctuations during menses; lack of or excess sleep; and alcohol or other chemical stimulation. Knowledge of a patient's susceptibility to specific triggers can be useful in management strategies involving lifestyle adjustments.

TABLE 15-3 SYMPTOMS ACCOMPANYING SEVERE MIGRAINE ATTACKS IN 500 PATIENTS

Symptom	Patients Affected, %
Nausea	87

Pathogenesis The sensory sensitivity that is characteristic of migraine is probably due to dysfunction of monoaminergic sensory control systems located in the brainstem and thalamus (Fig. 15-1).

Activation of cells in the trigeminal nucleus results in the release of vasoactive neuropeptides, particularly calcitonin gene-related peptide (CGRP), at vascular terminations of the trigeminal nerve. Recently, antagonists of CGRP have shown some early promise in the therapy of migraine. Centrally, the second-order trigeminal neurons cross the midline and project to ventrobasal and posterior nuclei of the thalamus for further processing. Additionally, there are projections to the periaqueductal gray and hypothalamus, from which reciprocal descending systems have established anti-nociceptive effects. Other brainstem regions likely to be involved in descending modulation of trigeminal pain include the nucleus locus coeruleus in the pons and the rostroventromedial medulla.

Pharmacologic and other data point to the involvement of the neurotransmitter 5-hydroxytryptamine (5-HT; also known as serotonin) in migraine. Approximately 50 years ago, methysergide was found to antagonize certain peripheral actions of 5-HT and was introduced as the first drug capable of preventing migraine attacks. The triptans are designed to selectively stimulate subpopulations of 5-HT receptors; at least 14 different 5-HT receptors exist in humans. The triptans are potent agonists of 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptors and are less potent at the 5-HT_{1A} receptor. A growing body of data indicates that the antimigraine efficacy of the triptans relates to their ability to stimulate 5-$HT_{1B/1D}$ receptors, which are located on both blood vessels and nerve terminals.

Data also support a role for dopamine in the pathophysiology of certain subtypes of migraine. Most migraine symptoms can be induced by dopaminergic stimulation. Moreover, there is dopamine receptor hypersensitivity in migraineurs, as demonstrated by the induction of yawning, nausea, vomiting, hypotension, and other symptoms of a migraine attack by dopaminergic agonists at doses that do not affect nonmigraineurs. Dopamine receptor antagonists are effective therapeutic agents in migraine, especially when given parenterally or concurrently with other antimigraine agents.

Migraine genes identified by studying families with familial hemiplegic migraine (FHM) reveal involvement of ion channels, suggesting that alterations in membrane excitability can predispose to migraine. Mutations involving the $Ca_v2.1$ (P/Q) type voltage-gated calcium channel *CACNA1A* gene are now known to cause FHM 1; this mutation is responsible for about 50% of FHM. Mutations in the Na^+-K^+ATPase *ATP1A2* gene, designated FHM 2, are responsible for about 20% of FHM. Mutations in the neuronal voltage-gated sodium channel *SCN1A* cause FHM 3. Functional neuroimaging has suggested that brainstem regions in migraine (Fig. 15-2) and the posterior hypothalamic gray matter region close to the human circadian pacemaker cells of the suprachiasmatic nucleus in cluster headache (Fig. 15-3) are good candidates for specific involvement in primary headache.

Diagnosis and Clinical Features Diagnostic criteria for migraine headache are listed in Table 15-4. A high index of suspicion is required to diagnose migraine: the migraine aura, consisting of visual disturbances with flashing lights or zigzag lines moving across the visual field or of other neurologic symptoms, is reported in only 20–25% of patients. A headache diary can often be helpful in making the diagnosis; this is also helpful in assessing disability and the frequency of treatment for acute attacks. Patients with episodes of migraine that occur daily or near-daily are considered to have chronic migraine (see "Chronic Daily Headache," below). Migraine must be differentiated from tension-type headache (discussed below), the most common primary headache syndrome seen in clinical practice. *Migraine at its most basic level is headache with associated features, and tension-type headache is headache that is featureless. Most patients with disabling headache probably have migraine.*

Patients with acephalgic migraine experience recurrent neurologic symptoms, often with nausea or vomiting, but with little or no headache. Vertigo can be prominent; it has been estimated that one-third of patients referred for vertigo or dizziness have a primary diagnosis of migraine.

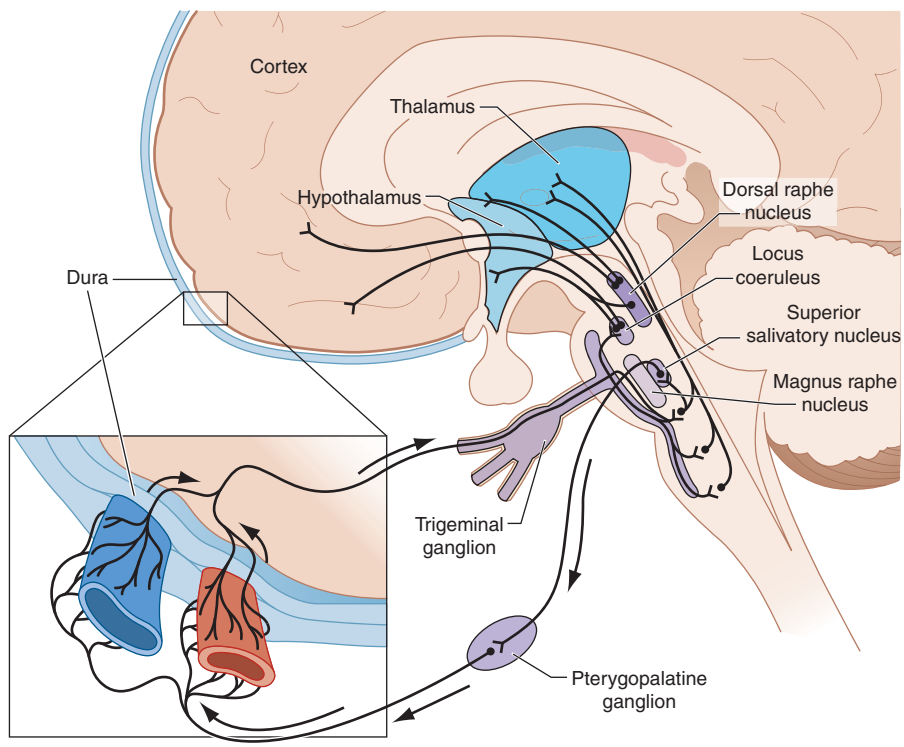

FIGURE 15-1 Brainstem pathways that modulate sensory input. The key pathway for pain in migraine is the trigeminovascular input from the meningeal vessels, which passes through the trigeminal ganglion and synapses on second-order neurons in the trigeminocervical complex. These neurons in turn project in the quintothalamic tract and, after decussating in the brainstem, synapse on neurons in the thalamus. Important modulation of the trigeminovascular nociceptive input comes from the dorsal raphe nucleus, locus coeruleus, and nucleus raphe magnus.

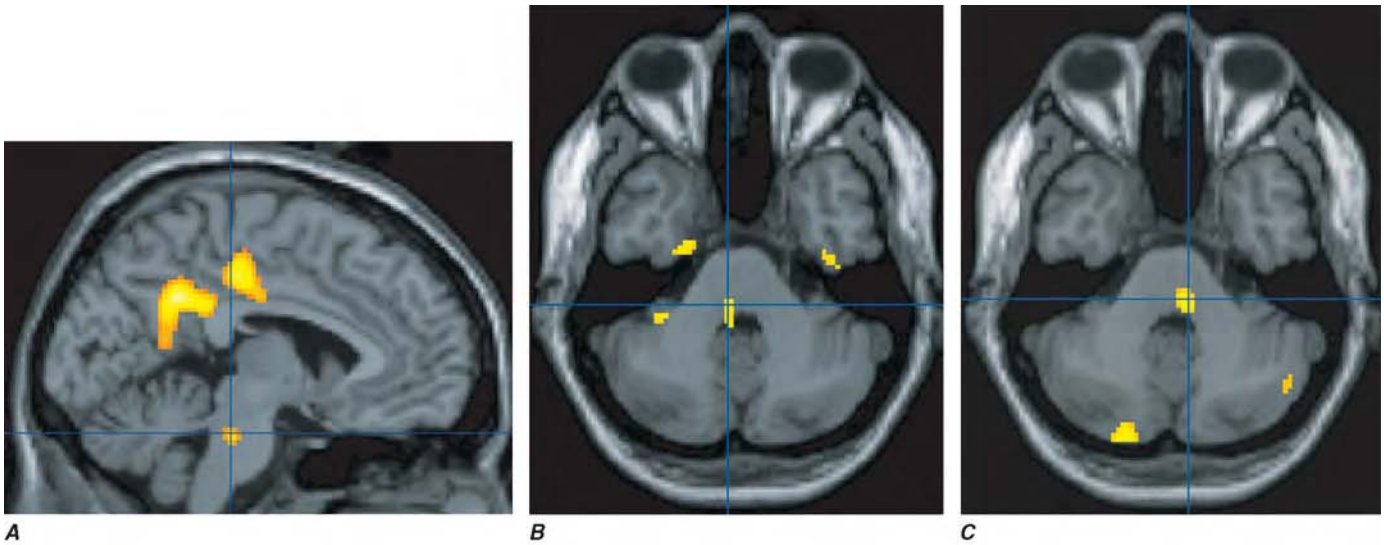

FIGURE 15-2 Positron emission tomography (PET) activation in migraine. In spontaneous attacks of episodic migraine (***A***) there is activation of the region of the dorsolateral pons (intersection of dark blue lines); an identical pattern is found in chronic migraine (not shown). This area, which includes the noradrenergic locus coeruleus, is fundamental to the expression of migraine. Moreover, lateralization of changes in this region of the brainstem correlates with lateralization of the head pain in hemicranial migraine; the scans shown in panels ***B*** and ***C*** are of patients with acute migraine headache on the right and left side, respectively. *(From S Afridi et al: Arch Neurol 62:1270, 2005; Brain 128:932, 2005.)*

℞ MIGRAINE HEADACHES

Once a diagnosis of migraine has been established, it is important to assess the extent of a patient's disease and disability. The Migraine Disability Assessment Score (MIDAS) is a well-validated, easy-to-use tool **(Fig. 15-4)**.

Patient education is an important aspect of migraine management. Information for patients is available at *www.achenet.org*, the website of the American Council for Headache Education (ACHE). It is helpful for patients to understand that migraine is an inherited tendency to headache; that migraine can be modified and controlled by lifestyle adjustments and medications, but it cannot be eradicated; and that, except in some occasions in women on oral estrogens or contraceptives, migraine is not associated with serious or life-threatening illnesses.

NONPHARMACOLOGIC MANAGEMENT Migraine can often be managed to some degree by a variety of nonpharmacologic approaches. Most patients benefit by the identification and avoidance of specific headache triggers. A regulated lifestyle is helpful, including a healthful diet, regular exercise, regular sleep patterns, avoidance of excess caffeine and alcohol, and avoidance of acute changes in stress levels.

The measures that benefit a given individual should be used routinely since they provide a simple, cost-effective approach to migraine management. Patients with migraine do not encounter more stress than headache-free individuals; overresponsiveness to stress appears to be the issue. Since the stresses of everyday living cannot be eliminated, lessening one's response to stress by various techniques is helpful for many patients. These may include yoga, transcendental meditation, hypnosis, and conditioning techniques such as biofeedback. For most patients, this approach is, at best, an adjunct to pharmacotherapy. Nonpharmacologic measures are unlikely to prevent all migraine attacks. When these measures fail to prevent an attack, pharmacologic approaches are then needed to abort an attack.

ACUTE ATTACK THERAPIES FOR MIGRAINE The mainstay of pharmacologic therapy is the judicious use of one or more of the many drugs that are effective in migraine **(Table 15-5)**. The selection of the optimal regimen for a given patient depends on a number of factors, the most important of which is the severity of the attack. Mild migraine attacks can usually be managed by oral agents; the average efficacy rate is 50–70%. Severe migraine attacks may require parenteral therapy. Most drugs effective in the treatment of migraine are members of one of three major pharmacologic classes: anti-inflammatory agents, $5HT_{1B/1D}$ receptor agonists, and dopamine receptor antagonists.

In general, an adequate dose of whichever agent is chosen should be used as soon as possible after the onset of an attack. If additional medication is required within 60 min because symptoms return or have not abat-

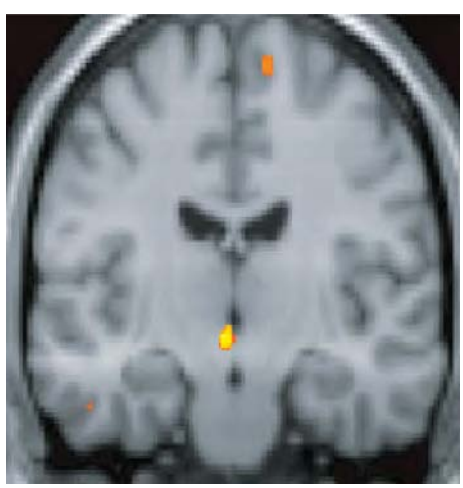

FIGURE 15-3 Posterior hypothalamic gray matter activation on positron emission tomography (PET) in a patient with acute cluster headache. TABLE 15-4 SIMPLIFIED DIAGNOSTIC CRITERIA FOR MIGRAINE

Repeated attacks of headache lasting 4–72 h in patients with a normal physical examination, no other reasonable cause for the headache, and:

At least 2 of the following features:	Plus at least 1 of the following features:
Unilateral pain	Nausea/vomiting
Throbbing pain	Photophobia and phonophobia
Aggravation by movement	
Moderate or severe intensity	

Source: Adapted from the International Headache Society Classification (Headache Classification Committee of the International Headache Society, 2004).

***MIDAS Questionnaire**

INSTRUCTIONS: Please answer the following questions about ALL headaches you have had over the last 3 months. Write zero if you did not do the activity in the last 3 months.

1. On how many days in the last 3 months did you miss work or school because of your headaches? ..... ____ days
2. How many days in the last 3 months was your productivity at work or school reduced by half or more because of your headaches *(do not include days you counted in question 1 where you missed work or school)*? ..... ____ days
3. On how many days in the last 3 months did you **not** do household work because of your headaches? ..... ____ days
4. How many days in the last 3 months was your productivity in household work reduced by half or more because of your headaches *(do not include days you counted in question 3 where you did not do household work)*? ..... ____ days
5. On how many days in the last 3 months did you miss family, social, or leisure activities because of your headaches? ..... ____ days

A. On how many days in the last 3 months did you have a headache? *(If a headache lasted more than one day, count each day.)* ..... ____ days

B. On a scale of 0–10, on average how painful were these headaches? *(Where 0 = no pain at all, and 10 = pain as bad as it can be.)* ..... ____

*Migraine Disability Assessment Score
(Questions 1–5 are used to calculate the MIDAS score.)
Grade I—Minimal or Infrequent Disability: 0–5
Grade II—Mild or Infrequent Disability: 6–10
Grade III—Moderate Disability: 11–20
Grade IV—Severe Disability: > 20

FIGURE 15-4 MIDAS Questionnaire.

ed, the initial dose should be increased for subsequent attacks. Migraine therapy must be individualized; a standard approach for all patients is not possible. A therapeutic regimen may need to be constantly refined until one is identified that provides the patient with rapid, complete, and consistent relief with minimal side effects **(Table 15-6)**.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) Both the severity and duration of a migraine attack can be reduced significantly by anti-inflammatory agents (Table 15-5). Indeed, many undiagnosed migraineurs are self-treated with nonprescription NSAIDs. A general consensus is that NSAIDs are most effective when taken early in the migraine attack. However, the effectiveness of anti-inflammatory agents in migraine is usually less than optimal in moderate or severe migraine attacks. The combination of acetaminophen, aspirin, and caffeine has been approved for use by the U.S. Food and Drug Administration (FDA) for the treatment of mild to moderate migraine. The combination of aspirin and metoclopramide has been shown to be equivalent to a single dose of sumatriptan. Important side effects of NSAIDs include dyspepsia and gastrointestinal irritation.

5-HT$_1$ AGONISTS **Oral** Stimulation of 5-HT$_{1B/1D}$ receptors can stop an acute migraine attack. Ergotamine and dihydroergotamine are nonselective receptor agonists, while the triptans are selective 5-HT$_{1B/1D}$ receptor agonists. A variety of triptans (e.g., naratriptan, rizatriptan, eletriptan, sumatriptan, zolmitriptan, almotriptan, frovatriptan) are now available for the treatment of migraine.

Each drug in the triptan class has similar pharmacologic properties but varies slightly in terms of clinical efficacy. Rizatriptan and eletriptan are the most efficacious of the triptans currently available in the United States. Sumatriptan and zolmitriptan have similar rates of efficacy as well as time to onset, whereas naratriptan and frovatriptan are the slowest-acting and least efficacious. Clinical efficacy appears to be related more to the t_{max} (time to peak plasma level) than to the potency, half-life, or bioavailability. This observation is consistent with a large body of data indicating that faster-acting analgesics are more effective than slower-acting agents.

Unfortunately, monotherapy with a selective oral 5-HT$_{1B/1D}$ agonist does not result in rapid, consistent, and complete relief of migraine in all patients. Triptans are not effective in migraine with aura unless given after the aura is completed and the headache initiated. Side effects are common though often mild and transient. Moreover, 5-HT$_{1B/1D}$ agonists are contraindicated in individuals with a history of cardiovascular and cerebrovascular disease. Recurrence of headache is another important limitation of triptan use and occurs at least occasionally in most patients.

Ergotamine preparations offer a nonselective means of stimulating 5-HT$_1$ receptors. A nonnauseating dose of ergotamine should be sought since a dose that provokes nausea is too high and may intensify head pain. Except for a sublingual formulation of ergotamine, oral formulations of ergotamine also contain 100 mg caffeine (theoretically to enhance ergotamine absorption and possibly to add additional analgesic activity). The average oral ergotamine dose for a migraine attack is 2 mg. Since the clinical studies demonstrating the efficacy of ergotamine in migraine predated the clinical trial methodologies used with the triptans, it is difficult to assess the clinical efficacy of ergotamine versus the triptans. In general, ergotamine appears to have a much higher incidence of nausea than triptans, but less headache recurrence.

Nasal The fastest-acting nonparenteral antimigraine therapies that can be self-administered include nasal formulations of dihydroergotamine (Migranal), zolmitriptan (Zomig nasal), or sumatriptan. The nasal sprays result in substantial blood levels within 30–60 min. Although in theory nasal sprays might provide faster and more effective relief of a migraine attack than oral formulations, their reported efficacy is only approximately 50–60%.

Parenteral Parenteral administration of drugs such as dihydroergotamine and sumatriptan is approved by the FDA for the rapid relief of a migraine attack. Peak plasma levels of dihydroergotamine are achieved 3 min after intravenous dosing, 30 min after intramuscular dosing, and 45 min after subcutaneous dosing. If an attack has not already peaked, subcutaneous or intramuscular administration of 1 mg dihydroergotamine suffices for about 80–90% of patients. Sumatriptan, 6 mg subcutaneously, is effective in ~70–80% of patients.

DOPAMINE ANTAGONISTS **Oral** Oral dopamine antagonists should be considered as adjunctive therapy in migraine. Drug absorption is impaired during migraine because of reduced gastrointestinal motility. Delayed absorption occurs even in the absence of nausea and is related to the severity of the attack and not its duration. Therefore, when oral NSAIDs and/or triptan agents fail, the addition of a dopamine antagonist such as metoclopramide, 10 mg, should be considered to enhance gastric absorption. In addition, dopamine antagonists decrease nausea/vomiting and restore normal gastric motility.

Parenteral Parenteral dopamine antagonists (e.g., chlorpromazine, prochlorperazine, metoclopramide) can also provide significant acute relief of migraine; they can be used in combination with parenteral 5-HT$_{1B/1D}$ agonists. A common intravenous protocol used for the treatment of severe migraine is the administration over 2 min of a mixture of 5 mg of prochlorperazine and 0.5 mg of dihydroergotamine.

OTHER MEDICATIONS FOR ACUTE MIGRAINE **Oral** The combination of acetaminophen, dichloralphenazone, and isometheptene, one to two capsules, has been classified by the FDA as "possibly" effective in the treatment of migraine. Since the clinical studies demonstrating the efficacy of this combination analgesic in migraine predated the clinical trial methodologies used with the triptans, it is difficult to compare the efficacy of this sympathomimetic compound to other agents.

Nasal A nasal preparation of butorphanol is available for the treatment of acute pain. As with all narcotics, the use of nasal butorphanol should be limited to a select group of migraineurs, as described below.

Parenteral Narcotics are effective in the acute treatment of migraine. For example, intravenous meperidine (50–100 mg) is given frequently in the emergency room. This regimen "works" in the sense that the pain of migraine is eliminated. However, this regimen is clearly suboptimal for patients with recurrent headache. Narcotics do not treat the underlying headache mechanism; rather, they act to alter the pain sensation. Moreover, in patients taking oral narcotics such as oxycodone or hydrocodone, narcotic addiction can greatly con-

TABLE 15-5 TREATMENT OF ACUTE MIGRAINE

Drug	Trade Name	Dosage
Simple Analgesics		
Acetaminophen, aspirin, caffeine	Excedrin Migraine	Two tablets or caplets q6h (max 8 per day)
NSAIDs		
Naproxen	Aleve, Anaprox, generic	220–550 mg PO bid
Ibuprofen	Advil, Motrin, Nuprin, generic	400 mg PO q3–4h
Tolfenamic acid	Clotam Rapid	200 mg PO. May repeat x 1 after 1–2 h
5-HT$_1$ Agonists		
Oral		
Ergotamine	Ergomar	One 2 mg sublingual tablet at onset and q$1/2$h (max 3 per day, 5 per week)
Ergotamine 1 mg, caffeine 100 mg	Ercaf, Wigraine	One or two tablets at onset, then one tablet q$1/2$h (max 6 per day, 10 per week)
Naratriptan	Amerge	2.5 mg tablet at onset; may repeat once after 4 h
Rizatriptan	Maxalt Maxalt-MLT	5–10 mg tablet at onset; may repeat after 2 h (max 30 mg/d)
Sumatriptan	Imitrex	50–100 mg tablet at onset; may repeat after 2 h (max 200 mg/d)
Frovatriptan	Frova	2.5 mg tablet at onset, may repeat after 2 h (max 5 mg/d)
Almotriptan	Axert	12.5 mg tablet at onset, may repeat after 2 h (max 25 mg/d)
Eletriptan	Relpax	40 or 80 mg
Zolmitriptan	Zomig Zomig Rapimelt	2.5 mg tablet at onset; may repeat after 2 h (max 10 mg/d)
Nasal		
Dihydroergotamine	Migranal Nasal Spray	Prior to nasal spray, the pump must be primed 4 times; 1 spray (0.5 mg) is administered, followed in 15 min by a second spray
Sumatriptan	Imitrex Nasal Spray	5–20 mg intranasal spray as 4 sprays of 5 mg or a single 20 mg spray (may repeat once after 2 h, not to exceed a dose of 40 mg/d)
Zolmitriptan	Zomig	5 mg intranasal spray as one spray (may repeat once after 2 h, not to exceed a dose of 10 mg/d)
Parenteral		
Dihydroergotamine	DHE-45	1 mg IV, IM, or SC at onset and q1h (max 3 mg/d, 6 mg per week)
Sumatriptan	Imitrex Injection	6 mg SC at onset (may repeat once after 1 h for max of 2 doses in 24 h)
Dopamine Antagonists		
Oral		
Metoclopramide	Reglan,[a] generic[a]	5–10 mg/d
Prochlorperazine	Compazine,[a] generic[a]	1–25 mg/d
Parenteral		
Chlorpromazine	Generic[a]	0.1 mg/kg IV at 2 mg/min; max 35 mg/d
Metoclopramide	Reglan,[a] generic	10 mg IV
Prochlorperazine	Compazine,[a] generic[a]	10 mg IV
Other		
Oral		
Acetaminophen, 325 mg, *plus* dichloralphenazone, 100 mg, *plus* isometheptene, 65 mg	Midrin, Duradrin, generic	Two capsules at onset followed by 1 capsule q1h (max 5 capsules)
Nasal		
Butorphanol	Stadol[a]	1 mg (1 spray in 1 nostril), may repeat if necessary in 1–2 h
Parenteral		
Narcotics	Generic[a]	Multiple preparations and dosages; see Table 12-1

[a]Not all drugs are specifically indicated by the FDA for migraine. Local regulations and guidelines should be consulted.
Note: Antiemetics (e.g., domperidone 10 mg or ondansetron) or prokinetics (e.g., metoclopramide 10 mg) are sometimes useful adjuncts.
Abbreviations: NSAIDs, nonsteroidal anti-inflammatory drugs; 5-HT, 5-hydroxytryptamine.

fuse the treatment of migraine. Narcotic craving and/or withdrawal can aggravate and accentuate migraine. Therefore, it is recommended that narcotic use in migraine be limited to patients with severe, but infrequent, headaches that are unresponsive to other pharmacologic approaches.

MEDICATION-OVERUSE HEADACHE

Acute attack medications, particularly codeine or barbiturate-containing compound analgesics, have a propensity to aggravate headache frequency and induce a state of refractory daily or near-daily headache called *medication-overuse headache*. This condition is likely not a separate headache entity but a reaction of the migraine patient to a particular medicine. Migraine patients who have two or more headache days a week should be cautioned about frequent analgesic use (see "Chronic Daily Headache," below).

PREVENTIVE TREATMENTS FOR MIGRAINE

Patients with an increasing frequency of migraine attacks, or with attacks that are either unresponsive or poorly responsive to abortive treatments, are good candidates for preventive agents. In general, a preventive medication should be considered in the subset of patients with five or more attacks a month. Significant side effects are associated with the use of many of these agents; furthermore, determination of dose can be difficult since the recommended doses have been derived for conditions other than migraine. The mechanism of action of these drugs is unclear; it seems likely that the brain sensitivity that underlies migraine is modified. Patients are usually started on a low dose of a chosen treatment; the dose is then gradually increased, up to a reasonable maximum to achieve clinical benefit.

Drugs that have the capacity to stabilize migraine are listed in **Table 15-7**. Drugs must be taken daily, and there is usually a lag of at least 2–12 weeks before an effect is seen. The drugs that have been approved by the FDA for the prophylactic treatment of migraine include propranolol, timolol, sodium valproate, topiramate, and methysergide (not available in the United States). In addition, a number of other drugs appear to display prophylactic efficacy. This group includes amitriptyline, nortriptyline, flunarizine, phenelzine, gabapentin, topiramate, and cyproheptadine. Phenelzine and methysergide are usually reserved for recalcitrant cases because of their serious potential side effects. Phenelzine is a monoamine oxidase inhibitor (MAOI); therefore, tyramine-containing foods, decongestants, and meperidine are contraindicated. Methysergide may cause retroperitoneal or cardiac valvular fibrosis when it is used for >6 months, and thus monitoring is required for patients using this drug; the risk of fibrosis is about 1:1500 and is likely to reverse after the drug is stopped.

The probability of success with any one of the antimigraine drugs is 50–75%. Many patients are managed adequately with low-dose amitriptyline, propranolol, topiramate, gabapentin, or valproate. If these agents fail or lead to unacceptable side effects, second-line agents such as methysergide or phenelzine can be used. Once effective stabilization is achieved, the drug is continued for 5–6 months and then slowly tapered to assess the continued need. Many patients are able to discontinue medication and experience fewer and milder attacks for long periods, suggesting that these drugs may alter the natural history of migraine.

TENSION-TYPE HEADACHE

Clinical Features

The term *tension-type headache* (TTH) is commonly used to describe a chronic head-pain syndrome characterized by bilateral tight, bandlike discomfort. The pain typically builds slowly,

TABLE 15-6 CLINICAL STRATIFICATION OF ACUTE SPECIFIC MIGRAINE TREATMENTS

Clinical Situation	Treatment Options
Failed NSAIDS/analgesics	**First tier**
	Sumatriptan 50 mg or 100 mg PO
	Almotriptan 12.5 mg PO
	Rizatriptan 10 mg PO
	Eletriptan 40 mg PO
	Zolmitriptan 2.5 mg PO
	Slower effect/better tolerability
	Naratriptan 2.5 mg PO
	Frovatriptan 2.5 mg PO
	Infrequent headache
	Ergotamine 1–2 mg PO
	Dihydroergotamine nasal spray 2 mg
Early nausea or difficulties taking tablets	Zolmitriptan 5 mg nasal spray
	Sumatriptan 20 mg nasal spray
	Rizatriptan 10 mg MLT wafer
Headache recurrence	Ergotamine 2 mg (most effective PR/usually with caffeine)
	Naratriptan 2.5 mg PO
	Almotriptan 12.5 mg PO
	Eletriptan 40 mg
Tolerating acute treatments poorly	Naratriptan 2.5 mg
	Almotriptan 12.5 mg
Early vomiting	Zolmitriptan 5 mg nasal spray
	Sumatriptan 25 mg PR
	Sumatriptan 6 mg SC
Menses-related headache	**Prevention**
	Ergotamine PO at night
	Estrogen patches
	Treatment
	Triptans
	Dihydroergotamine nasal spray
Very rapidly developing symptoms	Zolmitriptan 5 mg nasal spray
	Sumatriptan 6 mg SC
	Dihydroergotamine 1 mg IM

fluctuates in severity, and may persist more or less continuously for many days. The headache may be episodic or chronic (present >15 days per month).

A useful clinical approach is to diagnose TTH in patients whose headaches are completely without accompanying features such as nausea, vomiting, photophobia, phonophobia, osmophobia, throbbing, and aggravation with movement. Such an approach neatly separates migraine, which has one or more of these features and is the main differential diagnosis, from TTH. However, the International Headache Society's definition of TTH allows an admixture of nausea, photophobia, or phonophobia in various combinations, illustrating the difficulties in distinguishing these two clinical entities. Patients whose headaches fit the TTH phenotype and who have migraine at other times, along with a family history of migraine, migrainous illnesses of childhood, or typical migraine triggers to their migraine attacks, may be biologically different from those who have TTH headache with none of the features.

Pathophysiology The pathophysiology of TTH is incompletely understood. It seems likely that TTH is due to a primary disorder of CNS pain modulation alone, unlike migraine, which involves a more generalized disturbance of sensory modulation. Data suggest a genetic contribution to TTH, but this may not be a valid finding: given the current diagnostic criteria, the studies undoubtedly included many migraine patients. The name *tension-type headache* implies that pain is a product of *nervous tension*, but there is no clear evidence for tension as an etiology. Muscle contraction has been considered to be a feature that distinguishes TTH from migraine, but there appear to be no differences in contraction between the two headache types.

℞ TENSION-TYPE HEADACHE

The pain of TTH can generally be managed with simple analgesics such as acetaminophen, aspirin, or NSAIDs. Behavioral approaches including relaxation can also be effective. Clinical studies have demonstrated that triptans in pure TTH are not helpful, although triptans are effective in TTH when the patient also has migraine. For chronic TTH, amitriptyline is the only proven treatment (Table 15-7); other tricyclics, selective serotonin reuptake inhibitors, and the benzodiazepines have not been shown to be effective. There is no evidence for the efficacy of acupuncture. Placebo controlled trials of botulinum toxin type A in chronic TTH have not shown benefit.

TRIGEMINAL AUTONOMIC CEPHALALGIAS, INCLUDING CLUSTER HEADACHE

The trigeminal autonomic cephalalgias (TACs) are a group of primary headaches that includes cluster headache, paroxysmal hemicrania, and SUNCT (*s*hort-lasting *u*nilateral *n*euralgiform headache attacks with *c*onjunctival injection and *t*earing). TACs are characterized by relatively short-lasting attacks of head pain associated with cranial autonomic symptoms, such as lacrimation, conjunctival injection, or nasal congestion (Table 15-8). Pain is usually severe and may occur more than once a day. Because of the associated nasal congestion or rhinorrhea, patients are often misdiagnosed with "sinus headache" and treated with decongestants, which are ineffective.

TACs must be differentiated from short-lasting headaches that do not have prominent cranial autonomic syndromes, notably trigeminal neuralgia, primary stabbing headache, and hypnic headache. The cycling pattern and length, frequency, and timing of attacks are useful in classifying patients. Patients with TACs should undergo pituitary imaging and pituitary function tests as there is an excess of TAC presentations in patients with pituitary tumor–related headache.

Cluster Headache Cluster headache is a rare form of primary headache with a population frequency of 0.1%. The pain is deep, usually retroorbital, often excruciating in intensity, nonfluctuating, and explosive in quality. A core feature of cluster headache is periodicity. At least one of the daily attacks of pain recurs at about the same hour each day for the duration of a cluster bout. The typical cluster headache patient has daily bouts of one to two attacks of relatively short-duration unilateral pain for 8–10 weeks a year; this is usually followed by a pain-free interval that averages 1 year. Cluster headache is characterized as chronic when there is no period of sustained remission. Patients are generally perfectly well between episodes. Onset is nocturnal in about 50% of patients, and men are affected three times more often than women. Patients with cluster headache tend to move about during attacks, pacing, rocking, or rubbing their head for relief; some may even become aggressive during attacks. This is in sharp contrast to patients with migraine, who prefer to remain motionless during attacks.

Cluster headache is associated with ipsilateral symptoms of cranial parasympathetic autonomic activation: conjunctival injection or lacrimation, rhinorrhea or nasal congestion, or cranial sympathetic dysfunction such as ptosis. The sympathetic deficit is peripheral and likely to be due to parasympathetic activation with injury to ascending sympathetic fibers surrounding a dilated carotid artery as it passes into the cranial cavity. When present, photophobia and phonophobia are far more likely to be unilateral and on the same side of the pain, rather than bilateral, as is seen in migraine. This phenomenon of unilateral photophobia/phonophobia is characteristic of TACs. Cluster headache is likely to be a disorder involving central pacemaker neurons in the region of the posterior hypothalamus (Fig. 15-2).

℞ CLUSTER HEADACHE

The most satisfactory treatment is the administration of drugs to prevent cluster attacks until the bout is over. However, treatment of acute attacks is required for all cluster headache patients at some time.

ACUTE ATTACK TREATMENT Cluster headache attacks peak rapidly, and thus a treatment with quick onset is required. Many patients with acute cluster headache respond very well to oxygen inhalation. This should be given as 100% oxygen at 10–12 L/min for 15–20 min. It appears that high flow and high oxygen content are important. Sumatriptan 6 mg subcutaneously is rapid in onset and will usually shorten an attack to 10–15 min; there is no evidence of tachyphylaxis. Sumatriptan (20 mg) and zolmitriptan (5 mg) nasal sprays are both effective in acute cluster head-

TABLE 15-7 PREVENTIVE TREATMENTS IN MIGRAINE[a]

Drug	Dose	Selected Side Effects
Pizotifen[b]	0.5–2 mg qd	Weight gain Drowsiness
Beta blocker		
Propranolol	40–120 mg bid	Reduced energy Tiredness Postural symptoms *Contraindicated in asthma*
Tricyclics		
Amitriptyline	10–75 mg at night	Drowsiness
Dothiepin	25–75 mg at night	
Nortriptyline	25–75 mg at night	***Note:*** Some patients may only need a total dose of 10 mg, although generally 1–1.5 mg/kg body weight is required
Anticonvulsants		
Topiramate	25–200 mg/d	Paresthesias Cognitive symptoms Weight loss Glaucoma Caution with nephrolithiasis
Valproate	400–600 mg bid	Drowsiness Weight gain Tremor Hair loss Fetal abnormalities Hematologic or liver abnormalities
Gabapentin	900–3600 mg qd	Dizziness Sedation
Serotonergic drugs		
Methysergide	1–4 mg qd	Drowsiness Leg cramps Hair loss Retroperitoneal fibrosis (1-month drug holiday is required every 6 months)
Flunarizine[b]	5–15 mg qd	Drowsiness Weight gain Depression Parkinsonism
No convincing evidence from controlled trials		
Verapamil		
Controlled trials demonstrate *no effect*		
Nimodipine		
Clonidine		
SSRIs: fluoxetine		

[a]Commonly used preventives are listed with reasonable doses and common side effects. Not all listed medicines are approved by the FDA; local regulations and guidelines should be consulted.
[b]Not available in the United States.

ache, offering a useful option for patients who may not wish to self-inject daily. Oral sumatriptan is not effective for prevention or for acute treatment of cluster headache.

PREVENTIVE TREATMENTS **(Table 15-9)** The choice of a preventive treatment in cluster headache depends in part on the length of the bout. Patients with long bouts or those with chronic cluster headache require medicines that are safe when taken for long periods. For patients with relatively short bouts, limited courses of oral glucocorticoids or methysergide (not available in the United States) can be very useful. A 10-day course of prednisone, beginning at 60 mg daily for 7 days and followed by a rapid taper, may interrupt the pain bout for many patients. When ergotamine (1–2 mg) is used, it is most effective when given 1–2 h before an expected attack. Patients who use ergotamine daily must be educated regarding the early symptoms of ergotism, which may include vomiting, numbness, tingling, pain, and cyanosis of the limbs; a weekly limit of 14 mg should be adhered to. Lithium (600–900 mg qd) appears to be particularly useful for the chronic form of the disorder.

Many experts favor verapamil as the first-line preventive treatment for patients with chronic cluster headache or prolonged bouts. While verapamil compares favorably with lithium in practice, some patients require verapamil doses far in excess of those administered for cardiac disorders. The initial dose range is 40–80 mg twice daily; effective doses may be as high as 960 mg/d. Side effects such as constipation and leg swelling can be problematic. Of paramount concern, however, is the cardiovascular safety of verapamil, particularly at high doses. Verapamil can cause heart block by slowing conduction in the atrioventricular node, a condition that can be monitored by following the PR interval on a standard EKG. Approximately 20% of patients treated with verapamil develop EKG abnormalities, which can be observed with doses as low as 240 mg/d; these abnormalities can worsen over time in patients on stable doses. A baseline EKG is recommended for all patients. The EKG is repeated 10 days after a dose change in those patients whose dose is being increased above 240 mg daily. Dose increases are usually made in 80-mg increments. For patients on long-term verapamil, EKG monitoring every 6 months is advised.

NEUROSTIMULATION THERAPY When medical therapies fail in chronic cluster headache, neurostimulation therapy strategies can be employed. Deep-brain stimulation of the region of the posterior hypothalamic gray matter has proven successful in a substantial proportion of patients. Favorable results have also been reported with the less-invasive approach of occipital nerve stimulation.

Paroxysmal Hemicrania Paroxysmal hemicrania (PH) is characterized by frequent unilateral, severe, short-lasting episodes of headache. Like cluster headache, the pain tends to be retroorbital but may be experienced all over the head and is associated with autonomic phe-

TABLE 15-8 CLINICAL FEATURES OF THE TRIGEMINAL AUTONOMIC CEPHALALGIAS

	Cluster Headache	Paroxysmal Hemicrania	SUNCT
Gender	M>F	F=M	F~M
Pain			
Type	Stabbing, boring	Throbbing, boring, stabbing	Burning, stabbing, sharp
Severity	Excruciating	Excruciating	Severe to excruciating
Site	Orbit, temple	Orbit, temple	Periorbital
Attack frequency	1/alternate day–8/d	1–40/d (>5/d for more than half the time)	3–200/d
Duration of attack	15–180 min	2–30 min	5–240 s
Autonomic features	Yes	Yes	Yes (prominent conjunctival injection and lacrimation)[a]
Migrainous features[b]	Yes	Yes	Yes
Alcohol trigger	Yes	No	No
Cutaneous triggers	No	No	Yes

TABLE 15-9 PREVENTIVE MANAGEMENT OF CLUSTER HEADACHE

Short-Term Prevention	Long-Term Prevention
Episodic Cluster Headache	Episodic Cluster Headache & Prolonged Chronic Cluster Headache
Prednisone 1 mg/kg up to 60 mg qd, tapering over 21 days Methysergide 3–12 mg/d Verapamil 160–960 mg/d Greater occipital nerve injection	Verapamil 160–960 mg/d Lithium 400–800 mg/d Methysergide 3–12 mg/d Topiramate[a] 100–400 mg/d Gabapentin[a] 1200–3600 mg/d Melatonin[a] 9–12 mg/d

[a]Unproven but of potential benefit.

nomena such as lacrimation and nasal congestion. Patients with remissions are said to have episodic PH, while those with the nonremitting form are said to have chronic PH. The essential features of PH are: unilateral, very severe pain; short-lasting attacks (2–45 min); very frequent attacks (usually more than five a day); marked autonomic features ipsilateral to the pain; rapid course (<72 h); and excellent response to indomethacin. In contrast to cluster headache, which predominantly affects males, the male:female ratio in PH is close to 1:1.

Indomethacin (25–75 mg tid), which can completely suppress attacks of PH, is the treatment of choice. Although therapy may be complicated by indomethacin-induced gastrointestinal side effects, currently there are no consistently effective alternatives. Topiramate is helpful in some cases. Piroxicam has been used, although it is not as effective as indomethacin. Verapamil, an effective treatment for cluster headache, does not appear to be useful for PH. In occasional patients, PH can coexist with trigeminal neuralgia (PH-tic syndrome); similar to cluster-tic syndrome, each component may require separate treatment.

Secondary PH has been reported with lesions in the region of the sella turcica, including arteriovenous malformation, cavernous sinus meningioma, and epidermoid tumors. Secondary PH is more likely if the patient requires high doses (>200 mg/d) of indomethacin. In patients with apparent bilateral PH, raised CSF pressure should be suspected. It is important to note that indomethacin reduces CSF pressure. When a diagnosis of PH is considered, MRI is indicated to exclude a pituitary lesion.

SUNCT/SUNA SUNCT is a rare primary headache syndrome characterized by severe, unilateral orbital or temporal pain that is stabbing or throbbing in quality. Diagnosis requires at least 20 attacks, lasting for 5–240 s; ipsilateral conjunctival injection and lacrimation should be present. In some patients conjunctival injection or lacrimation are missing, and the diagnosis of SUNA (*s*hort-lasting *u*nilateral *n*euralgiform headache attacks with cranial *a*utonomic symptoms) has been suggested.

DIAGNOSIS The pain of SUNCT/SUNA is unilateral and may be located anywhere in the head. Three basic patterns can be seen: single stabs, which are usually short-lived; groups of stabs; or a longer attack comprising many stabs between which the pain does not completely resolve, thus giving a "saw-tooth" phenomenon with attacks lasting many minutes. Each pattern may be seen in the context of an underlying continuous head pain. Characteristics that lead to a suspected diagnosis of SUNCT are the cutaneous (or other) triggerability of attacks, a lack of refractory period to triggering between attacks, and the lack of a response to indomethacin. Apart from trigeminal sensory disturbance, the neurologic examination is normal in primary SUNCT.

The diagnosis of SUNCT is often confused with trigeminal neuralgia (TN) particularly in first-division TN (Chap. 371). Minimal or no cranial autonomic symptoms and a clear refractory period to triggering indicate a diagnosis of TN.

SECONDARY (SYMPTOMATIC) SUNCT SUNCT can be seen with posterior fossa or pituitary lesions. All patients with SUNCT/SUNA should be evaluated with pituitary function tests and a brain MRI with pituitary views.

TABLE 15-10 CLASSIFICATION OF CHRONIC DAILY HEADACHE

Primary		
>4 h Daily	<4 h Daily	Secondary
Chronic migraine[a]	Chronic cluster headache[b]	Posttraumatic Head injury Iatrogenic Postinfectious
Chronic tension-type headache[a]	Chronic paroxysmal hemicrania	Inflammatory, such as Giant cell arteritis Sarcoidosis Behçet's syndrome
Hemicrania continua[a]	SUNCT/SUNA	Chronic CNS infection
New daily persistent headache[a]	Hypnic headache	Medication-overuse headache[a]

[a]May be complicated by analgesic overuse.
[b]Some patients may have headache > 4 h per day.
Note: SUNCT, *s*hort-lasting *u*nilateral *n*euralgiform headache attacks with conjunctival injection and *t*earing; SUNA, *s*hort-lasting *u*nilateral *n*euralgiform headache *a*ttacks with cranial autonomic symptoms.

Rx SUNCT/SUNA

ABORTIVE THERAPY Therapy of acute attacks is not a useful concept in SUNCT/SUNA since the attacks are of such short duration. However, intravenous lidocaine, which arrests the symptoms, can be used in hospitalized patients.

PREVENTIVE THERAPY Long-term prevention to minimize disability and hospitalization is the goal of treatment. The most effective treatment for prevention is lamotrigine, 200–400 mg/d. Topiramate and gabapentin may also be effective. Carbamazepine, 400–500 mg/d, has been reported by patients to offer modest benefit.

Surgical approaches such as microvascular decompression or destructive trigeminal procedures are seldom useful and often produce long-term complications. Greater occipital nerve injection has produced limited benefit in some patients. Mixed success with occipital nerve stimulation has been observed. Complete control with deep-brain stimulation of the posterior hypothalamic region was reported in a single patient. For intractable cases, short-term prevention with intravenous lidocaine can be effective.

CHRONIC DAILY HEADACHE

The broad diagnosis of chronic daily headache (CDH) can be applied when a patient experiences headache on 15 days or more per month. CDH is not a single entity; it encompasses a number of different headache syndromes, including chronic TTH as well as headache secondary to trauma, inflammation, infection, medication overuse, and other causes (Table 15-10). Population-based estimates suggest that about 4% of adults have daily or near-daily headache. Daily headache may be primary or secondary, an important consideration in guiding management of this complaint.

APPROACH TO THE PATIENT: Chronic Daily Headache

The first step in the management of patients with CDH is to diagnose any underlying condition (Table 15-10). For patients with primary headaches, diagnosis of the headache type will guide therapy. Preventive treatments such as tricyclics, either amitriptyline or doxepin at doses up to 1 mg/kg, are very useful in patients with CDH. Tricyclics are started in low doses (10–25 mg) daily and may be given 12 h before the expected time of awakening in order to avoid excess morning sleepiness. Anticonvulsants, such as topiramate, valproate, and gabapentin, are also useful in migraineurs. Flunarizine can also be very effective for some patients, as can methysergide or phenelzine.

MANAGEMENT OF MEDICALLY INTRACTABLE DISABLING CHRONIC DAILY HEADACHE The management of medically intractable headache is difficult. At this time, the only promising approach is occipital nerve stimulation, which appears to modulate thalamic processing in mi-

graine and has shown promise in both chronic cluster headache and hemicrania continua (see below). Clinical trials using botulinum toxin in chronic migraine have failed to show any objective benefit.

MEDICATION-OVERUSE HEADACHE Overuse of analgesic medication for headache can aggravate headache frequency and induce a state of refractory daily or near-daily headache called *medication-overuse headache*. A proportion of patients who stop taking analgesics will experience substantial improvement in the severity and frequency of their headache. However, even after cessation of analgesic use, many patients continue to have headache, although they may feel clinically improved in some way, especially if they have been using codeine or barbiturates regularly. The residual symptoms probably represent the underlying headache disorder.

Management of Medication Overuse: Outpatients For patients who overuse medications, it is essential that analgesic use be reduced and eliminated. One approach is to reduce the medication dose by 10% every 1–2 weeks. Immediate cessation of analgesic use is possible for some patients, provided there is no contraindication. Both approaches are facilitated by the use of a medication diary maintained during the month or two before cessation; this helps to identify the scope of the problem. A small dose of an NSAID such as naproxen, 500 mg bid if tolerated, will help relieve residual pain as analgesic use is reduced. NSAID overuse is not usually a problem for patients with daily headache when the dose is taken once or twice daily; however, overuse problems may develop with more frequent dosing schedules. Once the patient has substantially reduced analgesic use, a preventive medication should be introduced. It must be emphasized that *preventives generally do not work in the presence of analgesic overuse*. The most common cause of unresponsiveness to treatment is the use of a preventive when analgesics continue to be used regularly. For some patients, discontinuing analgesics is very difficult; often the best approach is to directly inform the patient that some degree of pain is inevitable during this initial period.

Management of Medication Overuse: Inpatients Some patients will require hospitalization for detoxification. Such patients have typically failed efforts at outpatient withdrawal or have a significant medical condition, such as diabetes mellitus, which would complicate withdrawal as an outpatient. Following admission to the hospital, acute medications are withdrawn completely on the first day, in the absence of a contraindication. Antiemetics and fluids are administered as required; clonidine is used for opiate withdrawal symptoms. For acute intolerable pain during the waking hours aspirin, 1 g (not approved in United States) intravenously, is useful. Intramuscular chlorpromazine can be helpful at night; patients must be adequately hydrated. If the patient does not improve within 3–5 days, a course of intravenous dihydroergotamine (DHE) can be employed. DHE, administered every 8 h for 3 consecutive days, can induce a significant remission that allows a preventive treatment to be established. 5-HT_3 antagonists, such as ondansetron or granisetron, are often required with DHE to prevent significant nausea.

NEW DAILY PERSISTENT HEADACHE New daily persistent headache (NDPH) is a clinically distinct syndrome; its causes are listed in Table 15-11.

TABLE 15-11 DIFFERENTIAL DIAGNOSIS OF NEW DAILY PERSISTENT HEADACHE

Primary	Secondary
Migrainous-type	Subarachnoid hemorrhage
Featureless (tension-type)	Low CSF volume headache
	Raised CSF pressure headache
	Posttraumatic headache[a]
	Chronic meningitis

[a]Includes postinfectious forms.

Clinical Presentation The patient with NDPH presents with headache on most if not all days; the onset is recent and clearly recalled by the patient. The headache usually begins abruptly, but onset may be more gradual; evolution over 3 days has been proposed as the upper limit for this syndrome. Patients typically recall the exact day and circumstances of the onset of headache; the new, persistent head pain does not remit. The first priority is to distinguish between a primary and a secondary cause of this syndrome. Subarachnoid hemorrhage is the most serious of the secondary causes and must be excluded either by history or appropriate investigation (Chap. 269).

Secondary NDPH ***Low CSF Volume Headache*** In these syndromes, head pain is positional: it begins when the patient sits or stands upright and resolves upon reclining. The pain, which is occipitofrontal, is usually a dull ache but may be throbbing. Patients with chronic low CSF volume headache typically present with a history of headache from one day to the next that is generally not present on waking but worsens during the day. Recumbency usually improves the headache within minutes, but it takes only minutes to an hour for the pain to return when the patient resumes an upright position.

The most common cause of headache due to persistent low CSF volume is CSF leak following lumbar puncture (LP). Post-LP headache usually begins within 48 h but may be delayed for up to 12 days. Its incidence is between 10 and 30%. Beverages with caffeine may provide temporary relief. Besides LP, index events may include epidural injection or a vigorous Valsalva maneuver, such as from lifting, straining, coughing, clearing the eustachian tubes in an airplane, or multiple orgasms. Spontaneous CSF leaks are well recognized, and the diagnosis should be considered whenever the headache history is typical, even when there is no obvious index event. As time passes from the index event, the postural nature may become less apparent; cases in which the index event occurred several years before the eventual diagnosis have been recognized. Symptoms appear to result from low volume rather than low pressure: although low CSF pressures, typically 0–50 mmH_2O, are usually identified, a pressure as high as 140 mmH_2O has been noted with a documented leak. Postural orthostatic tachycardia syndrome [POTS (Chap. 370)] can present with orthostatic headache similar to low CSF volume headache and is a diagnosis that needs consideration here.

When imaging is indicated to identify the source of a presumed leak, an MRI with gadolinium is the initial study of choice (Fig. 15-5). A striking pattern of diffuse meningeal enhancement is so typical that in the appropriate clinical context the diagnosis is established. Chiari malformations may sometimes be noted on MRI; in such cases surgery to decompress the posterior fossa usually worsens the headache. The source of CSF leakage may be identified by spinal MRI, by CT myelogram, or with ^{111}In-DTPA CSF studies; in the absence of a directly identified site of leakage, early emptying of ^{111}In-DTPA tracer into the bladder or slow progress of tracer across the brain suggests a CSF leak.

Initial treatment for low CSF volume headache is bed rest. For patients with persistent pain, intravenous caffeine (500 mg in 500 mL saline administered over 2 h) is often very effective. An EKG to screen for arrhythmia should be performed before administration. It is reasonable to administer at least two infusions of caffeine before embarking on additional tests to identify the source of the CSF leak. Since intravenous caffeine is safe and can be curative, it spares many patients the need for further investigations. If unsuccessful, an abdominal binder may be helpful. If a leak can be identified, an autologous blood patch is usually curative. A blood patch is also effective for post-LP headache; in this setting the location is empirically determined to be the site of the LP. In patients with intractable pain, oral theophylline is a useful alternative; however, its effect is less rapid than caffeine.

Raised CSF Pressure Headache Raised CSF pressure is well recognized as a cause of headache. Brain imaging can often reveal the

FIGURE 15-5 Magnetic resonance image showing diffuse meningeal enhancement after gadolinium administration in a patient with low CSF volume headache.

cause, such as a space-occupying lesion. NDPH due to raised CSF pressure can be the presenting symptom for patients with idiopathic intracranial hypertension (pseudotumor cerebri) without visual problems, particularly when the fundi are normal. Persistently raised intracranial pressure can trigger chronic migraine. These patients typically present with a history of generalized headache that is present on waking and improves as the day goes on. It is generally worse with recumbency. Visual obscurations are frequent. The diagnosis is relatively straightforward when papilledema is present, but the possibility must be considered even in patients without fundoscopic changes. Formal visual-field testing should be performed even in the absence of overt ophthalmic involvement. Headache on rising in the morning or nocturnal headache is also characteristic of obstructive sleep apnea or poorly controlled hypertension.

Evaluation of patients suspected to have raised CSF pressure requires brain imaging. It is most efficient to obtain an MRI, including an MR venogram as the initial study. If there are no contraindications, the CSF pressure should be measured by LP; this should be done when the patient is symptomatic so that both the pressure and the response to removal of 20–30 mL of CSF can be determined. An elevated opening pressure and improvement in headache following removal of CSF is diagnostic.

Initial treatment is with acetazolamide (250–500 mg bid); the headache may improve within weeks. If ineffective, topiramate is the next treatment of choice; it has many actions that may be useful in this setting, including carbonic anhydrase inhibition, weight loss, and neuronal membrane stabilization, likely mediated via effects on phosphorylation pathways. Severely disabled patients who do not respond to medical treatment require intracranial pressure monitoring and may require shunting.

Post-Traumatic Headache A traumatic event can trigger a headache process that lasts for many months or years after the event. The term *trauma* is used in a very broad sense: headache can develop following an injury to the head, but it can also develop after an infectious episode, typically viral meningitis, a flulike illness, or a parasitic infection. Complaints of dizziness, vertigo, and impaired memory can accompany the headache. Symptoms may remit after several weeks or persist for months and even years after the injury. Typically the neurologic examination is normal and CT or MRI studies are unrevealing. Chronic subdural hematoma may on occasion mimic this disorder. In one series, one-third of patients with NDPH reported headache beginning after a transient flulike illness characterized by fever, neck stiffness, photophobia, and marked malaise. Evaluation reveals no apparent cause for the headache. There is no convincing evidence that persistent Epstein-Barr infection plays a role in this syndrome. A complicating factor is that many patients undergo LP during the acute illness; iatrogenic low CSF volume headache must be considered in these cases. Post-traumatic headache may also be seen after carotid dissection and subarachnoid hemorrhage, and following intracranial surgery. The underlying theme appears to be that a traumatic event involving the pain-producing meninges can trigger a headache process that lasts for many years.

Treatment is largely empirical. Tricyclic antidepressants, notably amitriptyline, and anticonvulsants such as topiramate, valproate, and gabapentin, have been used with reported benefit. The MAOI phenelzine may also be useful in carefully selected patients. The headache usually resolves within 3–5 years, but it can be quite disabling.

Primary NDPH Primary NDPH occurs in both males and females. It can be of the migrainous type, with features of migraine, or it can be featureless, appearing as new-onset TTH (Table 15-11). Migrainous features are common and include unilateral headache and throbbing pain; each feature is present in about one-third of patients. Nausea, photophobia, and/or phonophobia occur in about half of patients. Some patients have a previous history of migraine; however, the proportion of NDPH sufferers with preexisting migraine is no greater than the frequency of migraine in the general population. At 24 months, ~86% of patients are headache-free. Treatment of migrainous-type primary NDPH consists of using the preventive therapies effective in migraine (Table 15-7). Featureless NDPH is one of the primary headache forms most refractory to treatment. Standard preventive therapies can be offered but are often ineffective.

OTHER PRIMARY HEADACHES

Hemicrania Continua The essential features of hemicrania continua are moderate and continuous unilateral pain associated with fluctuations of severe pain; complete resolution of pain with indomethacin; and exacerbations that may be associated with autonomic features, including conjunctival injection, lacrimation, and photophobia on the affected side. The age of onset ranges from 11 to 58 years; women are affected twice as often as men. The cause is unknown.

℞ HEMICRANIA CONTINUA

Treatment consists of indomethacin; other NSAIDs appear to be of little or no benefit. The intramuscular injection of 100 mg indomethacin has been proposed as a diagnostic tool; administration with a placebo injection has been recommended. Alternatively, a trial of oral indomethacin, starting with 25 mg tid, then 50 mg tid, and then 75 mg tid, can be given. Up to 2 weeks may be necessary to assess whether a dose has a useful effect. Topiramate can be helpful in some patients. Occipital nerve stimulation may have a role in patients with hemicrania continua who are unable to tolerate indomethacin.

Primary Stabbing Headache The essential features of primary stabbing headache are stabbing pain confined to the head or, rarely, the face, lasting from 1 to many seconds or minutes and occurring as a single stab or a series of stabs; absence of associated cranial autonomic features; absence of cutaneous triggering of attacks; and a pattern of recurrence at irregular intervals (hours to days). The pains have been variously described as "ice-pick pains" or "jabs and jolts." They are more common in patients with other primary headaches, such as migraine, the TACs, and hemicrania continua.

℞ PRIMARY STABBING HEADACHE

The response of primary stabbing headache to indomethacin (25–50 mg two to three times daily) is usually excellent. As a general rule the symp-

toms wax and wane, and after a period of control on indomethacin, it is appropriate to withdraw treatment and observe the outcome.

Primary Cough Headache Primary cough headache is a generalized headache that begins suddenly, lasts for several minutes, and is precipitated by coughing; it is preventable by avoiding coughing or other precipitating events, which can include sneezing, straining, laughing, or stooping. In all patients with this syndrome serious etiologies must be excluded before a diagnosis of "benign" primary cough headache can be established. A Chiari malformation or any lesion causing obstruction of CSF pathways or displacing cerebral structures can be the cause of the head pain. Other conditions that can present with cough or exertional headache as the initial symptom include cerebral aneurysm, carotid stenosis, and vertebrobasilar disease. Benign cough headache can resemble benign exertional headache (below), but patients with the former condition are typically older.

Rx PRIMARY COUGH HEADACHE

Indomethacin 25–50 mg two to three times daily is the treatment of choice. Some patients with cough headache obtain pain relief with LP; this is a simple option when compared to prolonged use of indomethacin, and it is effective in about one-third of patients. The mechanism of this response is unclear.

Primary Exertional Headache Primary exertional headache has features resembling both cough headache and migraine. It may be precipitated by any form of exercise; it often has the pulsatile quality of migraine. The pain, which can last from 5 min to 24 h, is bilateral and throbbing at onset; migrainous features may develop in patients susceptible to migraine. Primary exertional headache can be prevented by avoiding excessive exertion, particularly in hot weather or at high altitude.

The mechanism of primary exertional headache is unclear. Acute venous distension likely explains one syndrome, the acute onset of headache with straining and breath holding, as in weightlifter's headache. As exertion can result in headache in a number of serious underlying conditions, these must be considered in patients with exertional headache. Pain from angina may be referred to the head, probably by central connections of vagal afferents, and may present as exertional headache (cardiac cephalgia). The link to exercise is the main clinical clue that headache is of cardiac origin. Pheochromocytoma may occasionally cause exertional headache. Intracranial lesions and stenosis of the carotid arteries are other possible etiologies.

Rx PRIMARY EXERTIONAL HEADACHE

Exercise regimens should begin modestly and progress gradually to higher levels of intensity. Indomethacin at daily doses from 25 to 150 mg is generally effective in benign exertional headache. Indomethacin (50 mg), ergotamine (1 mg orally), dihydroergotamine (2 mg by nasal spray), or methysergide (1–2 mg orally given 30–45 min before exercise) are useful prophylactic measures.

Primary Sex Headache Sex headache is precipitated by sexual excitement. The pain usually begins as a dull bilateral headache which suddenly becomes intense at orgasm. The headache can be prevented or eased by ceasing sexual activity before orgasm. Three types of sex headache are reported: a dull ache in the head and neck that intensifies as sexual excitement increases; a sudden, severe, explosive headache occurring at orgasm; and a postural headache developing after coitus that resembles the headache of low CSF pressure. The latter arises from vigorous sexual activity and is a form of low CSF pressure headache. Headaches developing at the time of orgasm are not always benign; 5–12% of cases of subarachnoid hemorrhage are precipitated by sexual intercourse. Sex headache is reported by men more often than women and may occur at any time during the years of sexual activity. It may develop on several occasions in succession and then not trouble the patient again, even without an obvious change in sexual activity. In patients who stop sexual activity when headache is first noticed, the pain may subside within a period of 5 min to 2 h. In about half of patients, sex headache will subside within 6 months. About half of patients with sex headache have a history of exertional headaches, but there is no excess of cough headache. Migraine is probably more common in patients with sex headache.

Rx PRIMARY SEX HEADACHE

Benign sex headaches recur irregularly and infrequently. Management can often be limited to reassurance and advice about ceasing sexual activity if a mild, warning headache develops. Propranolol can be used to prevent headache that recurs regularly or frequently, but the dosage required varies from 40 to 200 mg/d. An alternative is the calcium channel-blocking agent diltiazem, 60 mg tid. Ergotamine (1 mg) or indomethacin (25–50 mg) taken about 30–45 min prior to sexual activity can also be helpful.

Primary Thunderclap Headache Sudden onset of severe headache may occur in the absence of any known provocation. The differential diagnosis includes the sentinel bleed of an intracranial aneurysm, cervicocephalic arterial dissection, and cerebral venous thrombosis. Headaches of explosive onset may also be caused by the ingestion of sympathomimetic drugs or of tyramine-containing foods in a patient who is taking MAOIs, or they may be a symptom of pheochromocytoma. Whether thunderclap headache can be the presentation of an unruptured cerebral aneurysm is uncertain. When neuroimaging studies and LP exclude subarachnoid hemorrhage, patients with thunderclap headache usually do very well over the long term. In one study of patients whose CT scans and CSF findings were negative, ~15% had recurrent episodes of thunderclap headache, and nearly half subsequently developed migraine or tension-type headache.

The first presentation of any sudden-onset severe headache should be vigorously investigated with neuroimaging (CT or, when possible, MRI with MR angiography) and CSF examination. Formal cerebral angiography should be reserved for those cases in which no primary diagnosis is forthcoming and for clinical situations that are particularly suggestive of intracranial aneurysm. Reversible segmental cerebral vasoconstriction may be seen in primary thunderclap headache without an intracranial aneurysm. In the presence of posterior leukoencephalopathy, the differential diagnosis includes cerebral angiitis, drug toxicity (cyclosporine, intrathecal methotrexate/cytarabine, pseudoephedrine, or cocaine), posttransfusion effects, and postpartum angiopathy. Treatment with nimodipine may be helpful, although by definition the vasoconstriction of primary thunderclap headache resolves spontaneously.

Hypnic Headache This headache syndrome typically begins a few hours after sleep onset. The headaches last from 15 to 30 min and are typically moderately severe and generalized, although they may be unilateral and can be throbbing. Patients may report falling back to sleep only to be awakened by a further attack a few hours later; up to three repetitions of this pattern occur through the night. Daytime naps can also precipitate head pain. Most patients are female, and the onset is usually after age 60. Headaches are bilateral in most, but may be unilateral. Photophobia or phonophobia and nausea are usually absent. The major secondary consideration in this headache type is poorly controlled hypertension; 24-h blood pressure monitoring is recommended to detect this treatable condition.

Rx HYPNIC HEADACHE

Patients with hypnic headache generally respond to a bedtime dose of lithium carbonate (200–600 mg). For those intolerant of lithium, verapamil (160 mg) or methysergide (1–4 mg at bedtime) may be alternative strategies. One to two cups of coffee or caffeine, 60 mg orally, at bedtime may

be effective in approximately one-third of patients. Case reports suggest that flunarizine, 5 mg nightly, can be effective.

16 Back and Neck Pain

John W. Engstrom

The importance of back and neck pain in our society is underscored by the following: (1) the cost of back pain in the United States is ~$100 billion annually, including direct health care expenses plus costs due to loss of productivity; (2) back symptoms are the most common cause of disability in those <45 years; (3) low back pain is the second most common reason for visiting a physician in the United States; and (4) ~1% of the U.S. population is chronically disabled because of back pain.

ANATOMY OF THE SPINE

The anterior portion of the spine consists of cylindrical vertebral bodies separated by intervertebral disks and held together by the anterior and posterior longitudinal ligaments. The intervertebral disks are composed of a central gelatinous nucleus pulposus surrounded by a tough cartilaginous ring, the annulus fibrosis; disks are responsible for 25% of spinal column length (Figs. 16-1 and 16-2). The disks are largest in the cervical and lumbar regions where movements of the spine are greatest. The disks are elastic in youth and allow the bony vertebrae to move easily upon each other. Elasticity is lost with age. The function of the anterior spine is to absorb the shock of body movements such as walking and running.

The posterior portion of the spine consists of the vertebral arches and seven processes. Each arch consists of paired cylindrical pedicles anteriorly and paired laminae posteriorly. The vertebral arch gives rise to two transverse processes laterally, one spinous process posteriorly, plus two superior and two inferior articular facets. The apposition of a superior and inferior facet constitutes a *facet joint*. The functions of the posterior spine are to protect the spinal cord and nerves within the spinal canal and to stabilize the spine by providing sites for the attachment of muscles and ligaments. The contraction of muscles attached to the spinous and transverse processes produces a system of pulleys and levers that results in flexion, extension, and lateral bending movements of the spine.

Nerve root injury (*radiculopathy*) is a common cause of neck, arm, low back, and leg pain (Figs. 25-2 and 25-3). The nerve roots exit at a level above their respective vertebral bodies in the cervical region (the C7 nerve root exits at the C6-C7 level) and below their respective vertebral bodies in the thoracic and lumbar regions (the T1 nerve root exits at the T1-T2 level). The cervical nerve roots follow a short intraspinal course before exiting. By contrast, because the spinal cord ends at the vertebral L1 or L2 level, the lumbar nerve roots follow a long intraspinal course and can be injured anywhere from the upper lumbar spine to their exit at the intervertebral foramen. For example, disk herniation at the L4-L5 level commonly produces compression of the traversing S1 nerve root (Fig. 16-3).

Pain-sensitive structures in the spine include the periosteum of the vertebrae, dura, facet joints, annulus fibrosus of the intervertebral disk, epidural veins, and the posterior longitudinal ligament. Disease of these diverse structures may explain many cases of back pain without nerve root compression. The nucleus pulposus of the intervertebral disk is not pain-sensitive under normal circumstances. Pain sensation is conveyed partially by the sinuvertebral nerve that arises from the spinal nerve at each spine segment and reenters the spinal canal through the intervertebral foramen at the same level. The lumbar and cervical spine possess the greatest potential for movement and injury.

APPROACH TO THE PATIENT: Back Pain

TYPES OF BACK PAIN Understanding the type of pain experienced by the patient is the essential first step. Attention is also focused on identification of risk factors for serious underlying diseases; the majority of these are due to radiculopathy, fracture, tumor, infection, or referred pain from visceral structures (Table 16-1).

Local pain is caused by stretching of pain-sensitive structures that compress or irritate sensory nerve endings. The site of the pain is near the affected part of the back.

Pain referred to the back may arise from abdominal or pelvic viscera. The pain is usually described as primarily abdominal or pelvic but is accompanied by back pain and usually unaffected by posture. The patient may occasionally complain of back pain only.

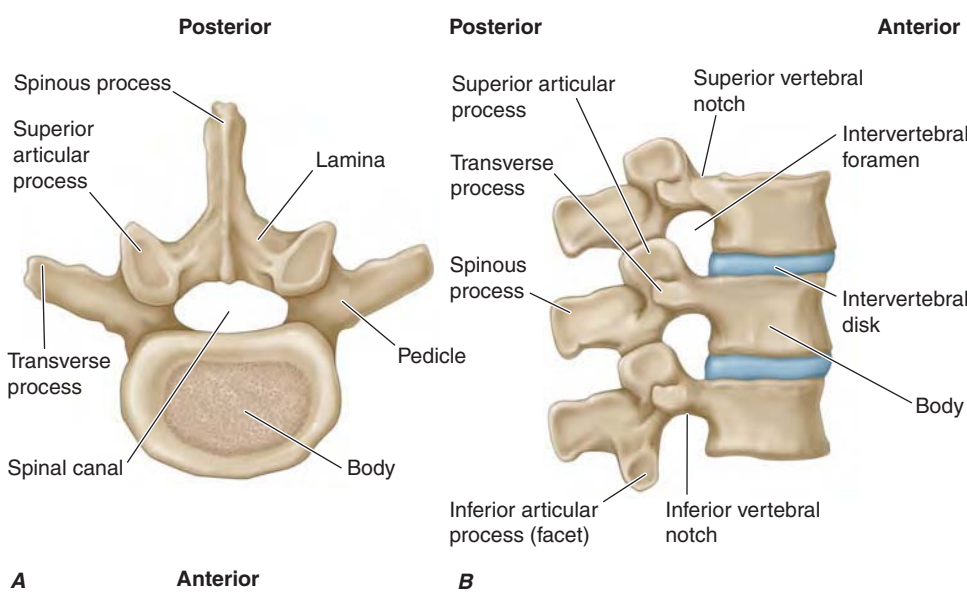

FIGURE 16-1 Vertebral anatomy. (*From A Gauthier Cornuelle, DH Gronefeld: Radiographic Anatomy Positioning. New York, McGraw-Hill, 1998; with permission.*)

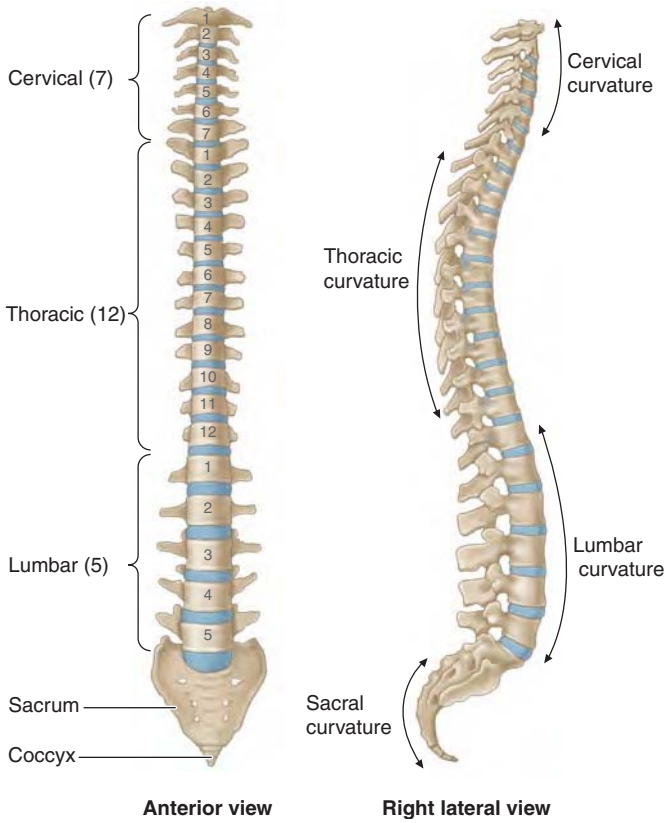

FIGURE 16-2 Spinal column. (*From: A Gauthier Cornuelle, DH Gronefeld: Radiographic Anatomy Positioning. New York, McGraw-Hill, 1998; with permission.*)

Pain of spine origin may be located in the back or referred to the buttocks or legs. Diseases affecting the upper lumbar spine tend to refer pain to the lumbar region, groin, or anterior thighs. Diseases affecting the lower lumbar spine tend to produce pain referred to the buttocks, posterior thighs, or rarely the calves or feet. Provocative injections into pain-sensitive structures of the lumbar spine may produce leg pain that does not follow a dermatomal distribution. This "sclerotomal" pain may explain some cases of back and leg pain without evidence of nerve root compression.

Radicular back pain is typically sharp and radiates from the lumbar spine to the leg within the territory of a nerve root (see "Lumbar Disk Disease," below). Coughing, sneezing, or voluntary contraction of abdominal muscles (lifting heavy objects or straining at stool) may elicit the radiating pain. The pain may increase in postures that stretch the nerves and nerve roots. Sitting stretches the sciatic nerve (L5 and S1 roots) because the nerve passes posterior to the hip. The femoral nerve (L2, L3, and L4 roots) passes anterior to the hip and is not stretched by sitting. The description of the pain alone often fails to distinguish between sclerotomal pain and radiculopathy.

Pain associated with muscle spasm, although of obscure origin, is commonly associated with many spine disorders. The spasms are accompanied by abnormal posture, taut paraspinal muscles, and dull pain.

Knowledge of the circumstances associated with the onset of back pain is important when weighing possible serious underlying causes for the pain. Some patients involved in accidents or work-related injuries may exaggerate their pain for the purpose of compensation or for psychological reasons.

EXAMINATION OF THE BACK A physical examination that includes the abdomen and rectum is advisable. Back pain referred from visceral organs may be reproduced during palpation of the abdomen [pancreatitis, abdominal aortic aneurysm (AAA)] or percussion over the costovertebral angles (pyelonephritis).

The normal spine has cervical and lumbar lordosis, and a thoracic kyphosis. Exaggeration of these normal alignments may result in hyperkyphosis of the thoracic spine or hyperlordosis of the lumbar spine. Inspection may reveal a lateral curvature of the spine (scoliosis) or an asymmetry in the paraspinal muscles, suggesting muscle spasm. Back pain of bony spine origin is often reproduced by palpation or percussion over the spinous process of the affected vertebrae.

Forward bending is often limited by paraspinal muscle spasm; the latter may flatten the usual lumbar lordosis. Flexion of the hips is normal in patients with lumbar spine disease, but flexion of the lumbar spine is limited and sometimes painful. Lateral bending to the side opposite the injured spinal element may stretch the damaged tissues, worsen pain, and limit motion. Hyperextension of the spine (with the patient prone or standing) is limited when nerve root compression, facet joint pathology, or other bony spine disease is present.

Pain from hip disease may mimic pain of lumbar spine disease. Hip pain can be reproduced by internal and external rotation at the hip with the knee and hip in flexion (Patrick sign) and by tapping the heel with the examiner's palm while the leg is extended.

With the patient lying flat, passive flexion of the extended leg at the hip stretches the L5 and S1 nerve roots and the sciatic nerve. Passive dorsiflexion of the foot during the maneuver adds to the stretch. While flexion to at least 80° is normally possible without causing pain, tight hamstring muscles are a source of pain in some patients. The *straight leg–raising (SLR)* test is positive if the maneuver reproduces the patient's usual back or limb pain. Eliciting the SLR sign in the sitting position may help determine if the finding is reproducible. The patient may describe pain in the low back, buttocks, posterior thigh, or lower leg, but the key feature is reproduction of the patient's usual pain. The *crossed*

TABLE 16-1 ACUTE LOW BACK PAIN: RISK FACTORS FOR AN IMPORTANT STRUCTURAL CAUSE

History
- Pain worse at rest or at night
- Prior history of cancer
- History of chronic infection (esp. lung, urinary tract, skin)
- History of trauma
- Incontinence
- Age > 50 years
- Intravenous drug use
- Glucocorticoid use
- History of a rapidly progressive neurologic deficit

Examination
- Unexplained fever
- Unexplained weight loss
- Percussion tenderness over the spine
- Abdominal, rectal, or pelvic mass
- Patrick's sign or heel percussion sign
- Straight leg or reverse straight-leg raising signs
- Progressive focal neurologic deficit

SLR sign is positive when flexion of one leg reproduces the pain in the opposite leg or buttocks. The crossed SLR sign is less sensitive but more specific for disk herniation than the SLR sign. The nerve or nerve root lesion is always on the side of the pain. The *reverse SLR sign* is elicited by standing the patient next to the examination table and passively extending each leg with the knee fully extended. This maneuver, which stretches the L2-L4 nerve roots and the femoral nerve, is considered positive if the patient's usual back or limb pain is reproduced.

The neurologic examination includes a search for focal weakness or muscle atrophy, focal reflex changes, diminished sensation in the legs, and signs of spinal cord injury. The examiner should be alert to the possibility of breakaway weakness, defined as fluctuating strength during muscle testing. Breakaway weakness may be due to pain or a combination of pain and underlying true weakness. Breakaway weakness without pain is due to lack of effort. In uncertain cases, electromyography (EMG) can determine whether or not true weakness is present. Findings with specific nerve root lesions are shown in Table 16-2 and are discussed below.

LABORATORY, IMAGING, AND EMG STUDIES Routine laboratory studies are rarely needed for the initial evaluation of nonspecific acute (<3 months duration) low back pain (ALBP). If risk factors for a serious underlying cause are present, then laboratory studies [complete blood count (CBC), erythrocyte sedimentation rate (ESR), urinalysis] are indicated.

CT scanning is superior to routine x-rays for the detection of fractures involving posterior spine structures, craniocervical and craniothoracic junctions, C1 and C2 vertebrae, bone fragments within the spinal canal, or malalignment; CT scans are increasingly used as a primary screening modality for moderate to severe trauma. In the absence of risk factors, these imaging studies are rarely helpful in nonspecific ALBP. MRI and CT-myelography are the radiologic tests of choice for evaluation of most serious diseases involving the spine. MRI is superior for the definition of soft tissue structures, whereas CT-myelography provides optimal imaging of the lateral recess of the spinal canal and bony lesions and is tolerated by claustrophobic patients. While the added diagnostic value of modern neuroimaging is significant, there is concern that these studies may be overutilized in patients with ALBP.

Electrodiagnostic studies can be used to assess the functional integrity of the peripheral nervous system (Chap. e30). Sensory nerve conduction studies are normal when focal sensory loss is due to nerve root damage because the nerve roots are proximal to the nerve cell bodies in the dorsal root ganglia. The diagnostic yield of needle EMG is higher than that of nerve conduction studies for radiculopathy. Denervation changes in a myotomal (segmental) distribution are detected by sampling multiple muscles supplied by different nerve roots and nerves; the pattern of muscle involvement indicates the nerve root(s) responsible for the injury. Needle EMG provides objective information about motor nerve fiber injury when the clinical evaluation of weakness is limited by pain or poor effort. EMG and nerve conduction studies will be normal when only limb pain or sensory nerve root injury or irritation is present.

CAUSES OF BACK PAIN (Table 16-3)

CONGENITAL ANOMALIES OF THE LUMBAR SPINE

Spondylolysis is a bony defect in the pars interarticularis (a segment near the junction of the pedicle with the lamina) of the vertebra; the etiology may be a stress fracture in a congenitally abnormal segment. The defect (usually bilateral) is best visualized on oblique projections in plain x-rays, CT scan, or single photon emission CT (SPECT) bone scan and occurs in the setting of a single injury, repeated minor injuries, or growth. Although frequently asymptomatic, it is the most common cause of persistent low back pain in adolescents and is often activity-related.

Spondylolisthesis is the anterior slippage of the vertebral body, pedicles, and superior articular facets, leaving the posterior elements behind. Spondylolisthesis can be associated with spondylolysis, congenital anomalies of the lumbosacral junction, infection, osteoporosis, tumor, trauma, prior surgery, or degenerative spine disease. It occurs more frequently in women. The slippage may be asymptomatic or may cause low back pain and hamstring tightness, nerve root injury (the L5 root most frequently), or symptomatic spinal stenosis. Tenderness may be elicited near the segment that has "slipped" forward (most often L4 on L5 or occasionally L5 on S1). A "step" may be present on deep palpation of the posterior elements of the segment above the spondylolisthetic joint. The trunk may be shortened and the abdomen protu-

TABLE 16-2 LUMBOSACRAL RADICULOPATHY—NEUROLOGIC FEATURES

Lumbosacral Nerve Roots	Examination Findings			Pain Distribution
	Reflex	Sensory	Motor	
L2[a]	—	Upper anterior thigh	Psoas (hip flexion)	Anterior thigh
L3[a]	—	Lower anterior thigh Anterior knee	Psoas (hip flexion) Quadriceps (knee extension) Thigh adduction	Anterior thigh, knee
L4[a]	Quadriceps (knee)	Medial calf	Quadriceps (knee extension)[b] Thigh adduction Tibialis anterior (foot dorsiflexion)	Knee, medial calf Anterolateral thigh
L5[c]	—	Dorsal surface—foot Lateral calf	Peroneii (foot eversion)[b] Tibialis anterior (foot dorsiflexion) Gluteus medius (hip abduction) Toe dorsiflexors	Lateral calf, dorsal foot, posterolateral thigh, buttocks
S1[c]	Gastrocnemius/soleus (ankle)	Plantar surface—foot Lateral aspect—foot	Gastrocnemius/soleus (foot plantar flexion)[b] Abductor hallucis (toe flexors)[b] Gluteus maximus (hip extension)	Bottom foot, posterior calf, posterior thigh, buttocks

TABLE 16-3 CAUSES OF BACK AND NECK PAIN

Congenital/developmental
Spondylolysis and spondylolisthesis[a]
Kyphoscoliosis[a]
Spina bifida occulta[a]
Tethered spinal cord[a]
Minor trauma
Strain or sprain
Whiplash injury[b]
Fractures
Traumatic—falls, motor vehicle accidents
Atraumatic—osteoporosis, neoplastic infiltration, exogenous steroids
Intervertebral disk herniation
Degenerative
Disk-osteophyte complex
Internal disk disruption
Spinal stenosis with neurogenic claudication[a]
Uncovertebral joint disease[b]
Atlantoaxial joint disease (e.g., rheumatoid arthritis)[a]
Arthritis
Spondylosis
Facet or sacroiliac arthropathy
Autoimmune (e.g., anklyosing spondylitis, Reiter's syndrome)
Neoplasms—metastatic, hematologic, primary bone tumors
Infection/inflammation
Vertebral osteomyelitis
Spinal epidural abscess
Septic disk
Meningitis
Lumbar arachnoiditis[a]
Metabolic
Osteoporosis—hyperparathyroidism, immobility
Osteosclerosis (e.g., Paget's disease)
Vascular
Abdominal aortic aneurysm
Vertebral artery dissection[b]
Other
Referred pain from visceral disease
Postural
Psychiatric, malingering, chronic pain syndromes

[a]Low back pain only.
[b]Neck pain only.

berant as a result of extreme forward displacement of L4 on L5; in severe cases cauda equina syndrome (CES) may occur (see below). Surgery is considered for symptoms persisting for >1 year that do not respond to conservative measures (e.g., rest, physical therapy). Surgery is usually indicated for cases with progressive neurologic deficit, abnormal gait or postural deformity, slippage > 50%, or scoliosis.

Spina bifida occulta is a failure of closure of one or several vertebral arches posteriorly; the meninges and spinal cord are normal. A dimple or small lipoma may overlie the defect. Most cases are asymptomatic and discovered incidentally during evaluation for back pain.

Tethered cord syndrome usually presents as a progressive cauda equina disorder (see below), although myelopathy may also be the initial manifestation. The patient is often a young adult who complains of perineal or perianal pain, sometimes following minor trauma. Neuroimaging studies reveal a low-lying conus (below L1-L2) and a short and thickened filum terminale.

TRAUMA

A patient complaining of back pain and inability to move the legs may have a spinal fracture or dislocation, and, with fractures above L1, spinal cord compression. Care must be taken to avoid further damage to the spinal cord or nerve roots by immobilizing the back pending results of x-rays.

Sprains and Strains The terms *low back sprain*, *strain*, or *mechanically induced muscle spasm* refer to minor, self-limited injuries associated with lifting a heavy object, a fall, or a sudden deceleration such as in an automobile accident. These terms are used loosely and do not clearly describe a specific anatomic lesion. The pain is usually confined to the lower back, and there is no radiation to the buttocks or legs. Patients with paraspinal muscle spasm often assume unusual postures.

Traumatic Vertebral Fractures Most traumatic fractures of the lumbar vertebral bodies result from injuries producing anterior wedging or compression. With severe trauma, the patient may sustain a fracture-dislocation or a "burst" fracture involving the vertebral body and posterior elements. Traumatic vertebral fractures are caused by falls from a height (a pars interarticularis fracture of the L5 vertebra is common), sudden deceleration in an automobile accident, or direct injury. Neurologic impairment is common, and early surgical treatment is indicated. In victims of blunt trauma, CT scans of the chest, abdomen, or pelvis can be reformatted to detect associated vertebral fractures.

LUMBAR DISK DISEASE

This is a common cause of chronic or recurrent low back and leg pain (Figs. 16-3 and 16-4). Disk disease is most likely to occur at the L4-L5 and L5-S1 levels, but upper lumbar levels are involved occasionally. The cause is often unknown; the risk is increased in overweight individuals. Disk herniation is unusual prior to age 20 and is rare in the fibrotic disks of the elderly. Degeneration of the nucleus pulposus and the annulus fibrosus increases with age and may be asymptomatic or painful. Genetic factors may play a role in predisposing some patients to disk degeneration. The pain may be located in the low back only or referred to the leg, buttock, or hip. A sneeze, cough, or trivial movement may cause the nucleus pulposus to prolapse, pushing the frayed and weakened annulus posteriorly. With severe disk disease, the nucleus may protrude through the annulus (herniation) or become extruded to lie as a free fragment in the spinal canal.

The mechanism by which intervertebral disk injury causes back pain is controversial. The inner annulus fibrosus and nucleus pulposus are normally devoid of innervation. Inflammation and production of proinflammatory cytokines within the protruding or ruptured disk may trigger or perpetuate back pain. Ingrowth of nociceptive (pain) nerve fibers into inner portions of a diseased disk may be responsible for chronic "diskogenic" pain. Nerve root injury (radiculopathy) from disk herniation may be due to compression, inflammation, or both; pathologically, demyelination and axonal loss are usually present.

Symptoms of a ruptured disk include back pain, abnormal posture, limitation of spine motion (particularly flexion), or radicular pain. A dermatomal pattern of sensory loss or a reduced or absent deep ten-

FIGURE 16-4 MRI of lumbar herniated disk; left S1 radiculopathy. Sagittal T1-weighted image on the left with arrows outlining disk margins. Sagittal T2 image on the right reveals a protruding disk at the L5-S1 level (*arrows*), which displaces the central thecal sac.

don reflex is more suggestive of a specific root lesion than is the pattern of pain. Motor findings (focal weakness, muscle atrophy, or fasciculations) occur less frequently than focal sensory or reflex changes. Symptoms and signs are usually unilateral, but bilateral involvement does occur with large central disk herniations that compress multiple descending nerve roots within the spinal canal. Clinical manifestations of specific nerve root lesions are summarized in Table 16-2. There is suggestive evidence that lumbar disk herniation with a nonprogressive nerve root deficit can be managed nonsurgically. The size of the disk protrusion may naturally decrease over time.

The differential diagnosis covers a variety of serious and treatable conditions, including epidural abscess, hematoma, or tumor. Fever, constant pain uninfluenced by position, sphincter abnormalities, or signs of spinal cord disease suggest an etiology other than lumbar disk disease. Bilateral absence of ankle reflexes can be a normal finding in old age or a sign of bilateral S1 radiculopathy. An absent deep tendon reflex or focal sensory loss may indicate injury to a nerve root, but other sites of injury along the nerve must also be considered. For example, an absent knee reflex may be due to a femoral neuropathy or an L4 nerve root injury. A loss of sensation over the foot and lateral lower calf may result from a peroneal or lateral sciatic neuropathy or an L5 nerve root injury. Focal muscle atrophy may reflect a nerve root or peripheral nerve injury, an anterior horn cell disease, or disuse.

An MRI scan or CT-myelogram is necessary to establish the location and type of pathology. Spinal MRI yields exquisite views of intraspinal and adjacent soft tissue anatomy. Bony lesions of the lateral recess or intervertebral foramen are optimally visualized by CT-myelography. The correlation of neuroradiologic findings to symptoms, particularly pain, is not simple. Contrast-enhancing tears in the annulus fibrosus or disk protrusions are widely accepted as common sources of back pain; however, many studies have found that most asymptomatic adults have similar findings. Asymptomatic disk protrusions are also common and may enhance with contrast. Furthermore, in patients with known disk herniation treated either medically or surgically, persistence of the herniation 10 years later had no relationship to the clinical outcome. In summary, MRI findings of disk protrusion, tears in the annulus fibrosus, or contrast enhancement are common incidental findings that, by themselves, should not dictate management decisions for patients with back pain.

There are four indications for intervertebral disk surgery: (1) progressive motor weakness from nerve root injury demonstrated on clinical examination or EMG, (2) bowel or bladder disturbance or other signs of spinal cord compression, (3) incapacitating nerve root pain despite conservative treatment for 4 weeks at a minimum, and (4) recurrent incapacitating pain despite conservative treatment. The latter two criteria are more subjective and less well established than the others. Surgical treatment should also be considered if steady pain and/or neurologic findings do not substantially improve over 4–12 weeks.

The usual surgical procedure is a partial hemilaminectomy with excision of the prolapsed disk. Fusion of the involved lumbar segments should be considered only if significant spinal instability is present (i.e., degenerative spondylolisthesis or isthmic spondylolysis). Over a recent 5-year period, the number of lumbar fusion procedures performed in the United States more than doubled, for uncertain reasons. There are no large prospective, randomized trials comparing fusion to other types of surgical intervention. In one study, patients with persistent low back pain despite an initial diskectomy fared no better with spine fusion than with a conservative regimen of cognitive intervention and exercise.

Cauda equina syndrome (CES) signifies an injury of multiple lumbosacral nerve roots within the spinal canal. Low back pain, weakness and areflexia in the legs, saddle anesthesia, and loss of bladder function may occur. The problem must be distinguished from disorders of the lower spinal cord (conus medullaris syndrome), acute transverse myelitis (Chap. 372), and Guillain-Barré syndrome (Chap. 380). Combined involvement of the conus medullaris and cauda equina can occur. CES is commonly due to a ruptured lumbosacral intervertebral disk, lumbosacral spine fracture, hematoma within the spinal canal (e.g., following lumbar puncture in patients with coagulopathy), compressive tumor, or other mass lesion. Treatment options include surgical decompression, sometimes urgently in an attempt to restore or preserve motor or sphincter function, or radiotherapy for metastatic tumors (Chap. 374).

DEGENERATIVE CONDITIONS

Lumbar spinal stenosis describes a narrowed lumbar spinal canal. *Neurogenic claudication* is the usual symptom, consisting of back and buttock or leg pain induced by walking or standing and relieved by sitting. Symptoms in the legs are usually bilateral. Lumbar stenosis, by itself, is frequently asymptomatic, and the correlation between the severity of symptoms and degree of stenosis of the spinal canal is poor. Unlike vascular claudication, symptoms are often provoked by standing without walking. Unlike lumbar disk disease, symptoms are usually relieved by sitting. Focal weakness, sensory loss, or reflex changes may occur when spinal stenosis is associated with radiculopathy. Severe neurologic deficits, including paralysis and urinary incontinence, occur rarely. Spinal stenosis can be acquired (75%), congenital, or due to a combination of these factors. Congenital forms (achondroplasia, idiopathic) are characterized by short, thick pedicles that produce both spinal canal and lateral recess stenosis. Acquired factors that contribute to spinal stenosis include degenerative diseases (spondylosis, spondylolisthesis, scoliosis), trauma, spine surgery, metabolic or endocrine disorders (epidural lipomatosis, osteoporosis, acromegaly, renal osteodystrophy, hypoparathyroidism), and Paget's disease. MRI provides the best definition of the abnormal anatomy (Fig. 16-5).

Conservative treatment of symptomatic spinal stenosis includes nonsteroidal anti-inflammatory drugs (NSAIDs), exercise programs, and symptomatic treatment of acute pain episodes. Surgical therapy is considered when medical therapy does not relieve symptoms sufficiently to allow for activities of daily living or when significant focal neurologic signs are present. Most patients with neurogenic claudication treated surgically experience at least 75% relief of back and leg pain. Up to 25% develop recurrent stenosis at the same spinal level or an adjacent level 5 years after the initial surgery; recurrent symptoms usually respond to a second surgical decompression.

Facet joint hypertrophy can produce unilateral radicular symptoms or signs due to bony compression; symptoms are often indistinguishable from disk-related radiculopathy. Stretch signs, focal motor weakness, hyporeflexia, or dermatomal sensory loss may be present. Hypertrophic superior or inferior facets can be visualized by x-rays, CT, or MRI. Surgical foraminotomy results in long-term relief of leg and back pain in 80–90% of these patients. The usefulness of therapeutic facet joint blocks for pain has not been rigorously studied.

ARTHRITIS

Spondylosis, or osteoarthritic spine disease, typically occurs in later life and primarily involves the cervical and lumbosacral spine. Patients of-

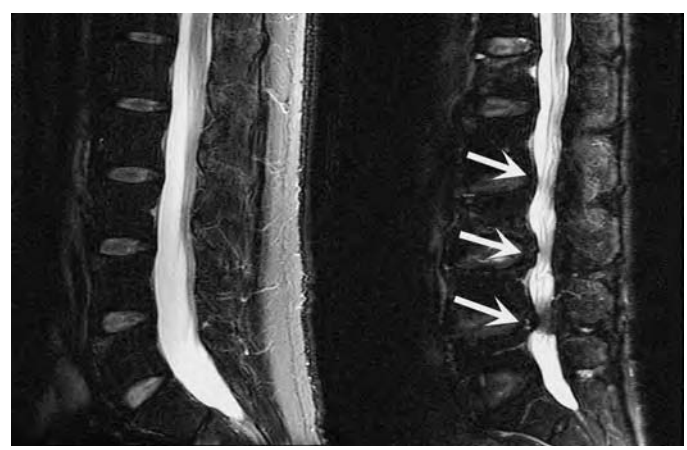

FIGURE 16-5 Spinal stenosis. Sagittal T2 fast spin echo magnetic resonance imaging of a normal (***left***) and stenotic (***right***) lumbar spine, revealing multifocal narrowing (*arrows*) of the cerebrospinal fluid spaces surrounding the nerve roots within the thecal sac.

ten complain of back pain that is increased with movement and associated with stiffness. The relationship between clinical symptoms and radiologic findings is usually not straightforward. Pain may be prominent when x-ray, CT, or MRI findings are minimal, and large osteophytes can be seen in asymptomatic patients. Radiculopathy occurs when hypertrophied facets and osteophytes compress nerve roots in the lateral recess or intervertebral foramen. Osteophytes arising from the vertebral body may cause or contribute to central spinal canal stenosis. Disc degeneration may also play a role in reducing the cross-sectional area of the intervertebral foramen; the descending pedicle may compress the exiting nerve root. Rarely, osteoarthritic changes in the lumbar spine are sufficient to compress the cauda equina.

Ankylosing Spondylitis (See also Chap. 318) This distinctive arthritic spine disease typically presents with the insidious onset of low back and buttock pain. Patients are often males below age 40. Associated features include morning back stiffness, nocturnal pain, pain unrelieved by rest, an elevated ESR, and the histocompatibility antigen HLA-B27. Onset at a young age and back pain improving with exercise are characteristic. Loss of the normal lumbar lordosis and exaggeration of thoracic kyphosis develop as the disease progresses. Inflammation and erosion of the outer fibers of the annulus fibrosus at the point of contact with the vertebral body are followed by ossification and bony growth that bridges adjacent vertebral bodies and reduces spine mobility in all planes. Radiologic hallmarks are periarticular destructive changes, sclerosis of the sacroiliac joints, and bridging of vertebral bodies to produce the fused "bamboo spine."

Stress fractures through the spontaneously ankylosed posterior bony elements of the rigid, osteoporotic spine may produce focal pain, spinal instability, spinal cord compression, or CES. Atlantoaxial subluxation with spinal cord compression occasionally occurs. Ankylosis of the ribs to the spine and a decrease in the height of the thoracic spine may compromise respiratory function. For many patients, therapy with anti-tumor necrosis factor agents is effective in reducing disease activity. Similar to ankylosing spondylitis, restricted movements may accompany Reiter's syndrome, psoriatic arthritis, and chronic inflammatory bowel disease.

NEOPLASMS

(See also Chap. 374) Back pain is the most common neurologic symptom in patients with systemic cancer and may be the presenting symptom. The cause is usually vertebral metastases. Metastatic carcinoma (breast, lung, prostate, thyroid, kidney, gastrointestinal tract), multiple myeloma, and non-Hodgkin's and Hodgkin's lymphomas frequently involve the spine. Cancer-related back pain tends to be constant, dull, unrelieved by rest, and worse at night. By contrast, mechanical low back pain usually improves with rest. Plain x-rays may or may not show destructive lesions in one or several vertebral bodies without disk space involvement. MRI, CT, and CT-myelography are the studies of choice when spinal metastasis is suspected. MRI is preferred, but the most rapidly available procedure is best because the patient's condition may worsen quickly. Fewer than 5% of patients who are nonambulatory at the time of diagnosis ever regain the ability to walk, thus early diagnosis is crucial.

INFECTIONS/INFLAMMATION

Vertebral osteomyelitis is usually caused by staphylococci, but other bacteria or tuberculosis (Pott's disease) may be responsible. The primary source of infection is usually the urinary tract, skin, or lungs. Intravenous drug use is a well-recognized risk factor. Whenever pyogenic osteomyelitis is found, the possibility of bacterial endocarditis should be considered. Back pain exacerbated by motion and unrelieved by rest, spine tenderness over the involved spine segment, and an elevated ESR are the most common findings in vertebral osteomyelitis. Fever or an elevated white blood cell count is found in a minority of patients. Plain radiographs may show a narrowed disk space with erosion of adjacent vertebrae; however, these diagnostic changes may take weeks or months to appear. MRI and CT are sensitive and specific for osteomyelitis; CT may be more readily available in emergency settings and better tolerated by some patients with severe back pain.

Spinal epidural abscess (Chap. 372) presents with back pain (aggravated by movement or palpation) and fever. Signs of nerve root injury or spinal cord compression may be present. The abscess may track over multiple spinal levels and is best delineated by spine MRI.

Lumbar adhesive arachnoiditis with radiculopathy is due to fibrosis following inflammation within the subarachnoid space. The fibrosis results in nerve root adhesions, and presents as back and leg pain associated with motor, sensory, or reflex changes. Causes of arachnoiditis include multiple lumbar operations, chronic spinal infections, spinal cord injury, intrathecal hemorrhage, myelography (rare), intrathecal injection of glucocorticoids or anesthetics, and foreign bodies. The MRI shows clumped nerve roots located centrally or adherent to the dura peripherally, or loculations of cerebrospinal fluid within the thecal sac. Clumped nerve roots may also occur with demyelinating polyneuropathy or neoplastic infiltration. Treatment is usually unsatisfactory. Microsurgical lysis of adhesions, dorsal rhizotomy, and dorsal root ganglionectomy have been tried, but outcomes have been poor. Dorsal column stimulation for pain relief has produced varying results. Epidural injections of glucocorticoids have been of limited value.

METABOLIC CAUSES

Osteoporosis and Osteosclerosis Immobilization or underlying conditions such as osteomalacia, hyperparathyroidism, hyperthyroidism, multiple myeloma, metastatic carcinoma, or glucocorticoid use may accelerate osteoporosis and weaken the vertebral body, leading to compression fractures and pain. The most common causes of nontraumatic vertebral body fractures are postmenopausal (type 1) or senile (type 2) osteoporosis (Chap. 348). Compression fractures occur in up to half of patients with severe osteoporosis, and those who sustain a fracture have a 4.5-fold increased risk for recurrence. The sole manifestation of a compression fracture may be localized back pain or radicular pain exacerbated by movement and often reproduced by palpation over the spinous process of the affected vertebra. The clinical context, neurologic signs, and x-ray appearance of the spine establish the diagnosis. Antiresorptive drugs including bisphosphonates (e.g., alendronate), transdermal estrogen, and tamoxifen have been shown to reduce the risk of osteoporotic fractures. Fewer than one-third of patients with prior compression fractures are adequately treated for osteoporosis despite the increased risk for future fractures; rates of primary prevention among individuals at risk, but without a history of fracture, are even less. Compression fractures above the midthoracic region suggest malignancy; if tumor is suspected, a bone biopsy or diagnostic search for a primary tumor is indicated. **For a complete discussion of diagnosis and management of osteoporosis, see Chap. 348.**

Interventions [percutaneous vertebroplasty (PVP), kyphoplasty] exist for osteoporotic compression fractures associated with debilitating pain. Candidates for PVP have midline back pain, palpation tenderness over the spinous process of the affected vertebral body, <80% loss of vertebral body height, and onset of symptoms within the prior 4 months. The PVP technique consists of injection of polymethylmethacrylate, under fluoroscopic guidance, into the affected vertebral body. Kyphoplasty adds the inflation of a balloon in the vertebral body prior to the injection of cement. Rare complications can include extravasation of cement into the epidural space (resulting in myelopathy) or fatal pulmonary embolism from migration of cement into paraspinal veins. Approximately three-quarters of patients who meet selection criteria have reported enhanced quality of life. Relief of pain following PVP has also been reported in patients with vertebral metastases, myeloma, or hemangiomas.

Osteosclerosis, an abnormally increased bone density often due to Paget's disease, is readily identifiable on routine x-ray studies and may or may not produce back pain. Spinal cord or nerve root compression may result from bony encroachment. **For further discussion of these bone disorders, see Chaps. 347–349.**

REFERRED PAIN FROM VISCERAL DISEASE

Diseases of the thorax, abdomen, or pelvis may refer pain to the posterior portion of the spinal segment that innervates the diseased organ. Oc-

casionally, back pain may be the first and only manifestation. Upper abdominal diseases generally refer pain to the lower thoracic or upper lumbar region (eighth thoracic to the first and second lumbar vertebrae), lower abdominal diseases to the mid-lumbar region (second to fourth lumbar vertebrae), and pelvic diseases to the sacral region. Local signs (pain with spine palpation, paraspinal muscle spasm) are absent, and little or no pain accompanies routine movements of the spine.

Low Thoracic or Lumbar Pain with Abdominal Disease Peptic ulcers or tumors of the posterior wall of the stomach or duodenum typically produce epigastric pain (Chaps. 87 and 287), but midline back or paraspinal pain may occur if retroperitoneal extension is present. Fatty foods are more likely to induce back pain associated with biliary disease. Diseases of the pancreas produce back pain to the right of the spine (head of the pancreas involved) or to the left (body or tail involved). Pathology in retroperitoneal structures (hemorrhage, tumors, pyelonephritis) produces paraspinal pain that radiates to the lower abdomen, groin, or anterior thighs. A mass in the iliopsoas region often produces unilateral lumbar pain with radiation toward the groin, labia, or testicles. The sudden appearance of lumbar pain in a patient receiving anticoagulants suggests retroperitoneal hemorrhage.

Isolated low back pain occurs in 15–20% of patients with a contained rupture of an abdominal aortic aneurysm (AAA). The classic clinical triad of abdominal pain, shock, and back pain occurs in <20% of patients. Two of these three features are present in two-thirds of patients, and hypotension is present in half. The typical patient is an elderly male smoker with back pain. Frequently, the diagnosis is initially missed because the symptoms and signs can be nonspecific. Common misdiagnoses include nonspecific back pain, diverticulitis, renal colic, sepsis, and myocardial infarction. A careful abdominal examination revealing a pulsatile mass (present in 50–75% of patients) is an important physical finding. Patients with suspected AAA should be evaluated with abdominal ultrasound, CT, or MRI (Chap. 242).

Inflammatory bowel disorders (colitis, diverticulitis) or cancers of the colon may produce lower abdominal pain, midlumbar back pain, or both. The pain may have a beltline distribution around the body. A lesion in the transverse or proximal descending colon may refer pain to the mid or left back at the L2-L3 level. Lesions of the sigmoid colon may refer pain to the upper sacral or midline suprapubic regions or left lower quadrant of the abdomen.

Sacral Pain with Gynecologic and Urologic Disease Pelvic organs rarely cause low back pain, except for gynecologic disorders involving the uterosacral ligaments. The pain is referred to the sacral region. Endometriosis or uterine cancers may invade the uterosacral ligaments. Pain associated with endometriosis is typically premenstrual and often continues until it merges with menstrual pain. Uterine malposition may cause uterosacral ligament traction (retroversion, descensus, and prolapse)or produce sacral pain after prolonged standing.

Menstrual pain may be felt in the sacral region. The poorly localized, cramping pain can radiate down the legs. Pain due to neoplastic infiltration of nerves is typically continuous, progressive in severity, and unrelieved by rest at night. Less commonly, radiation therapy of pelvic tumors may produce sacral pain from late radiation necrosis of tissue or nerves. Low back pain that radiates into one or both thighs is common in the last weeks of pregnancy.

Urologic sources of lumbosacral back pain include chronic prostatitis, prostate cancer with spinal metastasis (Chap. 91), and diseases of the kidney and ureter. Lesions of the bladder and testes do not usually produce back pain. Infectious, inflammatory, or neoplastic renal diseases may produce ipsilateral lumbosacral pain, as can renal artery or vein thrombosis. Paraspinal lumbar pain may be a symptom of ureteral obstruction due to nephrolithiasis.

OTHER CAUSES OF BACK PAIN

Postural Back Pain There is a group of patients with nonspecific chronic low back pain (CLBP) in whom no anatomic lesion can be found despite exhaustive investigation. These individuals complain of vague, diffuse back pain with prolonged sitting or standing that is relieved by rest. The physical examination is unrevealing except for "poor posture." Imaging studies and laboratory evaluations do not identify a specific cause. Exercises to strengthen the paraspinal and abdominal muscles are sometimes helpful.

Psychiatric Disease CLBP may be encountered in patients who seek financial compensation; in malingerers; or in those with concurrent substance abuse, chronic anxiety states, or depression. Many patients with CLBP have a history of psychiatric illness (depression, anxiety, substance abuse) or childhood trauma (physical or sexual abuse) that antedates the onset of back pain. Preoperative psychological assessment has been used to exclude patients with marked psychological impairments that predict a poor surgical outcome.

Unidentified The cause of low back pain occasionally remains unclear. Some patients have had multiple operations for disk disease but have persistent pain and disability. The original indications for surgery may have been questionable, with back pain only, no definite neurologic signs, or a minor disk bulge noted on CT or MRI. Scoring systems based upon neurologic signs, psychological factors, physiologic studies, and imaging studies have been devised to minimize the likelihood of unsuccessful surgery.

Rx BACK PAIN

ACUTE LOW BACK PAIN (ALBP) ALBP is defined as pain of <3 months' duration. Full recovery can be expected in 85% of adults with ALBP without leg pain. Most have purely "mechanical" symptoms (i.e., pain that is aggravated by motion and relieved by rest).

Observational studies have been used to justify a minimalist approach to this problem. These studies share a number of limitations: (1) a true placebo control group is often lacking; (2) patients who consult different provider groups (generalists, orthopedists, neurologists) are assumed to have similar etiologies for their back pain; (3) no information is provided about the details of treatment; and (4) no attempt to tabulate structural causes of ALBP is made.

The algorithms for the treatment of back pain **(Fig. 16-6)** draw from published clinical practice guidelines (CPGs). However, since CPGs are based on incomplete evidence, guidelines should not substitute for clinical judgment.

The initial assessment excludes serious causes of spine pathology that require urgent intervention, including infection, cancer, and trauma. Risk factors for a serious cause of ALBP are shown in Table 16-1. Laboratory studies are unnecessary if risk factors are absent. Plain spine films or CT are rarely indicated in the first month of symptoms unless a spine fracture is suspected.

Clinical trials have shown no benefit of >2 days of bed rest for uncomplicated ALBP. There is evidence that bed rest is also ineffective for patients with sciatica or for acute back pain with signs of nerve root injury. Similarly, traction is not effective for ALBP. Possible advantages of early ambulation for ALBP include maintenance of cardiovascular conditioning, improved disk and cartilage nutrition, improved bone and muscle strength, and increased endorphin levels. One trial of early vigorous exercise was negative, but the value of less vigorous exercise or other exercise programs are unknown. Early resumption of normal physical activity (without heavy manual labor) is likely to be beneficial.

Proof is lacking to support the treatment of acute back and neck pain with acupuncture, transcutaneous electrical nerve stimulation, massage, ultrasound, diathermy, magnets, or electrical stimulation. Cervical collars can be modestly helpful by limiting spontaneous and reflex neck movements that exacerbate pain. Evidence regarding the efficacy of ice is lacking; heat may provide a short-term reduction in pain and disability. These interventions are optional given the lack of negative evidence, low cost, and low risk. Biofeedback has not been studied rigorously. Facet joint, trigger point, and ligament injections are not recommended for acute treatment.

A role for modification of posture has not been validated by rigorous clinical studies. As a practical matter, temporary suspension of activity known to increase mechanical stress on the spine (heavy lifting, prolonged sitting, bending or twisting, straining at stool) may be helpful.

Education is an important part of treatment. Satisfaction and the likelihood of follow-up increase when patients are educated about prognosis,

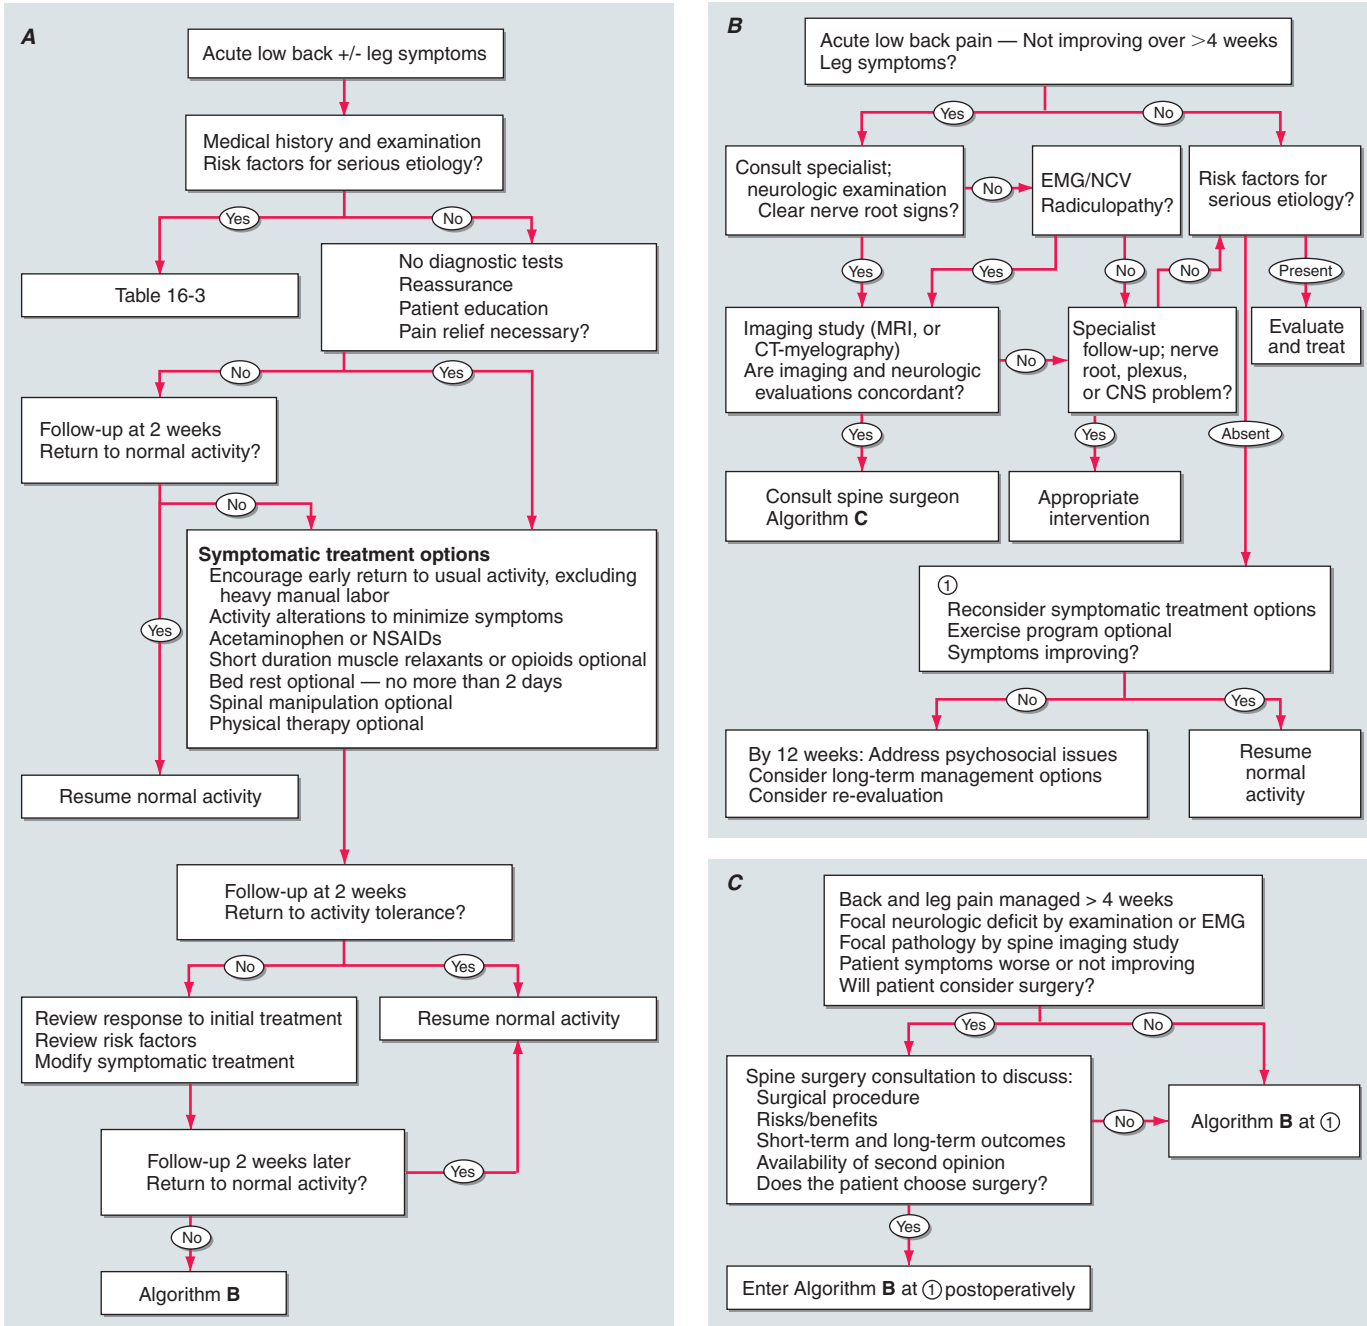

FIGURE 16-6 Algorithms for management of acute low back pain, age ≥ 18 years. ***A.*** Symptoms <3 months, first 4 weeks. ***B.*** Management weeks 4–12. ①, entry point from Algorithm *C* postoperatively or if patient declines surgery. ***C.*** Surgical options. (NSAIDs, nonsteroidal anti-inflammatory drugs; CBC, complete blood count; ESR, erythrocyte sedimentation rate; UA, urinalysis; EMG, electromyography; NCV, nerve conduction velocity studies; MRI, magnetic resonance imaging; CT, computed tomography; CNS, central nervous system.)

treatment methods, activity modifications, and strategies to prevent future exacerbations. In one study, patients who felt they did not receive an adequate explanation for their symptoms wanted further diagnostic tests. Evidence for the efficacy of structured education programs ("back school") is inconclusive; there is modest evidence for a short-term benefit, but evidence for a long-term benefit is lacking. Randomized studies of back school for primary prevention of low back injury and pain have failed to demonstrate any benefit.

NSAIDs and acetaminophen (see Table 12-1) are effective over-the-counter agents for ALBP. Muscle relaxants (cyclobenzaprine, 10 mg PO qhs as initial dose, up to 10 mg PO tid) provide short-term (4–7 days) benefit, particularly at night if sleep is affected, but drowsiness limits daytime use. Opioid analgesics are no more effective than NSAIDs or acetaminophen for initial treatment of ALBP, nor do they increase the likelihood of return to work. Short-term use of opioids may be necessary in patients unresponsive to or intolerant of acetaminophen or NSAIDs. There is no evidence to support the use of oral glucocorticoids or tricyclic antidepressants for ALBP.

Epidural glucocorticoids may occasionally produce short-term pain relief in ALBP with radiculopathy, but proof is lacking for pain relief beyond 1 month. Epidural glucocorticoids, anesthetics, or opioids are not indicated in the initial treatment of ALBP without radiculopathy. Diagnostic nerve root blocks have been advocated to determine if pain originates from a specific nerve root. However, improvement may result even when the nerve root is not responsible for the pain; this may occur as a placebo effect, from a pain-generating lesion located distally along the peripheral nerve, or from anesthesia of the sinuvertebral nerve. Therapeutic nerve root blocks with injection of glucocorticoids and a local anesthetic should be considered only after conservative measures fail, particularly when temporary relief of pain is necessary.

A short course of lumbar spinal manipulation or physical therapy (PT) for symptomatic relief of uncomplicated ALBP is a reasonable option. Prospective,

TABLE 16-4 CERVICAL RADICULOPATHY—NEUROLOGIC FEATURES

Cervical Nerve Roots	Examination Findings			
	Reflex	Sensory	Motor	Pain Distribution
C5	Biceps	Over lateral deltoid	Supraspinatus[a] (initial arm abduction) Infraspinatus[a] (arm external rotation) Deltoid[a] (arm abduction) Biceps (arm flexion)	Lateral arm, medial scapula
C6	Biceps	Thumb, index fingers Radial hand/ forearm	Biceps (arm flexion) Pronator teres (internal forearm rotation)	Lateral forearm, thumb, index finger
C7	Triceps	Middle fingers Dorsum forearm	Triceps[a] (arm extension) Wrist extensors[a] Extensor digitorum[a] (finger extension)	Posterior arm, dorsal forearm, lateral hand
C8	Finger flexors	Little finger Medial hand and forearm	Abductor pollicis brevis (abduction D1) First dorsal interosseous (abduction D2) Abductor digiti minimi (abduction D5)	4th and 5th fingers, medial forearm
T1	Finger flexors	Axilla and medial arm	Abductor pollicis brevis (abduction D1) First dorsal interosseous (abduction D2) Abductor digiti minimi (abduction D5)	Medial arm, axilla

[a]These muscles receive the majority of innervation from this root.

randomized studies are difficult to perform in part because there is no consensus about what constitutes an adequate placebo control. Specific PT or chiropractic protocols that may provide benefit have not been fully defined.

CHRONIC LOW BACK PAIN CLBP, defined as pain lasting >12 weeks, accounts for 50% of total back pain costs. Risk factors include obesity, female gender, older age, prior history of back pain, restricted spinal mobility, pain radiating into a leg, high levels of psychological distress, poor self-rated health, minimal physical activity, smoking, job dissatisfaction, and widespread pain. Combinations of these premorbid factors have been used to predict which individuals with ALBP are likely to develop CLBP. The initial approach to these patients is similar to that for ALBP. Treatment of this heterogeneous group of patients is directed toward the underlying cause when known; the ultimate goal is to restore function to the maximum extent possible.

Many conditions that produce CLBP can be identified by a combination of neuroimaging and electrophysiologic studies. Spine MRI and CT-myelography are almost always the imaging techniques of choice. Imaging studies should be performed only in circumstances when the results are likely to influence management.

Injection studies can be used diagnostically to help determine the anatomic source of back pain. Reproduction of the patient's typical pain with diskography has been used as evidence that a specific disk is the pain generator. Pain relief following a foraminal nerve root block or glucocorticoid injection into a facet has been similarly used as evidence that the facet joint or nerve root is the source. However, the possibility that the injection response was a placebo effect or due to systemic absorption of the glucocorticoids is usually not considered. The value of these procedures in the treatment of CLBP or in the selection of candidates for surgery is largely unknown despite their widespread use. The value of thermography in the assessment of radiculopathy also has not been rigorously studied.

The diagnosis of nerve root injury is most secure when the history, examination, results of imaging studies, and the EMG are concordant. The correlation between CT and EMG for localization of nerve root injury is between 65 and 73%. Up to one-third of asymptomatic adults have a disk protrusion detected by CT or MRI scans. Thus, surgical intervention based solely upon radiologic findings increases the likelihood of an unsuccessful outcome.

An unblinded study in patients with chronic sciatica found that surgery could hasten relief of symptoms by ~2 months; however, at 1 year there was no advantage of surgery over conservative medical therapy, and nearly all patients (95%) in both groups made a full recovery regardless of the treatment approach.

CLBP can be treated with a variety of conservative measures. Acute and subacute exacerbations are managed with NSAIDs and comfort measures. There is no good evidence to suggest that one NSAID is more effective than another. Bed rest should not exceed 2 days. Activity tolerance is the primary goal, while pain relief is secondary. Exercise programs can reverse atrophy in paraspinal muscles and strengthen extensors of the trunk. Intensive physical exercise or "work hardening" regimens (under the guidance of a physical therapist) have been effective in returning some patients to work, improving walking distances, and diminishing pain. The benefit can be sustained with home exercise regimens. It is difficult to endorse one specific exercise or PT regimen given the heterogeneous nature of this patient group. The role of manipulation, back school, or epidural steroid injections in the treatment of CLBP is unproven. There is no strong evidence to support the use of acupuncture or traction. A reduction in sick leave days, long-term health care utilization, and pension expenditures may offset the initial expense of multidisciplinary treatment programs. Studies of hydrotherapy for CLBP have yielded mixed results; however, given its low risk and cost, hydrotherapy can be considered as a treatment option. Transcutaneous electrical nerve stimulation (TENS) has not been adequately studied in CLBP.

PAIN IN THE NECK AND SHOULDER (Table 16-4)

Neck pain, which usually arises from diseases of the cervical spine and soft tissues of the neck, is common (4.6% of adults in one study). Neck pain arising from the cervical spine is typically precipitated by movement and may be accompanied by focal tenderness and limitation of motion. Pain arising from the brachial plexus, shoulder, or peripheral nerves can be confused with cervical spine disease, but the history and examination usually identify a more distal origin for the pain. Cervical spine trauma, disk disease, or spondylosis may be asymptomatic or painful and can produce a myelopathy, radiculopathy, or both. The nerve roots most commonly affected are C7 and C6.

TRAUMA TO THE CERVICAL SPINE

Trauma to the cervical spine (fractures, subluxation) places the spinal cord at risk for compression. Motor vehicle accidents, violent crimes, or falls account for 87% of spinal cord injuries (Chap. 372). Immediate immobilization of the neck is essential to minimize further spinal cord injury from movement of unstable cervical spine segments. A CT scan is the diagnostic procedure of choice for detection of acute fractures. Following major trauma to the cervical spine, injury to the vertebral arteries is common; most lesions are asymptomatic and can be visualized by MRI and angiography.

Whiplash injury is due to trauma (usually automobile accidents) causing cervical musculoligamental sprain or strain due to hyperflexion or hyperextension. This diagnosis should not be applied to patients with fractures, disk herniation, head injury, focal neurologic findings, or altered consciousness. Imaging of the cervical spine is not cost-effective acutely but is useful to detect disk herniations when symptoms persist for >6 weeks following the injury. Severe initial symptoms have been associated with a poor long-term outcome.

CERVICAL DISK DISEASE

Herniation of a lower cervical disk is a common cause of neck, shoulder, arm, or hand pain or tingling. Neck pain, stiffness, and a range of motion limited by pain are the usual manifestations. A herniated cervical disk is responsible for ~25% of cervical radiculopathies. Extension and lateral rotation of the neck narrows the ipsilateral intervertebral foramen and may reproduce radicular symptoms (Spurling's sign). In young persons, acute nerve root compression from a ruptured cervical disk is often due to trauma. Cervical disk herniations are usually posterolateral near the lateral recess and intervertebral foramen. Typical patterns of reflex, sensory, and motor changes that accompany specific cervical nerve root lesions are summarized in Table 16-4; however, (1) overlap in function between adjacent nerve roots is common, (2) symptoms and signs may

be evident in only part of the injured nerve root territory, and (3) the location of pain is the most variable of the clinical features.

CERVICAL SPONDYLOSIS

Osteoarthritis of the cervical spine may produce neck pain that radiates into the back of the head, shoulders, or arms, or may be the source of headaches in the posterior occipital region (supplied by the C2-C4 nerve roots). Osteophytes, disk protrusions, and hypertrophic facet or uncovertebral joints may compress one or several nerve roots at the intervertebral foramina (Fig. 16-7); this compression accounts for 75% of cervical radiculopathies. The roots most commonly affected are C7 and C6. Narrowing of the spinal canal by osteophytes, ossification of the posterior longitudinal ligament (OPLL), or a large central disk may compress the cervical spinal cord. Combinations of radiculopathy and myelopathy may also be present. Spinal cord involvement is suggested by Lhermitt's symptom, an electrical sensation elicited by neck flexion and radiating down the spine from the neck. When little or no neck pain accompanies cord compression, the diagnosis may be confused with amyotrophic lateral sclerosis (Chap. 369), multiple sclerosis (Chap. 375), spinal cord tumors, or syringomyelia (Chap. 372). The possibility of cervical spondylosis should be considered even when the patient presents with symptoms or signs in the legs only. MRI is the study of choice to define the anatomic abnormalities, but plain CT is adequate to assess bony spurs, foraminal narrowing, or OPLL. EMG and nerve conduction studies can localize and assess the severity of the nerve root injury.

OTHER CAUSES OF NECK PAIN

Rheumatoid arthritis (RA) (Chap. 314) of the cervical apophyseal joints produces neck pain, stiffness, and limitation of motion. In advanced RA, synovitis of the atlantoaxial joint (C1-C2; Fig. 16-2) may damage the transverse ligament of the atlas, producing forward displacement of the atlas on the axis (atlantoaxial subluxation). Radiologic evidence of atlantoaxial subluxation occurs in 30% of patients with RA. Not surprisingly, the degree of subluxation correlates with the severity of erosive disease. When subluxation is present, careful assessment is important to identify early signs of myelopathy. Occasional patients develop high spinal cord compression leading to quadriparesis, respiratory insufficiency, and death. Surgery should be considered when myelopathy or spinal instability is present.

Ankylosing spondylitis can cause neck pain and less commonly atlantoaxial subluxation; surgery may be required to prevent spinal cord compression. Acute *herpes zoster* presents as acute posterior occipital or neck pain prior to the outbreak of vesicles. *Neoplasms* metastatic to the cervical spine, *infections* (osteomyelitis and epidural abscess), and *metabolic bone diseases* may be the cause of neck pain. Neck pain may also be referred from the heart with coronary artery ischemia (cervical angina syndrome).

THORACIC OUTLET

The thoracic outlet contains the first rib, the subclavian artery and vein, the brachial plexus, the clavicle, and the lung apex. Injury to these structures may result in postural or movement-induced pain around the shoulder and supraclavicular region. *True neurogenic thoracic outlet syndrome* (TOS) results from compression of the lower trunk of the brachial plexus or ventral rami of the C8 or T1 nerve roots by an anomalous band of tissue connecting an elongate transverse process at C7 with the first rib. Signs include weakness of intrinsic muscles of the hand and diminished sensation on the palmar aspect of the fourth and fifth digits. EMG and nerve conduction studies confirm the diagnosis. Treatment consists of surgical resection of the anomalous band. The weakness and wasting of intrinsic hand muscles typically does not improve, but surgery halts the insidious progression of weakness. *Arterial TOS* results from compression of the subclavian artery by a cervical rib; the compression results in poststenotic dilatation of the artery and thrombus formation. Blood pressure is reduced in the affected limb, and signs of emboli may be present in the hand. Neurologic signs are absent. Ultrasound can confirm the diagnosis noninvasively. Treatment is with thrombolysis or anticoagulation (with or without embolectomy) and surgical excision of the cervical rib compressing the subclavian artery or vein. *Disputed TOS* includes a large number of patients with chronic arm and shoulder pain of unclear cause. The lack of sensitive and specific findings on physical examination or laboratory markers for this condition frequently results in diagnostic uncertainty. The role of surgery in disputed TOS is controversial. Multidisciplinary pain management is a conservative approach, although treatment is often unsuccessful.

BRACHIAL PLEXUS AND NERVES

Pain from injury to the brachial plexus or peripheral nerves of the arm can occasionally mimic pain of cervical spine origin. Neoplastic infiltration of the lower trunk of the brachial plexus may produce shoulder pain radiating down the arm, numbness of the fourth and fifth fingers, and weakness of intrinsic hand muscles innervated by the ulnar and median nerves. Postradiation fibrosis (most commonly from treatment of breast cancer) may produce similar findings, although pain is less often present. A Pancoast tumor of the lung (Chap. 85) is another cause and should be considered, especially when a Horner's syndrome is present. *Suprascapular neuropathy* may produce severe shoulder pain, weakness, and wasting of the supraspinatous and infraspinatous muscles. *Acute brachial neuritis* is often confused with radiculopathy; the acute onset of severe shoulder or scapular pain is followed over days to weeks by weakness of the proximal arm and shoulder girdle muscles innervated by the upper brachial plexus. The onset is often preceded by an infection. The suprascapular and long thoracic nerves are most often affected; the latter results in a winged scapula. Brachial neuritis may also present as an isolated paralysis of the diaphragm. Complete recovery occurs in 75% of patients after 2 years and in 89% after 3 years.

Occasional cases of carpal tunnel syndrome produce pain and paresthesias extending into the forearm, arm, and shoulder resembling a

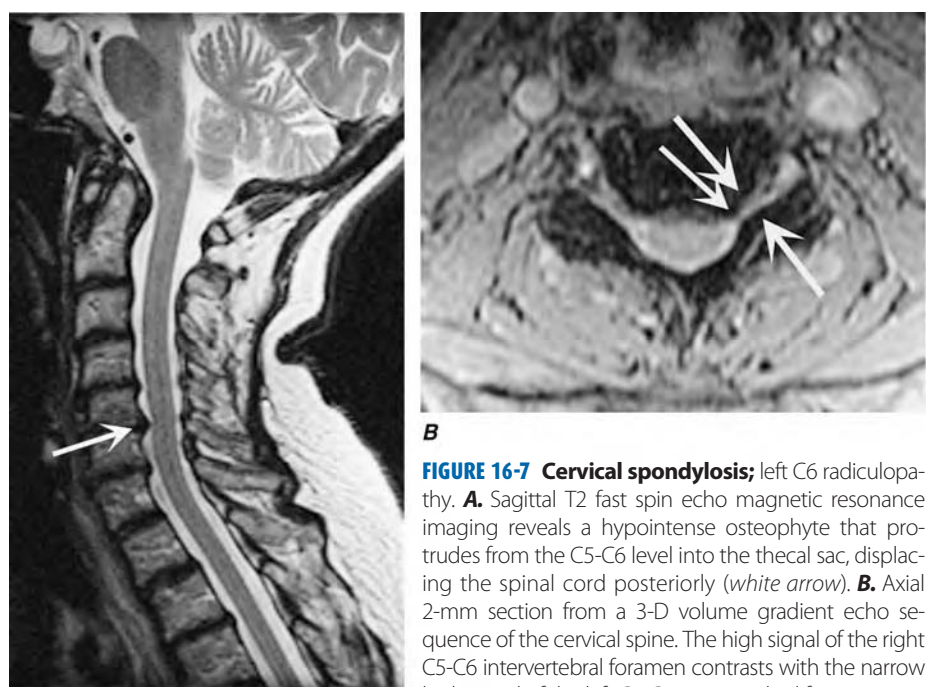

FIGURE 16-7 Cervical spondylosis; left C6 radiculopathy. ***A.*** Sagittal T2 fast spin echo magnetic resonance imaging reveals a hypointense osteophyte that protrudes from the C5-C6 level into the thecal sac, displacing the spinal cord posteriorly (*white arrow*). ***B.*** Axial 2-mm section from a 3-D volume gradient echo sequence of the cervical spine. The high signal of the right C5-C6 intervertebral foramen contrasts with the narrow high signal of the left C5-C6 intervertebral foramen produced by osteophytic spurring (*arrows*).

C5 or C6 root lesion. Lesions of the radial or ulnar nerve can mimic a radiculopathy at C7 or C8, respectively. EMG and nerve conduction studies can accurately localize lesions to the nerve roots, brachial plexus, or peripheral nerves. **For further discussion of peripheral nerve disorders, see Chap. 379.**

SHOULDER

Pain arising from the shoulder can on occasion mimic pain from the spine. If symptoms and signs of radiculopathy are absent, then the differential diagnosis includes mechanical shoulder pain (tendonitis, bursitis, rotator cuff tear, dislocation, adhesive capsulitis, and cuff impingement under the acromion) and referred pain (subdiaphragmatic irritation, angina, Pancoast tumor). Mechanical pain is often worse at night, associated with local shoulder tenderness and aggravated by abduction, internal rotation, or extension of the arm. Pain from shoulder disease may radiate into the arm or hand, but sensory, motor, and reflex changes are absent.

℞ NECK PAIN

There are few well-designed clinical trials that address optimal treatment of neck pain or cervical radiculopathy. Relief of pain, prevention of recurrence, and improved neurologic function are reasonable goals. Symptomatic treatment includes the use of analgesic medications and/or a soft cervical collar. Most treatment recommendations reflect anecdotal experience, case series, or conclusions derived from studies of the lumbar spine. Controlled studies of oral prednisone or transforaminal glucocorticoid injections have not been performed. Reasonable indications for cervical disk surgery include a progressive radicular motor deficit, pain that fails to respond to conservative management and limits activities of daily living, or cervical spinal cord compression. Surgical management of herniated cervical disks usually consists of an anterior approach with diskectomy followed by anterior interbody fusion. A simple posterior partial laminectomy with diskectomy is an acceptable alternative approach. Another surgical approach involves implantation of an artificial disk; in one prospective trial, outcomes after 2 years favored the implant over a traditional anterior cervical discectomy with fusion. The artificial disk is not yet approved for general use in the United States. The risk of subsequent radiculopathy or myelopathy at cervical segments adjacent to the fusion is ~3% per year and 26% per decade. Although this risk is sometimes portrayed as a late complication of surgery, it may also reflect the natural history of degenerative cervical disk disease.

Nonprogressive cervical radiculopathy due to a herniated cervical disk may be treated conservatively, even if a focal neurologic deficit is present, with a high rate of success. However, if the cervical radiculopathy is due to bony compression from cervical spondylosis, then surgical decompression is generally indicated to forestall the progression of neurologic signs.

Cervical spondylotic myelopathy is typically managed with either anterior decompression and fusion or laminectomy in order to forestall progression of the myelopathy known to occur in 20–30% of untreated patients. However, one prospective study comparing surgery vs. conservative treatment for mild cervical spondylotic myelopathy showed no difference in outcome after 2 years of follow-up.

SECTION 2 ALTERATIONS IN BODY TEMPERATURE

17 Fever and Hyperthermia

Charles A. Dinarello, Reuven Porat

Body temperature is controlled by the hypothalamus. Neurons in both the preoptic anterior hypothalamus and the posterior hypothalamus receive two kinds of signals: one from peripheral nerves that transmit information from warmth/cold receptors in the skin and the other from the temperature of the blood bathing the region. These two types of signals are integrated by the thermoregulatory center of the hypothalamus to maintain normal temperature. In a neutral temperature environment, the metabolic rate of humans produces more heat than is necessary to maintain the core body temperature at 37°C.

A normal body temperature is ordinarily maintained, despite environmental variations, because the hypothalamic thermoregulatory center balances the excess heat production derived from metabolic activity in muscle and the liver with heat dissipation from the skin and lungs. According to studies of healthy individuals 18–40 years of age, the mean oral temperature is 36.8° ± 0.4°C (98.2° ± 0.7°F), with low levels at 6 A.M. and higher levels at 4–6 P.M. The maximum normal oral temperature is 37.2°C (98.9°F) at 6 A.M. and 37.7°C (99.9°F) at 4 P.M.; these values define the 99th percentile for healthy individuals. In light of these studies, *an A.M. temperature of >37.2°C (>98.9°F) or a P.M. temperature of >37.7°C (>99.9°F) would define a fever*. The normal daily temperature variation is typically 0.5°C (0.9°F). However, in some individuals recovering from a febrile illness, this daily variation can be as great as 1.0°C. During a febrile illness, the diurnal variation is usually maintained but at higher, febrile levels. The daily temperature variation appears to be fixed in early childhood; in contrast, elderly individuals can exhibit a reduced ability to develop fever, with only a modest fever even in severe infections.

Rectal temperatures are generally 0.4°C (0.7°F) higher than oral readings. The lower oral readings are probably attributable to mouth breathing, which is a factor in patients with respiratory infections and rapid breathing. Lower-esophageal temperatures closely reflect core temperature. Tympanic membrane (TM) thermometers measure radiant heat from the tympanic membrane and nearby ear canal and display that absolute value (unadjusted mode) or a value automatically calculated from the absolute reading on the basis of nomograms relating the radiant temperature measured to actual core temperatures obtained in clinical studies (adjusted mode). These measurements, although convenient,

may be more variable than directly determined oral or rectal values. Studies in adults show that readings are lower with unadjusted-mode than with adjusted-mode TM thermometers and that unadjusted-mode TM values are 0.8°C (1.6°F) lower than rectal temperatures.

In women who menstruate, the A.M. temperature is generally lower in the 2 weeks before ovulation; it then rises by ~0.6°C (1°F) with ovulation and remains at that level until menses occur. Body temperature can be elevated in the postprandial state. Pregnancy and endocrinologic dysfunction also affect body temperature.

FEVER VERSUS HYPERTHERMIA

FEVER

Fever is an elevation of body temperature that exceeds the normal daily variation and occurs *in conjunction with an increase in the hypothalamic set point* (e.g., from 37°C to 39°C). This shift of the set point from "normothermic" to febrile levels very much resembles the resetting of the home thermostat to a higher level in order to raise the ambient temperature in a room. Once the hypothalamic set point is raised, neurons in the vasomotor center are activated and vasoconstriction commences. The individual first notices vasoconstriction in the hands and feet. Shunting of blood away from the periphery to the internal organs essentially decreases heat loss from the skin, and the person feels cold. For most fevers, body temperature increases by 1°–2°C. Shivering, which increases heat production from the muscles, may begin at this time; however, shivering is not required if heat conservation mechanisms raise blood temperature sufficiently. Nonshivering heat production from the liver also contributes to increasing core temperature. In humans, behavioral adjustments (e.g., putting on more clothing or bedding) help raise body temperature by decreasing heat loss.

The processes of heat conservation (vasoconstriction) and heat production (shivering and increased nonshivering thermogenesis) continue until the temperature of the blood bathing the hypothalamic neurons matches the new thermostat setting. Once that point is reached, the hypothalamus maintains the temperature at the febrile level by the same mechanisms of heat balance that function in the afebrile state. When the hypothalamic set point is again reset downward (in response to either a reduction in the concentration of pyrogens or the use of antipyretics), the processes of heat loss through vasodilation and sweating are initiated. Loss of heat by sweating and vasodilation continues until the blood temperature at the hypothalamic level matches the lower setting. Behavioral changes (e.g., removal of clothing) facilitate heat loss.

A fever of >41.5°C (>106.7°F) is called *hyperpyrexia*. This extraordinarily high fever can develop in patients with severe infections but most commonly occurs in patients with central nervous system (CNS) hemorrhages. In the preantibiotic era, fever due to a variety of infectious diseases rarely exceeded 106°F, and there has been speculation that this natural "thermal ceiling" is mediated by neuropeptides functioning as central antipyretics.

In rare cases, the hypothalamic set point is elevated as a result of local trauma, hemorrhage, tumor, or intrinsic hypothalamic malfunction. The term *hypothalamic fever* is sometimes used to describe elevated temperature caused by abnormal hypothalamic function. However, most patients with hypothalamic damage have *sub*normal, not *supra*normal, body temperatures.

HYPERTHERMIA

Although most patients with elevated body temperature have fever, there are circumstances in which elevated temperature represents not fever but hyperthermia (Table 17-1). Hyperthermia is characterized by an uncontrolled increase in body temperature that exceeds the body's ability to lose heat. The setting of the hypothalamic thermoregulatory center is unchanged. In contrast to fever in infections, hyperthermia does not involve pyrogenic molecules (see "Pyrogens," below). Exogenous heat exposure and endogenous heat production are two mechanisms by which hyperthermia can result in dangerously high internal temperatures. Excessive heat production can easily cause hyperthermia despite physiologic and behavioral control of body temperature.

TABLE 17-1 CAUSES OF HYPERTHERMIA SYNDROMES

Heat Stroke
Exertional: Exercise in higher-than-normal heat and/or humidity Nonexertional: Anticholinergics, including antihistamines; antiparkinsonian drugs; diuretics; phenothiazines
Drug-Induced Hyperthermia
Amphetamines, cocaine, phencyclidine (PCP), methylenedioxymethamphetamine (MDMA; "ecstasy"), lysergic acid diethylamide (LSD), salicylates, lithium, anticholinergics, sympathomimetics
Neuroleptic Malignant Syndrome
Phenothiazines; butyrophenones, including haloperidol and bromperidol; fluoxetine; loxapine; tricyclic dibenzodiazepines; metoclopramide; domperidone; thiothixene; molindone; withdrawal of dopaminergic agents
Serotonin Syndrome
Selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants
Malignant Hyperthermia
Inhalational anesthetics, succinylcholine
Endocrinopathy
Thyrotoxicosis, pheochromocytoma
Central Nervous System Damage
Cerebral hemorrhage, status epilepticus, hypothalamic injury

Source: After FJ Curley, RS Irwin, JM Rippe et al (eds): *Intensive Care Medicine*, 3d ed. Boston, Little, Brown, 1996.

For example, work or exercise in hot environments can produce heat faster than peripheral mechanisms can lose it.

Heat stroke in association with a warm environment may be categorized as exertional or nonexertional. *Exertional heat stroke* typically occurs in individuals exercising at elevated ambient temperatures and/or humidities. In a dry environment and at maximal efficiency, sweating can dissipate ~600 kcal/h, requiring the production of >1 L of sweat. Even in healthy individuals, dehydration or the use of common medications (e.g., over-the-counter antihistamines with anticholinergic side effects) may precipitate exertional heat stroke. *Nonexertional heat stroke* typically occurs in either very young or elderly individuals, particularly during heat waves. According to the Centers for Disease Control and Prevention, there were 7000 deaths attributed to heat injury in the United States from 1979 to 1997. The elderly, the bedridden, persons taking anticholinergic or antiparkinsonian drugs or diuretics, and individuals confined to poorly ventilated and non-air-conditioned environments are most susceptible.

Drug-induced hyperthermia has become increasingly common as a result of the increased use of prescription psychotropic drugs and illicit drugs. Drug-induced hyperthermia may be caused by monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants, and amphetamines and by the illicit use of phencyclidine (PCP), lysergic acid diethylamide (LSD), methylenedioxymethamphetamine (MDMA, "ecstasy"), or cocaine.

Malignant hyperthermia occurs in individuals with an inherited abnormality of skeletal-muscle sarcoplasmic reticulum that causes a rapid increase in intracellular calcium levels in response to halothane and other inhalational anesthetics or to succinylcholine. Elevated temperature, increased muscle metabolism, muscle rigidity, rhabdomyolysis, acidosis, and cardiovascular instability develop within minutes. This rare condition is often fatal. The *neuroleptic malignant syndrome* occurs in the setting of neuroleptic agent use (antipsychotic phenothiazines, haloperidol, prochlorperazine, metoclopramide) or the withdrawal of dopaminergic drugs and is characterized by "lead-pipe" muscle rigidity, extrapyramidal side effects, autonomic dysregulation, and hyperthermia. This disorder appears to be caused by the inhibition of central dopamine receptors in the hypothalamus, which results in increased heat generation and decreased heat dissipation. The *serotonin syndrome*, seen with selective se-

rotonin uptake inhibitors (SSRIs), MAOIs, and other serotonergic medications, has many overlapping features, including hyperthermia, but may be distinguished by the presence of diarrhea, tremor, and myoclonus rather than the lead-pipe rigidity of the neuroleptic malignant syndrome. Thyrotoxicosis and pheochromocytoma can also cause increased thermogenesis.

It is important to distinguish between fever and hyperthermia since hyperthermia can be rapidly fatal and characteristically does not respond to antipyretics. In an emergency situation, however, making this distinction can be difficult. For example, in systemic sepsis, fever (hyperpyrexia) can be rapid in onset, and temperatures can exceed 40.5°C. Hyperthermia is often diagnosed on the basis of the events immediately preceding the elevation of core temperature—e.g., heat exposure or treatment with drugs that interfere with thermoregulation. In patients with heat stroke syndromes and in those taking drugs that block sweating, the skin is hot but dry, whereas in fever the skin can be cold as a consequence of vasoconstriction. Antipyretics do not reduce the elevated temperature in hyperthermia, whereas in fever—and even in hyperpyrexia—adequate doses of either aspirin or acetaminophen usually result in some decrease in body temperature.

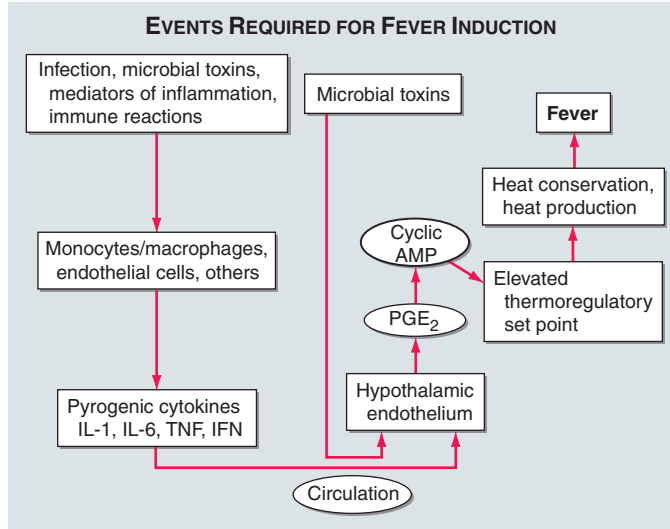

FIGURE 17-1 Chronology of events required for the induction of fever. AMP, adenosine 5′-monophosphate; IFN, interferon; IL, interleukin; PGE_2, prostaglandin E_2; TNF, tumor necrosis factor.

PATHOGENESIS OF FEVER

PYROGENS

The term *pyrogen* is used to describe any substance that causes fever. *Exogenous* pyrogens are derived from outside the patient; most are microbial products, microbial toxins, or whole microorganisms. The classic example of an exogenous pyrogen is the lipopolysaccharide (endotoxin) produced by all gram-negative bacteria. Pyrogenic products of gram-positive organisms include the enterotoxins of *Staphylococcus aureus* and the group A and B streptococcal toxins, also called *superantigens*. One staphylococcal toxin of clinical importance is that associated with isolates of *S. aureus* from patients with toxic shock syndrome. These products of staphylococci and streptococci cause fever in experimental animals when injected intravenously at concentrations of 1–10 μg/kg. Endotoxin is a highly pyrogenic molecule in humans: when injected intravenously into volunteers, a dose of 2–3 ng/kg produces fever, leukocytosis, acute-phase proteins, and generalized symptoms of malaise.

PYROGENIC CYTOKINES

Cytokines are small proteins (molecular mass, 10,000–20,000 Da) that regulate immune, inflammatory, and hematopoietic processes. For example, the elevated leukocytosis seen in several infections with an absolute neutrophilia is the result of the cytokines interleukin (IL) 1 and IL-6. Some cytokines also cause fever; formerly referred to as *endogenous pyrogens*, they are now called *pyrogenic cytokines*. The pyrogenic cytokines include IL-1, IL-6, tumor necrosis factor (TNF), ciliary neurotropic factor (CNTF), and interferon (IFN) α. (IL-18, a member of the IL-1 family, does not appear to be a pyrogenic cytokine.) Other pyrogenic cytokines probably exist. Each cytokine is encoded by a separate gene, and each pyrogenic cytokine has been shown to cause fever in laboratory animals and in humans. When injected into humans, IL-1 and TNF produce fever at low doses (10–100 ng/kg); in contrast, for IL-6, a dose of 1–10 μg/kg is required for fever production.

A wide spectrum of bacterial and fungal products induce the synthesis and release of pyrogenic cytokines, as do viruses. However, fever can be a manifestation of disease in the absence of microbial infection. For example, inflammatory processes, trauma, tissue necrosis, or antigen-antibody complexes can induce the production of IL-1, TNF, and/or IL-6, which—individually or in combination—trigger the hypothalamus to raise the set point to febrile levels.

ELEVATION OF THE HYPOTHALAMIC SET POINT BY CYTOKINES

During fever, levels of prostaglandin E_2 (PGE_2) are elevated in hypothalamic tissue and the third cerebral ventricle. The concentrations of PGE_2 are highest near the circumventricular vascular organs (organum vasculosum of lamina terminalis)—networks of enlarged capillaries surrounding the hypothalamic regulatory centers. Destruction of these organs reduces the ability of pyrogens to produce fever. Most studies in animals have failed to show, however, that pyrogenic cytokines pass from the circulation into the brain itself. Thus, it appears that both exogenous and endogenous pyrogens interact with the endothelium of these capillaries and that this interaction is the first step in initiating fever—i.e., in raising the set point to febrile levels.

The key events in the production of fever are illustrated in Fig. 17-1. As has been mentioned, several cell types can produce pyrogenic cytokines. Pyrogenic cytokines such as IL-1, IL-6, and TNF are released from the cells and enter the systemic circulation. Although the systemic effects of these circulating cytokines lead to fever by inducing the synthesis of PGE_2, they also induce PGE_2 in peripheral tissues. The increase in PGE_2 in the periphery accounts for the nonspecific myalgias and arthralgias that often accompany fever. It is thought that some systemic PGE_2 escapes destruction by the lung and gains access to the hypothalamus via the internal carotid. However, it is the elevation of PGE_2 in the brain that starts the process of raising the hypothalamic set point for core temperature.

There are four receptors for PGE_2, and each signals the cell in different ways. Of the four receptors, the third (EP-3) is essential for fever: when the gene for this receptor is deleted in mice, no fever follows the injection of IL-1 or endotoxin. Deletion of the other PGE_2 receptor genes leaves the fever mechanism intact. Although PGE_2 is essential for fever, it is not a neurotransmitter. Rather, the release of PGE_2 from the brain side of the hypothalamic endothelium triggers the PGE_2 receptor on glial cells, and this stimulation results in the rapid release of cyclic adenosine 5′-monophosphate (cyclic AMP), which is a neurotransmitter. As shown in Fig. 17-1, the release of cyclic AMP from the glial cells activates neuronal endings from the thermoregulatory center that extend into the area. The elevation of cyclic AMP is thought to account for changes in the hypothalamic set point either directly or indirectly (by inducing the release of neurotransmitters). Distinct receptors for microbial products are located on the hypothalamic endothelium. These receptors are called *Toll-like receptors* and are similar in many ways to IL-1 receptors. The direct activation of Toll-like receptors also results in PGE_2 production and fever.

PRODUCTION OF CYTOKINES IN THE CNS

Several viral diseases produce active infection in the brain. Glial and possibly neuronal cells synthesize IL-1, TNF, and IL-6. CNTF is also synthesized by neural as well as neuronal cells. What role in the production of fever is played by these cytokines produced in the brain itself? In experimental animals, the concentrations of cytokine required

to cause fever are several orders of magnitude lower with direct injection into the brain than with IV injection. Therefore, CNS production of these cytokines apparently can raise the hypothalamic set point, bypassing the circumventricular organs involved in fever caused by circulating cytokines. CNS cytokines may account for the hyperpyrexia of CNS hemorrhage, trauma, or infection.

APPROACH TO THE PATIENT: Fever or Hyperthermia

PHYSICAL EXAMINATION Attention must be paid to the chronology of events and to other signs and symptoms preceding the fever. The temperature may be taken orally or rectally, but the site used should be consistent. Axillary temperatures are notoriously unreliable. Electronic devices for measuring tympanic membrane temperatures are reliable and preferred over oral temperature measurements in patients with pulmonary disease such as acute infection or asthma.

LABORATORY TESTS The workup should include a complete blood count; a differential count should be performed manually or with an instrument sensitive to the identification of eosinophils, juvenile or band forms, toxic granulations, and Döhle bodies, the last three of which are suggestive of bacterial infection. Neutropenia may be present with some viral infections.

Measurement of circulating cytokines in patients with fever is of little use since levels of pyrogenic cytokines in the circulation often are below the detection limit of the assay or do not coincide with the fever. Although some studies have shown correlations between circulating IL-6 levels and peak febrile elevations, the most valuable measurements in patients with fever are C-reactive protein level and erythrocyte sedimentation rate. These markers of pathologic processes are particularly helpful in identifying disease in patients with small elevations in body temperature.

FEVER IN RECIPIENTS OF ANTICYTOKINE THERAPY As of this writing, more than 750,000 patients in the United States are receiving chronic anticytokine therapy for Crohn's disease, rheumatoid arthritis, or psoriasis. Does such therapy mask infection by preventing fever? With the increasing use of anticytokines to reduce the activity of IL-1, IL-6, IL-12, and TNF, the effect of these agents on the febrile response must be considered.

The blocking of cytokine activity has the distinct clinical drawback of lowering the level of host defenses against both routine bacterial and opportunistic infections. The opportunistic infections reported in patients given neutralizing antibodies to TNF-α (infliximab or adalimumab) are similar to those reported in the HIV-1-infected population (e.g., new infection with or reactivation of *Mycobacterium tuberculosis*, with dissemination). A soluble receptor for TNF, etanercept, is also associated with opportunistic infections but less so than the neutralizing antibodies.

In nearly all reported cases of infection associated with anticytokine therapy, fever is among the presenting signs. However, the extent to which the febrile response is reduced in these patients remains unknown. Fever in a patient who develops an infection during anticytokine treatment is likely to be due to the direct action of microbial products on the hypothalamic thermoregulatory center, with induction of PGE_2. For example, blocking the activity of IL-1 or TNF during experimental endotoxin-induced fever in volunteers does not affect the febrile response.

Rx FEVER AND HYPERTHERMIA

THE DECISION TO TREAT FEVER Most fevers are associated with self-limited infections, such as common viral diseases. The use of antipyretics is not contraindicated in these infections: there is no significant clinical evidence that antipyretics delay the resolution of viral or bacterial infections, nor is there evidence that fever facilitates recovery from infection or acts as an adjuvant to the immune system. In fact, peripheral PGE_2 production is a potent immunosuppressant. In short, treatment of fever and its symptoms does no harm and does not slow the resolution of common viral and bacterial infections.

However, in bacterial infections, withholding antipyretic therapy can be helpful in evaluating the effectiveness of a particular antibiotic therapy, particularly in the absence of cultural identification of the infecting organism. The routine use of antipyretics can mask an inadequately treated bacterial infection. Withholding antipyretics in some cases may facilitate the diagnosis of an unusual febrile disease. For example, the usual times of peak and trough temperatures may be reversed in typhoid fever and disseminated tuberculosis. Temperature-pulse dissociation (relative bradycardia) occurs in typhoid fever, brucellosis, leptospirosis, some drug-induced fevers, and factitious fever. In newborns, the elderly, patients with chronic renal failure, and patients taking glucocorticoids, fever may not be present despite infection, or core temperature may be hypothermic. Hypothermia is often observed in patients with septic shock.

Some infections have characteristic patterns in which febrile episodes are separated by intervals of normal temperature. For example, *Plasmodium vivax* causes fever every third day, whereas fever occurs every fourth day with *P. malariae*. Other relapsing fevers are related to *Borrelia* infections, with days of fever followed by a several-day afebrile period and then a relapse of days of fever. In the Pel-Ebstein pattern, fever lasting 3–10 days is followed by afebrile periods of 3–10 days; this pattern can be classic for Hodgkin's disease and other lymphomas. In cyclic neutropenia, fevers occur every 21 days and accompany the neutropenia. There is no periodicity of fever in patients with familial Mediterranean fever.

Recurrent fever is documented at some point in most autoimmune diseases and all autoinflammatory diseases. The autoinflammatory diseases include adult and juvenile Still's disease, familial Mediterranean fever, hyper-IgD syndrome, familial cold-induced autoinflammatory syndrome, neonatal-onset multisystem autoinflammatory disease, Blau syndrome, Schnitzler syndrome, Muckle-Wells syndrome, and TNF receptor–associated periodic syndrome. Besides recurrent fevers, neutrophilia and serosal inflammation characterize these diseases. The fevers associated with these illnesses are dramatically reduced by blocking of IL-1β activity. Anticytokines therefore reduce fever in autoimmune and autoinflammatory diseases. Although fevers in autoinflammatory diseases are mediated by IL-1β, patients also respond to antipyretics.

MECHANISMS OF ANTIPYRETIC AGENTS The reduction of fever by lowering of the elevated hypothalamic set point is a direct function of reducing the level of PGE_2 in the thermoregulatory center. The synthesis of PGE_2 depends on the constitutively expressed enzyme cyclooxygenase. The substrate for cyclooxygenase is arachidonic acid released from the cell membrane, and this release is the rate-limiting step in the synthesis of PGE_2. Therefore, inhibitors of cyclooxygenase are potent antipyretics. The antipyretic potency of various drugs is directly correlated with the inhibition of brain cyclooxygenase. Acetaminophen is a poor cyclooxygenase inhibitor in peripheral tissue and lacks noteworthy anti-inflammatory activity; in the brain, however, acetaminophen is oxidized by the p450 cytochrome system, and the oxidized form inhibits cyclooxygenase activity. Moreover, in the brain, the inhibition of another enzyme, COX-3, by acetaminophen may account for the antipyretic effect of this agent. However, COX-3 is not found outside the CNS.

Oral aspirin and acetaminophen are equally effective in reducing fever in humans. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and specific inhibitors of COX-2 are also excellent antipyretics. Chronic, high-dose therapy with antipyretics such as aspirin or any NSAID does not reduce normal core body temperature. Thus, PGE_2 appears to play no role in normal thermoregulation.

As effective antipyretics, glucocorticoids act at two levels. First, similar to the cyclooxygenase inhibitors, glucocorticoids reduce PGE_2 synthesis by inhibiting the activity of phospholipase A_2, which is needed to release arachidonic acid from the cell membrane. Second, glucocorticoids block the transcription of the mRNA for the pyrogenic cytokines. Limited experimental evidence indicates that ibuprofen and COX-2 inhibitors reduce IL-1-induced IL-6 production and may contribute to the antipyretic activity of NSAIDs.

REGIMENS FOR THE TREATMENT OF FEVER The objectives in treating fever are first to reduce the elevated hypothalamic set point and second to facilitate heat loss. Reducing fever with antipyretics also reduces systemic symptoms of headache, myalgias, and arthralgias.

Oral aspirin and NSAIDs effectively reduce fever but can adversely affect platelets and the gastrointestinal tract. Therefore, acetaminophen is preferred to all of these agents as an antipyretic. In children, acetaminophen must be used because aspirin increases the risk of Reye's syndrome. If the patient cannot take oral antipyretics, parenteral preparations of NSAIDs and rectal suppository preparations of various antipyretics can be used.

Treatment of fever in some patients is highly recommended. Fever increases the demand for oxygen (i.e., for every increase of 1°C over 37°C, there is a 13% increase in oxygen consumption) and can aggravate preexisting cardiac, cerebrovascular, or pulmonary insufficiency. Elevated temperature can induce mental changes in patients with organic brain disease. Children with a history of febrile or nonfebrile seizure should be aggressively treated to reduce fever, although it is unclear what triggers the febrile seizure and there is no correlation between absolute temperature elevation and onset of a febrile seizure in susceptible children.

In hyperpyrexia, the use of cooling blankets facilitates the reduction of temperature; however, cooling blankets should not be used without oral antipyretics. In hyperpyretic patients with CNS disease or trauma, reducing core temperature mitigates the ill effects of high temperature on the brain.

TREATING HYPERTHERMIA A high core temperature in a patient with an appropriate history (e.g., environmental heat exposure or treatment with anticholinergic or neuroleptic drugs, tricyclic antidepressants, succinylcholine, or halothane) along with appropriate clinical findings (dry skin, hallucinations, delirium, pupil dilation, muscle rigidity, and/or elevated levels of creatine phosphokinase) suggests hyperthermia. Attempts to lower the already normal hypothalamic set point are of little use. Physical cooling with sponging, fans, cooling blankets, and even ice baths should be initiated immediately in conjunction with the administration of IV fluids and appropriate pharmacologic agents (see below). If insufficient cooling is achieved by external means, internal cooling can be achieved by gastric or peritoneal lavage with iced saline. In extreme circumstances, hemodialysis or even cardiopulmonary bypass with cooling of blood may be performed.

Malignant hyperthermia should be treated immediately with cessation of anesthesia and IV administration of dantrolene sodium. The recommended dose of dantrolene is 1–2.5 mg/kg given intravenously every 6 h for at least 24–48 h—until oral dantrolene can be administered, if needed. Procainamide should also be administered to patients with malignant hyperthermia because of the likelihood of ventricular fibrillation in this syndrome. Dantrolene at similar doses is indicated in the neuroleptic malignant syndrome and in drug-induced hyperthermia and may even be useful in the hyperthermia of the serotonin syndrome and thyrotoxicosis. The neuroleptic malignant syndrome may also be treated with bromocriptine, levodopa, amantadine, or nifedipine or by induction of muscle paralysis with curare and pancuronium. Tricyclic antidepressant overdose may be treated with physostigmine.

18 Fever and Rash

Elaine T. Kaye, Kenneth M. Kaye

The acutely ill patient with fever and rash often presents a diagnostic challenge for physicians. The distinctive appearance of an eruption in concert with a clinical syndrome may facilitate a prompt diagnosis and the institution of life-saving therapy or critical infection-control interventions. **Representative images of many of the rashes discussed in this chapter are included in Chap. e5.**

APPROACH TO THE PATIENT: Fever and Rash

A thorough history of patients with fever and rash includes the following relevant information: immune status, medications taken within the previous month, specific travel history, immunization status, exposure to domestic pets and other animals, history of animal (including arthropod) bites, existence of cardiac abnormalities, presence of prosthetic material, recent exposure to ill individuals, and exposure to sexually transmitted diseases. The history should also include the site of onset of the rash and its direction and rate of spread.

A thorough physical examination entails close attention to the rash, with an assessment and precise definition of its salient features. First, it is critical to determine the *type* of lesions that make up the eruption. *Macules* are flat lesions defined by an area of changed color (i.e., a blanchable erythema). *Papules* are raised, solid lesions <5 mm in diameter; *plaques* are lesions >5 mm in diameter with a flat, plateau-like surface; and *nodules* are lesions >5 mm in diameter with a more rounded configuration. *Wheals* (urticaria, hives) are papules or plaques that are pale pink and may appear annular (ringlike) as they enlarge; classic (nonvasculitic) wheals are transient, lasting only 24–48 h in any defined area. *Vesicles* (<5 mm) and *bullae* (>5 mm) are circumscribed, elevated lesions containing fluid. *Pustules* are raised lesions containing purulent exudate; vesicular processes such as varicella or herpes simplex may evolve to pustules. *Nonpalpable purpura* is a flat lesion that is due to bleeding into the skin; if <3 mm in diameter, the purpuric lesions are termed *petechiae*; if >3 mm, they are termed *ecchymoses*. *Palpable purpura* is a raised lesion that is due to inflammation of the vessel wall (vasculitis) with subsequent hemorrhage. An *ulcer* is a defect in the skin extending at least into the upper layer of the dermis, and an *eschar* (tâche noire) is a necrotic lesion covered with a black crust.

Other pertinent features of rashes include their *configuration* (i.e., annular or target), the *arrangement* of their lesions, and their *distribution* (i.e., central or peripheral). **For further discussion, see Chaps. 52, 54, and 115.**

CLASSIFICATION OF RASH

This chapter reviews rashes that reflect systemic disease, but it does not include localized skin eruptions (i.e., cellulitis, impetigo) that may also be associated with fever (Chap. 119). Rashes are classified herein on the basis of the morphology and distribution of lesions. For practical pur-

poses, this classification system is based on the most typical disease presentations. However, morphology may vary as rashes evolve, and the presentation of diseases with rashes is subject to many variations (Chap. 54). For instance, the classic petechial rash of Rocky Mountain spotted fever (RMSF; Chap. 167) may initially consist of blanchable erythematous macules distributed peripherally; at times, the rash associated with RMSF may not be predominantly acral, or a rash may not develop at all.

Diseases with fever and rash may be classified by type of eruption: centrally distributed maculopapular, peripheral, confluent desquamative erythematous, vesiculobullous, urticarial, nodular, purpuric, ulcerated, or eschar (Table 18-1). For a more detailed discussion of each disease associated with a rash, the reader is referred to the chapter dealing with that specific disease. (Reference chapters are cited in the text and listed in Table 18-1.)

TABLE 18-1 DISEASES ASSOCIATED WITH FEVER AND RASH

Disease	Etiology	Description	Group Affected/ Epidemiologic Factors	Clinical Syndrome	Chapter
Centrally Distributed Maculopapular Eruptions					
Acute meningococcemia[a]	—	—	—	—	136
Rubeola (measles, first disease)	Paramyxovirus	Discrete lesions that become confluent as rash spreads from hairline downward, sparing palms and soles; lasts ≥3 days; Koplik's spots	Nonimmune individuals	Cough, conjunctivitis, coryza, severe prostration	185
Rubella (German measles, third disease)	Togavirus	Spreads from hairline downward, clearing as it spreads; Forschheimer spots	Nonimmune individuals	Adenopathy, arthritis	186
Erythema infectiosum (fifth disease)	Human parvovirus B19	Bright-red "slapped-cheek" appearance followed by lacy reticular rash that waxes and wanes over 3 weeks; rarely, papular-purpuric "gloves-and-socks" syndrome on hands and feet	Most common in children aged 3–12 years; occurs in winter and spring	Mild fever; arthritis in adults; rash following resolution of fever	177
Exanthem subitum (roseola, sixth disease)	Human herpesvirus 6	Diffuse maculopapular eruption (sparing face); resolves within 2 days	Usually affects children <3 years old	Rash following resolution of fever; similar to Boston exanthem (echovirus 16)	175
Primary HIV infection	HIV	Nonspecific diffuse macules and papules; may be urticarial; oral or genital ulcers in some cases	Individuals recently infected with HIV	Pharyngitis, adenopathy, arthralgias	182
Infectious mononucleosis	Epstein-Barr virus	Diffuse maculopapular eruption (10–15% of cases; 90% if ampicillin is given); urticaria in some cases; periorbital edema (50%); palatal petechiae (25%)	Adolescents, young adults	Hepatosplenomegaly, pharyngitis, cervical lymphadenopathy, atypical lymphocytosis, heterophile antibody	174
Other viral exanthems	Echoviruses 2, 4, 9, 11, 16, 19, and 25; coxsackieviruses A9, B1, and B5; etc.	Skin findings mimicking rubella or measles	Affect children more commonly than adults	Nonspecific viral syndromes	184
Exanthematous drug-induced eruption	Drugs (antibiotics, anticonvulsants, diuretics, etc.)	Intensely pruritic, bright-red macules and papules, symmetric on trunk and extremities; may become confluent	Occurs 2–3 d after exposure in previously sensitized individuals; otherwise, after 2–3 weeks (but can occur anytime, even shortly after drug is discontinued)	Variable findings: fever and eosinophilia	56
Epidemic typhus	*Rickettsia prowazekii*	Maculopapular eruption appearing in axillae, spreading to trunk and later to extremities; usually spares face, palms, soles; evolves from blanchable macules to confluent eruption with petechiae; rash evanescent in recrudescent typhus (Brill-Zinsser disease)	Exposure to body lice; occurrence of recrudescent typhus as relapse after 30–50 years	Headache, myalgias; 10–40% mortality if untreated; milder clinical presentation in recrudescent form	167
Endemic (murine) typhus	*Rickettsia typhi*	Maculopapular eruption, usually sparing palms, soles	Exposure to rat or cat fleas	Headache, myalgias	167
Scrub typhus	*Orientia tsutsugamushi*	Diffuse macular rash starting on trunk; eschar at site of mite bite	Endemic in South Pacific, Australia, Asia; transmitted by mites	Headache, myalgias, regional adenopathy; mortality up to 30% if untreated	167
Rickettsial spotted fevers	*Rickettsia conorii* (boutonneuse fever), *Rickettsia australis* (North Queensland tick typhus), *Rickettsia sibirica* (Siberian tick typhus), and others	Eschar common at bite site; maculopapular (rarely, vesicular and petechial) eruption on proximal extremities, spreading to trunk and face	Exposure to ticks; *R. conorii* in Mediterranean region, India, Africa; *R. australis* in Australia; *R. sibirica* in Siberia, Mongolia	Headache, myalgias, regional adenopathy	167

(continued)

TABLE 18-1 DISEASES ASSOCIATED WITH FEVER AND RASH (CONTINUED)

Disease	Etiology	Description	Group Affected/ Epidemiologic Factors	Clinical Syndrome	Chapter
Human monocytotropic ehrlichiosis[b]	*Ehrlichia chaffeensis*	Maculopapular eruption (40% of cases), involves trunk and extremities; may be petechial	Tick-borne; most common in U.S. Southeast, southern Midwest, and mid-Atlantic regions	Headache, myalgias, leukopenia	167
Leptospirosis	*Leptospira interrogans*	Maculopapular eruption; conjunctivitis; scleral hemorrhage in some cases	Exposure to water contaminated with animal urine	Myalgias; aseptic meningitis; *fulminant form*: icterohemorrhagic fever (Weil's disease)	164
Lyme disease	*Borrelia burgdorferi*	Papule expanding to erythematous annular lesion with central clearing (erythema chronicum migrans or ECM; average diameter, 15 cm), sometimes with concentric rings, sometimes with indurated or vesicular center; multiple secondary ECM lesions in some cases	Bite of tick vector	Headache, myalgias, chills, photophobia occurring acutely; CNS disease, myocardial disease, arthritis weeks to months later in some cases	166
Typhoid fever	*Salmonella typhi*	Transient, blanchable erythematous macules and papules, 2–4 mm, usually on trunk (rose spots)	Ingestion of contaminated food or water (rare in U.S.)	Variable abdominal pain and diarrhea; headache, myalgias, hepatosplenomegaly	146
Dengue fever[c]	Dengue virus (4 serotypes; flaviviruses)	Rash in 50% of cases; initially diffuse flushing; midway through illness, onset of maculopapular rash, which begins on trunk and spreads centrifugally to extremities and face; pruritus, hyperesthesia in some cases; after defervescence, petechiae on extremities in some cases	Occurs in tropics and subtropics; transmitted by mosquito	Headache, musculoskeletal pain ("breakbone fever"); leukopenia; occasionally biphasic ("saddleback") fever	189
Rat-bite fever (sodoku)	*Spirillum minus*	Eschar at bite site; then blotchy violaceous or red-brown rash involving trunk and extremities	Rat bite; primarily found in Asia; rare in U.S.	Regional adenopathy, recurrent fevers if untreated	…
Relapsing fever	*Borrelia* species	Central rash at end of febrile episode; petechiae in some cases	Exposure to ticks or body lice	Recurrent fever, headache, myalgias, hepatosplenomegaly	165
Erythema marginatum (rheumatic fever)	Group A *Streptococcus*	Erythematous annular papules and plaques occurring as polycyclic lesions in waves over trunk, proximal extremities; evolving and resolving within hours	Patients with rheumatic fever	Pharyngitis preceding polyarthritis, carditis, subcutaneous nodules, chorea	315
Systemic lupus erythematosus	Autoimmune disease	Macular and papular erythema, often in sun-exposed areas; discoid lupus lesions (local atrophy, scale, pigmentary changes); periungual telangiectasis; malar rash; vasculitis sometimes causing urticaria, palpable purpura; oral erosions in some cases	Most common in young to middle-aged women; flares precipitated by sun exposure	Arthritis; cardiac, pulmonary, renal, hematologic, and vasculitic disease	313
Still's disease	Autoimmune disease	Transient 2- to 5-mm erythematous papules appearing at height of fever on trunk, proximal extremities; lesions evanescent	Children and young adults	High spiking fever, polyarthritis, splenomegaly; erythrocyte sedimentation rate, >100 mm/h	331
Arcanobacterial pharyngitis	*Arcanobacterium (Corynebacterium) haemolyticum*	Diffuse, erythematous, maculopapular eruption involving trunk and proximal extremities; may desquamate	Children and young adults	Exudative pharyngitis, lymphadenopathy	131
Peripheral Eruptions					
Chronic meningococcemia, disseminated gonococcal infection[a], human parvovirus B19 infection[g]	—	—	—	—	136, 137, 177
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Rash beginning on wrists and ankles and spreading centripetally; appears on palms and soles later in disease; lesion evolution from blanchable macules to petechiae	Tick vector; widespread but more common in southeastern and southwest-central U.S.	Headache, myalgias, abdominal pain; mortality up to 40% if untreated	167

(continued)

TABLE 18-1 DISEASES ASSOCIATED WITH FEVER AND RASH (CONTINUED)

Disease	Etiology	Description	Group Affected/ Epidemiologic Factors	Clinical Syndrome	Chapter
Secondary syphilis	*Treponema pallidum*	Coincident primary chancre in 10% of cases; copper-colored, scaly papular eruption, diffuse but prominent on palms and soles; rash never vesicular in adults; condyloma latum, mucous patches, and alopecia in some cases	Sexually transmitted	Fever, constitutional symptoms	162
Atypical measles	Paramyxovirus	Maculopapular eruption beginning on distal extremities and spreading centripetally; may evolve into vesicles or petechiae; edema of extremities; Koplik's spots absent	Individuals contracting measles who received killed measles vaccine in 1963–1967 in U.S. without subsequent live vaccine	Headache, nodular pneumonia	185
Hand-foot-and-mouth disease	Coxsackievirus A16 most common cause	Tender vesicles, erosions in mouth; 0.25-cm papules on hands and feet with rim of erythema evolving into tender vesicles	Summer and fall; primarily children <10 years old; multiple family members	Transient fever	184
Erythema multiforme	Drugs, infection, idiopathic causes	Target lesions (central erythema surrounded by area of clearing and another rim of erythema) up to 2 cm; symmetric on knees, elbows, palms, soles; may become diffuse; may involve mucosal surfaces; life-threatening in maximal form (Stevens-Johnson syndrome)	Drug intake (i.e., sulfa, phenytoin, penicillin); herpes simplex virus or *Mycoplasma pneumoniae* infection	Varies with predisposing factor	—[d]
Rat-bite fever (Haverhill fever)	*Streptobacillus moniliformis*	Maculopapular eruption over palms, soles, and extremities; tends to be more severe at joints; eruption sometimes becoming generalized; may be purpuric; may desquamate	Rat bite, ingestion of contaminated food	Myalgias; arthritis (50%); fever recurrence in some cases	…
Bacterial endocarditis	*Streptococcus*, *Staphylococcus*, etc.	*Subacute course*: Osler's nodes (tender pink nodules on finger or toe pads); petechiae on skin and mucosa; splinter hemorrhages. *Acute course* (*Staphylococcus aureus*): Janeway lesions (painless erythematous or hemorrhagic macules, usually on palms and soles)	Abnormal heart valve, intravenous drug use	New heart murmur	118
Confluent Desquamative Erythemas					
Scarlet fever (second disease)	Group A *Streptococcus* (pyrogenic exotoxins A, B, C)	Diffuse blanchable erythema beginning on face and spreading to trunk and extremities; circumoral pallor; "sandpaper" texture to skin; accentuation of linear erythema in skin folds (Pastia's lines); enanthem of white evolving into red "strawberry" tongue; desquamation in second week	Most common in children aged 2–10 years; usually follows group A streptococcal pharyngitis	Fever, pharyngitis, headache	130
Kawasaki disease	Idiopathic causes	Rash similar to scarlet fever (scarlatiniform) or erythema multiforme; fissuring of lips, strawberry tongue; conjunctivitis; edema of hands, feet; desquamation later in disease	Children <8 years	Cervical adenopathy, pharyngitis, coronary artery vasculitis	54, 319
Streptococcal toxic shock syndrome	Group A *Streptococcus* (associated with pyrogenic exotoxin A and/or B or certain M types)	When present, rash often scarlatiniform	May occur in setting of severe group A streptococcal infections, such as necrotizing fasciitis, bacteremia, pneumonia	Multiorgan failure, hypotension; 30% mortality rate	130
Staphylococcal toxic shock syndrome	*S. aureus* (toxic shock syndrome toxin 1, enterotoxin B or C)	Diffuse erythema involving palms; pronounced erythema of mucosal surfaces; conjunctivitis; desquamation 7–10 days into illness	Colonization with toxin-producing *S. aureus*	Fever >39°C (102°F), hypotension, multiorgan dysfunction	129
Staphylococcal scalded-skin syndrome	*S. aureus*, phage group II	Diffuse tender erythema, often with bullae and desquamation; Nikolsky's sign	Colonization with toxin-producing *S. aureus*; occurs in children <10 years old (termed "Ritter's disease" in neonates) or adults with renal dysfunction	Irritability; nasal or conjunctival secretions	129

(continued)

TABLE 18-1 DISEASES ASSOCIATED WITH FEVER AND RASH (CONTINUED)

Disease	Etiology	Description	Group Affected/ Epidemiologic Factors	Clinical Syndrome	Chapter
Exfoliative erythroderma syndrome	Underlying psoriasis, eczema, drug eruption, mycosis fungoides	Diffuse erythema (often scaling) interspersed with lesions of underlying condition	Usually occurs in adults over age 50; more common in men	Fever, chills (i.e., difficulty with thermoregulation); lymphadenopathy	53, 56
Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN)	Drugs, other causes (infection, neoplasm, graft-vs.-host disease)	Diffuse erythema or target-like lesions progressing to bullae, with sloughing and necrosis of entire epidermis; Nikolsky's sign. *TEN:* maximal form of SJS. *SJS:* maximal form of erythema multiforme	Uncommon in children; more common in patients with HIV infection or graft-vs.-host disease	Dehydration, sepsis sometimes resulting from lack of normal skin integrity; 25% mortality	56
Vesiculobullous Eruptions					
Hand-foot-and-mouth syndrome[e]; staphylococcal scalded-skin syndrome; toxic epidermal necrolysis[f]	—	—	—	—	—[d]
Varicella (chickenpox)	Varicella-zoster virus	Macules (2–3 mm) evolving into papules, then vesicles (sometimes umbilicated), on an erythematous base ("dewdrops on a rose petal"); pustules then forming and crusting; lesions appearing in crops; may involve scalp, mouth; intensely pruritic	Usually affects children; 10% of adults susceptible; most common in late winter and spring	Malaise; generally mild disease in healthy children; more severe disease with complications in adults and immunocompromised children	173
Pseudomonas "hot-tub" folliculitis	*Pseudomonas aeruginosa*	Pruritic, erythematous follicular, papular, vesicular, or pustular lesions that may involve axillae, buttocks, abdomen, and especially areas occluded by bathing suits; can manifest as tender isolated nodules on palmar or plantar surfaces (the latter designated "*Pseudomonas* hot-foot syndrome")	Bathers in hot tubs or swimming pools; occurs in outbreaks	Earache, sore eyes and/or throat; generally self-limited	145
Variola (smallpox)	Variola major virus	Red macules on tongue, palate evolving to papules and vesicles; skin macules evolving to papules, then vesicles, then pustules over 1 week, with subsequent lesion crusting; lesions initially appearing on face and spreading centrifugally from trunk to extremities; differs from varicella in that (1) skin lesions in any given area are at same stage of development and (2) there is a prominent distribution of lesions on face and extremities (including palms, soles) as opposed to prominent rash on trunk	Nonimmune individuals exposed to smallpox	Prodrome of fever, headache, backache, myalgias; vomiting in 50% of cases	214
Primary herpes simplex virus (HSV) infection	HSV	Erythema rapidly followed by hallmark *grouped vesicles* that may evolve into pustules; painful lesions that may ulcerate, especially on mucosal surfaces; lesions at site of inoculation: commonly gingivostomatitis for HSV-1 and genital lesions for HSV-2; recurrent disease milder (e.g., herpes labialis does not involve oral mucosa)	Primary infection most common in children and young adults for HSV-1 and in sexually active young adults for HSV-2; no fever in recurrent infection	Regional lymphadenopathy	172

(continued)

TABLE 18-1 DISEASES ASSOCIATED WITH FEVER AND RASH (CONTINUED)

Disease	Etiology	Description	Group Affected/ Epidemiologic Factors	Clinical Syndrome	Chapter
Disseminated herpesvirus infection	Varicella-zoster virus or HSV	Generalized vesicles that can evolve to pustules and ulcerations; individual lesions similar for varicella-zoster and HSV. *Zoster cutaneous dissemination*: >25 lesions extending outside involved dermatome. *HSV*: extensive, progressive mucocutaneous lesions in some cases; HSV lesions sometimes disseminate in eczematous skin (eczema herpeticum); HSV visceral dissemination may occur with only limited skin lesions	Immunosuppressed individuals, eczema	Visceral organ involvement (especially liver) in some cases	172, 173, 376
Rickettsialpox	*Rickettsia akari*	Eschar found at site of mite bite; generalized rash involving face, trunk, extremities; may involve palms and soles; <100 papules and plaques (2–10 mm); tops of lesions develop vesicles that may evolve into pustules	Seen in urban settings; transmitted by mouse mites	Headache, myalgias, regional adenopathy; mild disease	167
Disseminated *Vibrio vulnificus* infection	*V. vulnificus*	Erythematous lesions evolving into hemorrhagic bullae and then into necrotic ulcers	Patients with cirrhosis, diabetes, renal failure; exposure by ingestion of contaminated saltwater seafood	Hypotension; 50% mortality	149
Ecthyma gangrenosum	*P. aeruginosa*, other gram-negative rods, fungi	Indurated plaque evolving into hemorrhagic bulla or pustule that sloughs, resulting in eschar formation; erythematous halo; most common in axillary, groin, perianal regions	Usually affects neutropenic patients; occurs in up to 28% of individuals with *Pseudomonas* bacteremia	Clinical signs of sepsis	145
Urticarial Eruptions					
Urticarial vasculitis	Serum sickness, often due to infection (including hepatitis B viral, enteroviral, parasitic), drugs (including penicillins, sulfonamides, salicylates, barbiturates); connective tissue disease; idiopathic causes	Erythematous, circumscribed areas of edema; occasionally indurated; pruritic or burning; lesions sometimes purpuric; individual lesions lasting up to 5 days	In serum sickness, occurs 8–14 days after antigen exposure in nonsensitized individuals; may occur within 36 h in sensitized individuals	Malaise, lymphadenopathy, myalgias, arthralgias	319[d]
Nodular Eruptions					
Disseminated infection	Fungi (e.g., candidiasis, histoplasmosis, cryptococcosis, sporotrichosis, coccidioidomycosis); mycobacteria	Subcutaneous nodules (up to 3 cm); fluctuance, draining common with mycobacteria; necrotic nodules (extremities, periorbital or nasal regions) common with *Aspergillus*, *Mucor*	Immunocompromised hosts (i.e., bone marrow transplant recipients, patients undergoing chemotherapy, HIV-infected patients, alcoholics)	Features vary with organism	—[d]
Erythema nodosum (septal panniculitis)	Infections (e.g., streptococcal, fungal, mycobacterial, yersinial); drugs (e.g., sulfas, penicillins, oral contraceptives); sarcoidosis; idiopathic causes	Large, violaceous, nonulcerative, subcutaneous nodules; exquisitely tender; usually on lower legs but also on upper extremities	More common in females 15–30 years old	Arthralgias (50%); features vary with associated condition	—[d]
Sweet's syndrome (acute febrile neutrophilic dermatosis)	Yersinial infection; lymphoproliferative disorders; idiopathic causes	Tender red or blue edematous nodules giving impression of vesiculation; usually on face, neck, upper extremities; when on lower extremities, may mimic erythema nodosum	More common in women and in persons 30–60 years old; 20% of cases associated with malignancy (men and women equally affected in this group)	Headache, arthralgias, leukocytosis	54
Bacillary angiomatosis	*Bartonella henselae* or *Bartonella quintana*	Many forms, including erythematous, smooth vascular nodules; friable, exophytic lesions; erythematous plaques (may be dry, scaly); subcutaneous nodules (may be erythematous)	Usually in HIV infection	Peliosis of liver and spleen in some cases; lesions may involve multiple organs; bacteremia	153

(continued)

TABLE 18-1 DISEASES ASSOCIATED WITH FEVER AND RASH (CONTINUED)

Disease	Etiology	Description	Group Affected/ Epidemiologic Factors	Clinical Syndrome	Chapter
Purpuric Eruptions					
Rocky Mountain spotted fever, rat-bite fever, endocarditis[e]; epidemic typhus[g]; dengue fever[c]; human parvovirus B19 infection[g]	—	—	—	—	—[d]
Acute meningococcemia	*Neisseria meningitidis*	Initially pink maculopapular lesions evolving into petechiae; petechiae rapidly becoming numerous, sometimes enlarging and becoming vesicular; trunk, extremities most commonly involved; may appear on face, hands, feet; may include purpura fulminans reflecting disseminated intravascular coagulation (see below)	Most common in children, individuals with asplenia or terminal complement component deficiency (C5-C8)	Hypotension, meningitis (sometimes preceded by upper respiratory infection)	136
Purpura fulminans	Severe disseminated intravascular coagulation	Large ecchymoses with sharply irregular shapes evolving into hemorrhagic bullae and then into black necrotic lesions	Individuals with sepsis (e.g., involving *N. meningitidis*), malignancy, or massive trauma; asplenic patients at high risk for sepsis	Hypotension	136, 265
Chronic meningococcemia	*N. meningitidis*	Variety of recurrent eruptions, including pink maculopapular; nodular (usually on lower extremities); petechial (sometimes developing vesicular centers); purpuric areas with pale blue-gray centers	Individuals with complement deficiencies	Fevers, sometimes intermittent; arthritis, myalgias, headache	136
Disseminated gonococcal infection	*Neisseria gonorrhoeae*	Papules (1–5 mm) evolving over 1–2 days into hemorrhagic pustules with gray necrotic centers; hemorrhagic bullae occurring rarely; lesions (usually fewer than 40) distributed peripherally near joints (more commonly on upper extremities)	Sexually active individuals (more often females), some with complement deficiency	Low-grade fever, tenosynovitis, arthritis	137
Enteroviral petechial rash	Usually echovirus 9 or coxsackievirus A9	Disseminated petechial lesions (may also be maculopapular, vesicular, or urticarial)	Often occurs in outbreaks	Pharyngitis, headache; aseptic meningitis with echovirus 9	184
Viral hemorrhagic fever	Arboviruses and arenaviruses	Petechial rash	Residence in or travel to endemic areas or other virus exposure	Triad of fever, shock, hemorrhage from mucosa or gastrointestinal tract	189, 190
Thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome	Idiopathic, *Escherichia coli* O157:H7 (Shiga toxin), drugs	Petechiae	Individuals with *E. coli* O157:H7 gastroenteritis (especially children), cancer chemotherapy, HIV infection, autoimmune diseases; pregnant/postpartum women	Fever (not always present), hemolytic anemia, thrombocytopenia, renal dysfunction, neurologic dysfunction; coagulation studies normal	54, 101, 109, 143, 147
Cutaneous small-vessel vasculitis (leukocytoclastic vasculitis)	Infections (including group A *Streptococcus*, viral hepatitis), drugs, chemicals, food allergens, idiopathic causes	Palpable purpuric lesions appearing in crops on legs or other dependent areas; may become vesicular or ulcerative; usually resolve over 3–4 weeks	Occurs in a wide spectrum of diseases, including connective tissue disease, cryoglobulinemia, malignancy, Henoch-Schönlein purpura (HSP); more common in children	Fever, malaise, arthralgias, myalgias; systemic vasculitis in some cases; renal, joint, and gastrointestinal involvement commonly seen in HSP	54

TABLE 18-1 DISEASES ASSOCIATED WITH FEVER AND RASH (CONTINUED)

Disease	Etiology	Description	Group Affected/ Epidemiologic Factors	Clinical Syndrome	Chapter
Eruptions with Ulcers and/or Eschars					
Scrub typhus, rickettsial spotted fevers, rat-bite fever[g]; rickettsialpox, ecthyma gangrenosum[h]	—	—	—	—	—[d]
Tularemia	*Francisella tularensis*	Ulceroglandular form: erythematous, tender papule evolves into necrotic, tender ulcer with raised borders; in 35% of cases, eruptions (maculopapular, vesiculopapular, acneiform, urticarial, erythema nodosum, or erythema multiforme) may occur	Exposure to ticks, biting flies, infected animals	Fever, headache, lymphadenopathy	151
Anthrax	*Bacillus anthracis*	Pruritic papule enlarging and evolving into a 1- by 3-cm painless ulcer surrounded by vesicles and then developing a central eschar with edema; residual scar	Exposure to infected animals or animal products or other exposure to anthrax spores	Lymphadenopathy, headache	214

[a]See "Purpuric eruptions."
[b]In human granulocytotropic ehrlichiosis, or anaplasmosis (caused by *Anaplasma phagocytophila*; most common in the upper midwestern and northeastern regions of the United States), rash is rare.
[c]See "Viral hemorrhagic fever" under "Purpuric eruptions" for dengue hemorrhagic fever/dengue shock syndrome.
[d]See etiology-specific chapters.
[e]See "Peripheral eruptions."
[f]See "Confluent desquamative erythemas."
[g]See "Centrally distributed maculopapular eruptions."
[h]See "Vesiculobullous eruptions."

CENTRALLY DISTRIBUTED MACULOPAPULAR ERUPTIONS

Centrally distributed rashes, in which lesions are primarily truncal, are the most common type of eruption. The rash of *rubeola* (measles) starts at the hairline 2–3 days into the illness and moves down the body, sparing the palms and soles (Chap. 185). It begins as discrete erythematous lesions, which become confluent as the rash spreads. Koplik's spots (1- to 2-mm white or bluish lesions with an erythematous halo on the buccal mucosa) are pathognomonic for measles and are generally seen during the first 2 days of symptoms. They should not be confused with Fordyce's spots (ectopic sebaceous glands), which have no erythematous halos and are found in the mouth of healthy individuals. Koplik's spots may briefly overlap with the measles exanthem.

Rubella (German measles) also spreads from the hairline downward; unlike that of measles, however, the rash of rubella tends to clear from originally affected areas as it migrates, and it may be pruritic (Chap. 186). Forchheimer spots (palatal petechiae) may develop but are nonspecific since they also develop in mononucleosis (Chap. 174) and scarlet fever (Chap. 130). Postauricular and suboccipital adenopathy and arthritis are common among adults with German measles. Exposure of pregnant women to ill individuals should be avoided, as rubella causes severe congenital abnormalities. Numerous strains of enteroviruses (Chap. 184), primarily echoviruses and coxsackieviruses, cause nonspecific syndromes of fever and eruptions that may mimic rubella or measles. Patients with infectious mononucleosis caused by Epstein-Barr virus (Chap. 174) or with primary infection caused by HIV (Chap. 182) may exhibit pharyngitis, lymphadenopathy, and a nonspecific maculopapular exanthem.

The rash of *erythema infectiosum* (fifth disease), which is caused by human parvovirus B19, primarily affects children 3–12 years old; it develops after fever has resolved as a bright blanchable erythema on the cheeks ("slapped cheeks") with perioral pallor (Chap. 177). A more diffuse rash (often pruritic) appears the next day on the trunk and extremities and then rapidly develops into a lacy reticular eruption that may wax and wane (especially with temperature change) over 3 weeks. Adults with fifth disease often have arthritis, and fetal hydrops can develop in association with this condition in pregnant women.

Exanthem subitum (roseola) is caused by human herpesvirus 6 and is most common among children <3 years of age (Chap. 175). As in erythema infectiosum, the rash usually appears after fever has subsided. It consists of 2- to 3-mm rose-pink macules and papules that rarely coalesce, occur initially on the trunk and sometimes on the extremities (sparing the face), and fade within 2 days.

Although drug reactions have many manifestations, including urticaria, exanthematous *drug-induced eruptions* (Chap. 56) are most common and are often difficult to distinguish from viral exanthems. Eruptions elicited by drugs are usually more intensely erythematous and pruritic than viral exanthems, but this distinction is not reliable. A history of new medications and an absence of prostration may help to distinguish a drug-related rash from an eruption of another etiology. Rashes may persist for up to 2 weeks after administration of the offending agent is discontinued. Certain populations are more prone than others to drug rashes. Of HIV-infected patients, 50–60% develop a rash in response to sulfa drugs; 90% of patients with mononucleosis due to Epstein-Barr virus develop a rash when given ampicillin.

Rickettsial illnesses (Chap. 167) should be considered in the evaluation of individuals with centrally distributed maculopapular eruptions. The usual setting for *epidemic typhus* is a site of war or natural disaster in which people are exposed to body lice. A diagnosis of recrudescent typhus should be considered in European immigrants to the United States. However, an indigenous form of typhus, presumably transmitted by flying squirrels, has been reported in the southeastern United States. *Endemic typhus* or *leptospirosis* (the latter caused by a spirochete; Chap. 164) may be seen in urban environments where rodents proliferate. Outside the United States, other rickettsial diseases cause a spotted-fever syndrome and should be considered in residents of or travelers to endemic areas. Similarly, *typhoid fever*, a nonrickettsial disease caused by *Salmonella typhi* (Chap. 146), is usually acquired during travel outside the United States. Dengue fever, caused by a mosquito-transmitted flavivirus, occurs in tropical and subtropical regions of the world (Chap. 189).

Some centrally distributed maculopapular eruptions have distinctive features. Erythema chronicum migrans (ECM), the rash of Lyme disease (Chap. 166), typically manifests as singular or multiple annular plaques. Untreated ECM lesions usually fade within a month but may persist for more than a year. *Erythema marginatum*, the rash of acute rheumatic fever (Chap. 315), has a distinctive pattern of enlarging and shifting transient annular lesions.

Collagen vascular diseases may cause fever and rash. Patients with *systemic lupus erythematosus* (Chap. 313) typically develop a sharply defined, erythematous eruption in a butterfly distribution on the cheeks (malar rash) as well as many other skin manifestations. *Still's disease* (Chap. 331) manifests as an evanescent salmon-colored rash on the trunk and proximal extremities that coincides with fever spikes.

PERIPHERAL ERUPTIONS

These rashes are alike in that they are most prominent peripherally or begin in peripheral (acral) areas before spreading centripetally. Early diagnosis and therapy are critical in RMSF (Chap. 167) because of its grave prognosis if untreated. Lesions evolve from macular to petechial, start on the wrists and ankles, spread centripetally, and appear on the palms and soles only later in the disease. The rash of *secondary syphilis* (Chap. 162), which may be generalized but is prominent on the palms and soles, should be considered in the differential diagnosis of pityriasis rosea, especially in sexually active patients. *Atypical measles* (Chap. 185) is seen in individuals contracting measles who received the killed measles vaccine between 1963 and 1967 in the United States and who were not subsequently protected with the live vaccine. *Hand-foot-and-mouth disease* (Chap. 184), most commonly caused by coxsackievirus A16, is distinguished by tender vesicles distributed peripherally and in the mouth; outbreaks commonly occur within families. The classic target lesions of *erythema multiforme* (EM) appear symmetrically on the elbows, knees, palms, soles, and face. In severe cases, these lesions spread diffusely and involve mucosal surfaces. Stevens-Johnson syndrome is considered a maximal form of erythema multiforme and is life-threatening. Lesions may develop on the hands and feet in *endocarditis* (Chap. 118).

CONFLUENT DESQUAMATIVE ERYTHEMAS

These eruptions consist of diffuse erythema frequently followed by desquamation. The eruptions caused by group A *Streptococcus* or *Staphylococcus aureus* are toxin mediated. *Scarlet fever* (Chap. 130) usually follows pharyngitis; patients have a facial flush, a "strawberry" tongue, and accentuated petechiae in body folds (Pastia's lines). *Kawasaki disease* (Chaps. 54 and 319) presents in the pediatric population as fissuring of the lips, a strawberry tongue, conjunctivitis, adenopathy, and sometimes cardiac abnormalities. *Streptococcal toxic shock syndrome* (Chap. 130) manifests with hypotension, multiorgan failure, and often a severe group A streptococcal infection (e.g., necrotizing fasciitis). *Staphylococcal toxic shock syndrome* (Chap. 129) also presents with hypotension and multiorgan failure, but usually only *S. aureus* colonization—not a severe *S. aureus* infection—is documented. *Staphylococcal scalded-skin syndrome* (Chap. 129) is seen primarily in children and in immunocompromised adults. Generalized erythema is often evident during the prodrome of fever and malaise; profound tenderness of the skin is distinctive. In the exfoliative stage, the skin can be induced to form bullae with light lateral pressure (Nikolsky's sign). In a mild form, a scarlatiniform eruption mimics scarlet fever, but the patient does not exhibit a strawberry tongue or circumoral pallor. In contrast to the staphylococcal scalded-skin syndrome, in which the cleavage plane is superficial in the epidermis, *toxic epidermal necrolysis* (Chap. 56), a maximal variant of Stevens-Johnson syndrome, involves sloughing of the entire epidermis, resulting in severe disease. *Exfoliative erythroderma syndrome* (Chaps. 53 and 56) is a serious reaction associated with systemic toxicity that is often due to eczema, psoriasis, mycosis fungoides, or a severe drug reaction.

VESICULOBULLOUS ERUPTIONS

Varicella (Chap. 173) is highly contagious, often occurring in winter or spring. At any point in time, within a given region of the body, varicella lesions are in different stages of development. In immunocompromised hosts, varicella vesicles may lack the characteristic erythematous base or may appear hemorrhagic. Lesions of *Pseudomonas* "hot-tub" folliculitis (Chap. 145) are also pruritic and may appear similar to those of varicella. However, hot-tub folliculitis generally occurs in outbreaks after bathing in hot tubs or swimming pools, and lesions occur in regions occluded by bathing suits. Lesions of *variola* (smallpox; Chap. 214) also appear similar to those of varicella but are all at the same stage of development in a given region of the body. Variola lesions are most prominent on the face and extremities, while varicella lesions are most prominent on the trunk. Herpes simplex virus infection (Chap. 172) is characterized by hallmark grouped vesicles on an erythematous base. Primary herpes infection is accompanied by fever and toxicity, while recurrent disease is milder. *Rickettsialpox* (Chap. 167) is often documented in urban settings and is characterized by vesicles. It can be distinguished from varicella by an eschar at the site of the mouse-mite bite and the papule/plaque base of each vesicle. Disseminated *Vibrio vulnificus* infection (Chap. 149) or *ecthyma gangrenosum* due to *Pseudomonas aeruginosa* (Chap. 145) should be considered in immunosuppressed individuals with sepsis and hemorrhagic bullae.

URTICARIAL ERUPTIONS

Individuals with classic urticaria ("hives") usually have a hypersensitivity reaction without associated fever. In the presence of fever, urticarial eruptions are usually due to *urticarial vasculitis* (Chap. 319). Unlike individual lesions of classic urticaria, which last up to 48 h, these lesions may last up to 5 days. Etiologies include serum sickness (often induced by drugs such as penicillins, sulfas, salicylates, or barbiturates), connective-tissue disease (e.g., systemic lupus erythematosus or Sjögren's syndrome), and infection (e.g., with hepatitis B virus, enteroviruses, or parasites). Malignancy may be associated with fever and chronic urticaria (Chap. 54).

NODULAR ERUPTIONS

In immunocompromised hosts, nodular lesions often represent disseminated infection. Patients with disseminated *candidiasis* (often due to *Candida tropicalis*) may have a triad of fever, myalgias, and eruptive nodules (Chap. 196). Disseminated *cryptococcosis* lesions (Chap. 195) may resemble molluscum contagiosum (Chap. 176). Necrosis of nodules should raise the suspicion of *aspergillosis* (Chap. 197) or *mucormycosis* (Chap. 198). *Erythema nodosum* presents with exquisitely tender nodules on the lower extremities. *Sweet's syndrome* (Chap. 54) should be considered in individuals with multiple nodules and plaques, often so edematous that they give the appearance of vesicles or bullae. Sweet's syndrome may affect either healthy individuals or persons with lymphoproliferative disease.

PURPURIC ERUPTIONS

Acute meningococcemia (Chap. 136) classically presents in children as a petechial eruption, but initial lesions may appear as blanchable macules or urticaria. RMSF should be considered in the differential diagnosis of acute meningococcemia. *Echovirus 9 infection* (Chap. 184) may mimic acute meningococcemia; patients should be treated as if they have bacterial sepsis since prompt differentiation of these conditions may be impossible. Large ecchymotic areas of *purpura fulminans* (Chaps. 136 and 265) reflect severe underlying disseminated intravascular coagulation, which may be due to infectious or noninfectious causes. The lesions of *chronic meningococcemia* (Chap. 136) may have a variety of morphologies, including petechial. Purpuric nodules may develop on the legs and resemble erythema nodosum but lack its exquisite tenderness. Lesions of *disseminated gonococcemia* (Chap. 137) are distinctive, sparse, countable hemorrhagic pustules, usually located near joints. The lesions of chronic meningococcemia and those of gonococcemia may be indistinguishable in terms of appearance and distribution. *Viral hemorrhagic fever* (Chaps. 189 and 190) should be considered in patients with an appropriate travel history and a petechial rash. *Thrombotic thrombocytopenic purpura* (Chaps. 54, 101, and 109) and *hemolytic-uremic syndrome* (Chaps. 109, 143, and 147) are closely related and are noninfectious causes of fever and petechiae. *Cutaneous small-vessel vasculitis* (*leukocytoclastic vasculitis*) typically manifests as palpable purpura and has a wide variety of causes (Chap. 54).

ERUPTIONS WITH ULCERS OR ESCHARS

The presence of an ulcer or eschar in the setting of a more widespread eruption can provide an important diagnostic clue. For example, the presence of an eschar may suggest the diagnosis of scrub typhus or rickettsialpox (Chap. 167) in the appropriate setting. In

other illnesses (e.g., anthrax; Chap. 214), an ulcer or eschar may be the only skin manifestation.

19 Fever of Unknown Origin

Jeffrey A. Gelfand, Michael V. Callahan

DEFINITION AND CLASSIFICATION

Fever of unknown origin (FUO) was defined by Petersdorf and Beeson in 1961 as (1) temperatures of >38.3°C (>101°F) on several occasions; (2) a duration of fever of >3 weeks; and (3) failure to reach a diagnosis despite 1 week of inpatient investigation. While this classification has stood for more than 30 years, Durack and Street have proposed a new system for classification of FUO: (1) classic FUO; (2) nosocomial FUO; (3) neutropenic FUO; and (4) FUO associated with HIV infection.

Classic FUO corresponds closely to the earlier definition of FUO, differing only with regard to the prior requirement for 1 week's study in the hospital. The newer definition is broader, stipulating three outpatient visits or 3 days in the hospital without elucidation of a cause or 1 week of "intelligent and invasive" ambulatory investigation. In *nosocomial FUO*, a temperature of ≥38.3°C (≥101°F) develops on several occasions in a hospitalized patient who is receiving acute care and in whom infection was not manifest or incubating on admission. Three days of investigation, including at least 2 days' incubation of cultures, is the minimum requirement for this diagnosis. *Neutropenic FUO* is defined as a temperature of ≥38.3°C (≥101°F) on several occasions in a patient whose neutrophil count is <500/μL or is expected to fall to that level in 1–2 days. The diagnosis of neutropenic FUO is invoked if a specific cause is not identified after 3 days of investigation, including at least 2 days' incubation of cultures. *HIV-associated FUO* is defined by a temperature of ≥38.3°C (≥101°F) on several occasions over a period of >4 weeks for outpatients or >3 days for hospitalized patients with HIV infection. This diagnosis is invoked if appropriate investigation over 3 days, including 2 days' incubation of cultures, reveals no source.

Adoption of these categories of FUO in the literature has allowed a more rational compilation of data regarding these disparate groups. In the remainder of this chapter, the discussion will focus on classic FUO in the adult unless otherwise specified.

CAUSES OF CLASSIC FUO

Table 19-1 summarizes the findings of several large studies of FUO carried out since the advent of the antibiotic era, including a prospective study of 167 adult patients with FUO encompassing all eight university hospitals in the Netherlands and using a standardized protocol in which the first author reviewed every patient. Coincident with the widespread use of antibiotics, increasingly useful diagnostic technologies—both noninvasive and invasive—have been developed. Newer studies reflect not only changing patterns of disease but also the impact of diagnostic techniques that make it possible to eliminate many patients with specific illness from the FUO category. The ubiquitous use of potent broad-spectrum antibiotics may have decreased the number of infections causing FUO. The wide availability of ultrasonography, CT, MRI, radionuclide scanning, and positron emission tomography (PET) scanning has enhanced the detection of localized infections and of occult neoplasms and lymphomas in patients previously thought to have FUO. Likewise, the widespread availability of highly specific and sensitive immunologic testing has reduced the number of undetected cases of systemic lupus erythematosus and other autoimmune diseases.

Infections, especially extrapulmonary tuberculosis, remain the leading diagnosable cause of FUO. Prolonged mononucleosis syndromes caused by Epstein-Barr virus, cytomegalovirus (CMV), or HIV are conditions whose consideration as a cause of FUO is sometimes confounded by delayed antibody responses. Intraabdominal abscesses (sometimes poorly localized) and renal, retroperitoneal, and paraspinal abscesses continue to be difficult to diagnose. Renal malacoplakia, with submucosal plaques or nodules involving the urinary tract, may cause FUO and is often fatal if untreated. It is associated with intracellular bacterial infection, is seen most often in patients with defects of intracellular bacterial killing, and is treated with fluoroquinolones or trimethoprim-sulfamethoxazole. Occasionally, other organs may be involved. Osteomyelitis, especially where prosthetic devices have been implanted, and infective endocarditis must be considered. Although true culture-negative infective endocarditis is rare, one may be misled by slow-growing organisms of the HACEK group (*Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*; Chap. 140), *Bartonella* spp. (previously *Rochalimaea*), *Legionella* spp., *Coxiella burnetii*, *Chlamydophila psittaci*, and fungi. Prostatitis, dental abscesses, sinusitis, and cholangitis continue to be sources of occult fever.

Fungal disease, most notably histoplasmosis involving the reticuloendothelial system, may cause FUO. FUO with headache should

e5 Atlas of Rashes Associated with Fever

Kenneth M. Kaye, Elaine T. Kaye

Given the extremely broad differential diagnosis, the presentation of a patient with fever and rash often poses a thorny diagnostic challenge for even the most astute and experienced clinician. Rapid narrowing of the differential by prompt recognition of a rash's key features can result in appropriate and sometimes life-saving therapy. This atlas presents high-quality images of a variety of rashes that have an infectious etiology and are commonly associated with fever.

FIGURE e5-1 Lacy reticular rash of **erythema infectiosum** (fifth disease).

FIGURE e5-2 **Koplik's spots,** which manifest as white or bluish lesions with an erythematous halo on the buccal mucosa, usually occur in the first 2 days of measles symptoms and may briefly overlap the measles exanthem. The presence of the erythematous halo differentiates Koplik's spots from Fordyce's spots (ectopic sebaceous glands), which occur in the mouths of healthy individuals. *(Source: CDC. Photo selected by Kenneth M. Kaye, MD.)*

FIGURE e5-3 In **measles,** discrete erythematous lesions become confluent on the face and neck over 2–3 days as the rash spreads downward to the trunk and arms, where lesions remain discrete. *(Reprinted from K Wolff, RA Johnson: Color Atlas & Synopsis of Clinical Dermatology, 5th ed. New York, McGraw-Hill, 2005, p 788.)*

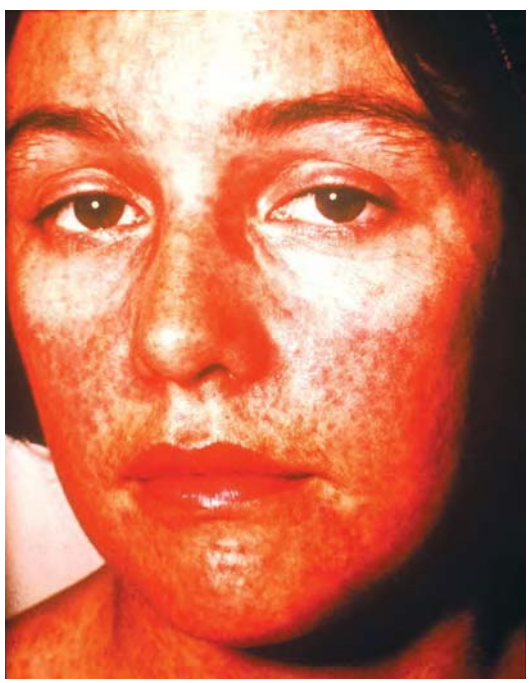

FIGURE e5-4 In **rubella,** an erythematous exanthem spreads from the hairline downward and clears as it spreads. *(Photo courtesy of Stephen E. Gellis, MD; with permission.)*

prompt examination of spinal fluid for *Cryptococcus neoformans*. Malaria (which may result from transfusion, the failure to take a prescribed prophylactic agent, or infection with a drug-resistant strain) continues to be a cause, particularly of asynchronous FUO. A related protozoan infection, babesiosis, may cause FUO and is increasing in geographic distribution and in incidence, especially among the elderly and immunosuppressed.

In most earlier series, neoplasms were the next most common cause of FUO after infections (Table 19-1). In more recent series, a decrease in the percentage of FUO cases due to malignancy was attributed to improvement in diagnostic technologies—in particular, high-resolution tomography, MRI, PET scanning, and tumor antigen assays. This observation does not diminish the importance of considering neoplasia in the initial diagnostic evaluation of a patient with fever. A number of patients in these series had temporal arteritis, adult Still's disease, drug-related fever, and factitious fever. In recent series, ~25–30% of cases of FUO have remained undiagnosed. The general term *noninfectious inflammatory diseases* applies to systemic rheumatologic or vasculitic diseases such as polymyalgia rheumatica, lupus, and adult Still's disease as well as to granulomatous diseases such as sarcoidosis and Crohn's and granulomatous hepatitis.

In the elderly, multisystem disease is the most frequent cause of FUO, giant-cell arteritis being the leading etiologic entity in this category. In patients >50 years of age, this disease accounts for 15–20% of FUO cases. Tuberculosis is the most common infection causing FUO in the elderly, and colon cancer is an important cause of FUO with malignancy in this age group.

Many diseases have been grouped in the various studies as "miscellaneous." On this list are drug fever, pulmonary embolism, factitious fever, the hereditary periodic fever syndromes (familial Mediterranean fever, hyper-IgD syndrome, tumor necrosis factor receptor–associated periodic syndrome, familial cold urticaria, and the Muckle-Wells syndrome), and Fabry disease.

A drug-related etiology must be considered in any case of prolonged fever. Any febrile pattern may be elicited by a drug. Virtually all classes of drugs cause fever, but antimicrobial agents (especially β-lactam antibiotics), cardiovascular drugs (e.g., quinidine), antineoplastic drugs, and drugs acting on the central nervous system (e.g., phenytoin) are particularly common causes.

It is axiomatic that, as the duration of fever increases, the likelihood of an infectious cause decreases, even for the more indolent infectious etiologies (e.g., brucellosis, paracoccidioidomycosis, malaria due to *Plasmodium malariae*). In a series of 347 patients referred to the National Institutes of Health from 1961 to 1977, only 6% had an infection (Table 19-2). A significant proportion (9%) had factitious fevers—i.e., fevers due either to false elevations of temperature or to self-induced disease. A substantial number of these factitious cases were in young women in the health professions. It is worth noting that 8% of the patients with prolonged fevers (some of whom had completely normal liver function studies) had granulomatous hepatitis, and 6% had adult Still's disease. After prolonged investigation, 19% of cases still had no specific diagnosis. A total of 27% of patients had no actual fever during inpatient observation or had an exaggerated circadian temperature rhythm without chills, elevated pulse, or other abnormalities.

More than 200 conditions may be considered in the differential diagnosis of classic FUO in adults; the most common of these are listed in Table 19-3. This list applies strictly to the United States. Geographic considerations are paramount. For example, in Japan, human T cell lymphotropic virus type I is a consideration; in China, infection plays a greater role and tuberculosis is prominent; and in Spain, visceral leishmaniasis may be a more common cause of FUO. The frequency of global travel underscores the need for a detailed travel history, and the continuing emergence of new infectious diseases makes this listing potentially incomplete. The possibility of international and domestic terrorist activity involving the intentional release of infectious agents, many of which cause illnesses presenting with prolonged fever, underscores the need for obtaining an insightful environmental, occupational, and professional history, with early notification of public health authorities in cases of suspicious etiology (Chap. 214).

TABLE 19-2 CAUSES OF FUO LASTING >6 MONTHS

Cause	Cases, %
None identified	19
Miscellaneous causes	13
Factitious causes	9
Granulomatous hepatitis	8
Neoplasm	7
Still's disease	6
Infection	6
Collagen vascular disease	4
Familial Mediterranean fever	3
No fever[a]	27

[a]No actual fever observed during 2–3 weeks of inpatient observation. Includes patients with exaggerated circadian rhythm.

Source: From a study of 347 patients referred to the National Institutes of Health from 1961 to 1977 with a presumptive diagnosis of FUO of >6 months' duration (R Aduan et al. Prolonged fever of unknown origin. Clin Res 26:558A, 1978).

SPECIALIZED DIAGNOSTIC STUDIES

Classic FUO A stepwise flow chart depicting the diagnostic workup and therapeutic management of FUO is provided in Fig. 19-1. In this flow chart, reference is made to "potentially diagnostic clues," as outlined by de Kleijn and colleagues; these clues may be key findings in the history (e.g., travel), localizing signs, or key symptoms. Certain specific diagnostic maneuvers become critical in dealing with prolonged fevers. If factitious fever is suspected, electronic thermometers should be used, temperature-taking should be supervised, and simultaneous urine and body temperatures should be measured. Thick blood smears should be examined for *Plasmodium*; thin blood smears, prepared with proper technique and quality stains and subjected to expert microscopy, should be used to speciate *Plasmodium* and to identify *Babesia*, *Trypanosoma*, *Leishmania*, *Rickettsia*, and *Borrelia*. Any tissue removed during prior relevant surgery should be reexamined; slides should be requested, and, if need be, paraffin blocks of fixed pathologic material should be reexamined and additional special studies performed. Relevant x-rays should be reexamined; reviewing of prior radiologic reports may be insufficient. Serum should be set aside in the laboratory as soon as possible and retained for future examination for rising antibody titers.

Febrile agglutinins is a vague term that in most laboratories refers to serologic studies for salmonellosis, brucellosis, and rickettsial diseases. These studies are seldom useful, having low sensitivity and variable specificity. Multiple blood samples (no fewer than three and rarely more than six, including samples for anaerobic culture) should be cultured in the laboratory for at least 2 weeks to ensure that any HACEK group organisms that may be present have ample time to grow (Chap. 140). Lysis-centrifugation blood culture techniques should be employed in cases where prior antimicrobial therapy or fungal or atypical mycobacterial infection is suspected. Blood culture media should be supplemented with L-cysteine or pyridoxal to assist in the isolation of nutritionally variant streptococci. It should be noted that sequential cultures positive for multiple organisms may reflect self-injection of contaminated substances. Urine cultures, including cultures for mycobacteria, fungi, and CMV, are indicated. In the setting of recurrent fevers with lymphocytic meningitis (Mollaret's meningitis), cerebrospinal fluid can be tested for herpesvirus, with use of the polymerase chain reaction (PCR) to amplify and detect viral nucleic acid (Chap. 172). A recent report described a highly multiplexed oligonucleotide microarray using PCR amplification and containing probes for all recognized vertebrate virus species and for 135 bacterial, 73 fungal, and 63 parasitic genera and species. The eventual clinical validation of such microarrays will further diminish rates of undiagnosed FUO of infectious etiology.

In any FUO workup, the erythrocyte sedimentation rate (ESR) should be determined. Striking elevation of the ESR and anemia of chronic disease are frequently seen in association with giant-cell arteritis

Factitious Fevers

"Afebrile" FUO (<38.3°C)

Source: Modified from RK Root, RG Petersdorf, in JD Wilson et al (eds): *Harrison's Principles of Internal Medicine,* 12th ed. New York, McGraw-Hill, 1991.

or polymyalgia rheumatica—common causes of FUO in patients >50 years of age. Still's disease is suggested by elevations of ESR, leukocytosis, and anemia and is often accompanied by arthralgias, polyserositis (pleuritis, pericarditis), lymphadenopathy, splenomegaly, and rash. The C-reactive protein level may be a useful cross-reference for the ESR and is a more sensitive and specific indicator of an "acute-phase" inflammatory metabolic response. Antinuclear antibody, antineutrophil cytoplasmic antibody, rheumatoid factor, and serum cryoglobulins should be measured to rule out other collagen vascular diseases and vasculitis. Elevated levels of angiotensin-converting enzyme in serum may point to sarcoi-

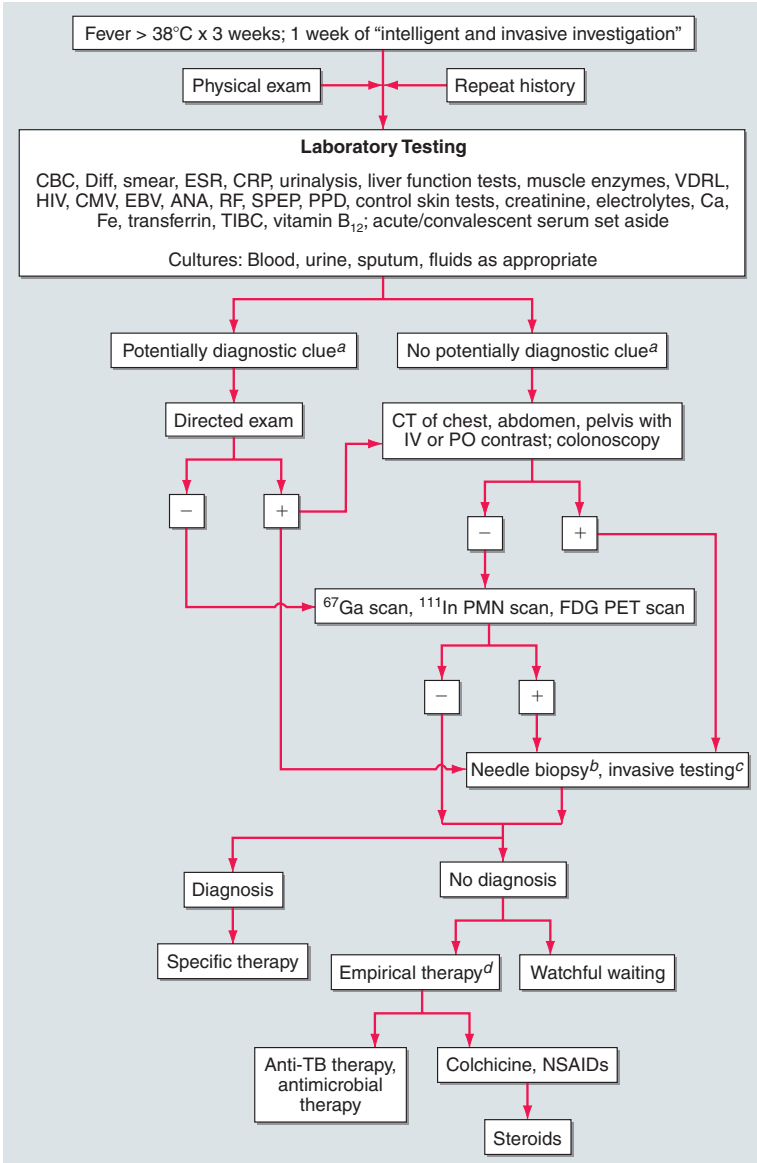

FIGURE 19-1 Approach to the patient with classic FUO. [a]"Potentially diagnostic clues," as outlined by de Kleijn and colleagues (1997, Part II), may be key findings in the history, localizing signs, or key symptoms. ANA, antinuclear antibody; CBC, complete blood count; CMV, cytomegalovirus; CRP, C-reactive protein; CT, computed tomography; Diff, differential; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; FDG, fluorodeoxyglucose F18; NSAIDs, nonsteroidal anti-inflammatory drugs; PET, positron emission tomography; PMN, polymorphonuclear leukocyte; PPD, purified protein derivative; RF, rheumatoid factor; SPEP, serum protein electrophoresis; TB, tuberculosis; TIBC, total iron-binding capacity; VDRL, Venereal Disease Research Laboratory test. [b]Needle biopsy of liver as well as any other tissue indicated by "potentially diagnostic clues." [c]Invasive testing could involve laparoscopy. [d]Empirical therapy is a last resort, given the good prognosis of most patients with FUO persisting without a diagnosis.

dosis. With rare exceptions, the intermediate-strength purified protein derivative (PPD) skin test should be used to screen for tuberculosis in patients with classic FUO. Concurrent control tests, such as the mumps skin test antigen (Aventis-Pasteur, Swiftwater, PA), should be employed. It should be kept in mind that both the PPD skin test and control tests may yield negative results in miliary tuberculosis, sarcoidosis, Hodgkin's disease, malnutrition, or AIDS.

Noninvasive procedures should include an upper gastrointestinal contrast study with small-bowel follow-through and colonoscopy to examine the terminal ileum and cecum. Colonoscopy is especially strongly indicated in the elderly. Chest x-rays should be repeated if new symptoms arise. Sputum should be induced with an ultrasonic nebulizer for cultures and cytology. If there are pulmonary signs or symptoms, bronchoscopy with bronchoalveolar lavage for cultures and cytology should be considered. High-resolution spiral CT of the chest and abdomen should be performed with both IV and oral contrast. If a spinal or paraspinal lesion is suspected, however, MRI is preferred. MRI may be superior to CT in demonstrating intraabdominal abscesses and aortic dissection, but the relative utility of MRI and CT in the diagnosis of FUO is unknown. At present, abdominal CT with contrast should be used unless MRI is specifically indicated. Arteriography may be useful for patients in whom systemic necrotizing vasculitis is suspected. Saccular aneurysms may be seen, most commonly in renal or hepatic vessels, and may permit diagnosis of arteritis when biopsy is difficult. Ultrasonography of the abdomen is useful for investigation of the hepatobiliary tract, kidneys, spleen, and pelvis. Echocardiography may be helpful in an evaluation for bacterial endocarditis, pericarditis, nonbacterial thrombotic endocarditis, and atrial myxomas. Transesophageal echocardiography is especially sensitive for these lesions.

Radionuclide scanning procedures using technetium (Tc) 99m sulfur colloid, gallium (Ga) 67 citrate, or indium (In) 111–labeled leukocytes may be useful in identifying and/or localizing inflammatory processes. In one study, Ga scintigraphy yielded useful diagnostic information in almost one-third of cases, and it was suggested that this procedure might actually be used before other imaging techniques if no specific organ is suspected of being abnormal. It is likely that PET scanning, which provides quicker results (hours vs days), will prove even more sensitive and specific than ^{67}Ga scanning in FUO. ^{99m}Tc bone scan should be undertaken to look for osteomyelitis or bony metastases; ^{67}Ga scan may be used to identify sarcoidosis (Chap. 322) or *Pneumocystis* infection (Chap. 200) in the lungs or Crohn's disease (Chap. 289) in the abdomen. ^{111}In-labeled white blood cell (WBC) scan may be used to locate abscesses. With these scans, false-positive and false-negative findings are common. Fluorodeoxyglucose F18 (FDG) PET scanning appears to be superior to other forms of nuclear imaging. The FDG used in PET scans accumulates in tumors and at sites of inflammation and has even been shown to accumulate reliably at sites of vasculitis. Where available, FDG PET scanning should therefore be chosen over ^{67}Ga scanning in the diagnosis of FUO.

Biopsy of the liver and bone marrow should be considered in the workup of FUO if the studies mentioned above are unrevealing and if fever is prolonged. Granulomatous hepatitis has been diagnosed by liver biopsy, even when liver enzymes are normal and no other diagnostic clues point to liver disease. All biopsy specimens should be cultured for bacteria, mycobacteria, and fungi. Likewise, in the absence of clues pointing to the bone marrow, bone marrow biopsy (not simple aspiration) for histology and culture has yielded diagnoses late in the workup. When possible, a section of the tissue block should be retained for further sections or stains. PCR technology makes it possible in some cases to identify and speciate mycobacterial DNA in paraffin-embedded, fixed tissues at some research centers. Thus, in some cases, a retrospective diagnosis can be made on the basis of studies of long-fixed pathologic tissues. In a patient over age 50 (or occasionally in a younger patient) with the appropriate symptoms and laboratory findings, "blind biopsy" of one or both temporal arteries may yield a diagnosis of arteritis. Tenderness or decreased pulsation, if noted, should guide the selection of a site for biopsy. Lymph node biopsy may be helpful if nodes are enlarged, but inguinal nodes are often palpable and are seldom diagnostically useful.

Exploratory laparotomy has been performed when all other diagnostic procedures fail but has largely been replaced by imaging and guided-

biopsy techniques. Laparoscopic biopsy may provide more adequate guided sampling of lymph nodes or liver, with less invasive morbidity.

Nosocomial FUO (See also Chap. 125) The primary considerations in diagnosing nosocomial FUO are the underlying susceptibility of the patient coupled with the potential complications of hospitalization. The original surgical or procedural field is the place to begin a directed physical and laboratory examination for abscesses, hematomas, or infected foreign bodies. More than 50% of patients with nosocomial FUO are infected. Intravascular lines, septic phlebitis, and prostheses are all suspect. In this setting, the best approach is to focus on sites where occult infections may be sequestered, such as the sinuses of intubated patients or a prostatic abscess in a man with a urinary catheter. *Clostridium difficile* colitis may be associated with fever and leukocytosis before the onset of diarrhea. In ~25% of patients with nosocomial FUO, the fever has a noninfectious cause. Among these causes are acalculous cholecystitis, deep-vein thrombophlebitis, and pulmonary embolism. Drug fever, transfusion reactions, alcohol/drug withdrawal, adrenal insufficiency, thyroiditis, pancreatitis, gout, and pseudogout are among the many possible causes to consider. As in classic FUO, repeated meticulous physical examinations, coupled with focused diagnostic techniques, are imperative. Multiple blood, wound, and fluid cultures are mandatory. The pace of diagnostic tests is accelerated, and the threshold for procedures—CT scans, ultrasonography, ^{111}In WBC scans, noninvasive venous studies—is low. Even so, 20% of cases of nosocomial FUO may go undiagnosed.

Like diagnostic measures, therapeutic maneuvers must be swift and decisive, as many patients are already critically ill. IV lines must be changed (and cultured), drugs stopped for 72 h, and empirical therapy started if bacteremia is a threat. In many hospital settings, empirical antibiotic coverage for nosocomial FUO now includes vancomycin for coverage of methicillin-resistant *Staphylococcus aureus* as well as broad-spectrum gram-negative coverage with piperacillin/tazobactam, ticarcillin/clavulanate, imipenem, or meropenem. Practice guidelines covering many of these issues have been published jointly by the Infectious Diseases Society of America (IDSA) and the Society for Critical Care Medicine and can be accessed on the IDSA website (*www.journals.uchicago.edu/IDSA/guidelines*).

Neutropenic FUO (See also Chap. 82) Neutropenic patients are susceptible to focal bacterial and fungal infections, to bacteremic infections, to infections involving catheters (including septic thrombophlebitis), and to perianal infections. *Candida* and *Aspergillus* infections are common. Infections due to herpes simplex virus or CMV are sometimes causes of FUO in this group. While the duration of illness may be short in these patients, the consequences of untreated infection may be catastrophic; 50–60% of febrile neutropenic patients are infected, and 20% are bacteremic. The IDSA has published extensive practice guidelines covering these critically ill neutropenic patients; these guidelines appear on the website cited in the previous section. In these patients, severe mucositis, quinolone prophylaxis, colonization with methicillin-resistant *S. aureus*, obvious catheter-related infection, or hypotension dictates the use of vancomycin plus ceftazidime, cefepime, or a carbapenem with or without an aminoglycoside to provide empirical coverage for bacterial sepsis.

HIV-Associated FUO HIV infection alone may be a cause of fever. Infection due to *Mycobacterium avium* or *Mycobacterium intracellulare*, tuberculosis, toxoplasmosis, CMV infection, *Pneumocystis* infection, salmonellosis, cryptococcosis, histoplasmosis, non-Hodgkin's lymphoma, and (of particular importance) drug fever are all possible causes of FUO. Mycobacterial infection can be diagnosed by blood cultures and by liver, bone marrow, and lymph node biopsies. Chest CT should be performed to identify enlarged mediastinal nodes. Serologic studies may reveal cryptococcal antigen, and ^{67}Ga scan may help identify *Pneumocystis* pulmonary infection. FUO has an infectious etiology in >80% of HIV-infected patients, but drug fever and lymphoma remain important considerations. Treatment of HIV-associated FUO depends on many factors and is discussed in Chap. 182.

Rx FEVER OF UNKNOWN ORIGIN

The focus here is on classic FUO. Other modifiers of FUO—neutropenia, HIV infection, a nosocomial setting—all vastly affect the risk equation and dictate therapy based on the probability of various causes of fever and on the calculated risks and benefits of a guided empirical approach. The age and physical state of the patient are factors as well: the frail elderly patient may merit a trial of empirical therapy earlier than the robust young adult.

The emphasis in patients with classic FUO is on continued observation and examination, with the avoidance of "shotgun" empirical therapy. Antibiotic therapy (even that for tuberculosis) may irrevocably alter the ability to culture fastidious bacteria or mycobacteria and delineate ultimate cause. However, vital-sign instability or neutropenia is an indication for empirical therapy with a fluoroquinolone plus piperacillin or the regimen mentioned above (see "Nosocomial FUO"), for example. Cirrhosis, asplenia, intercurrent immunosuppressive drug use, or recent exotic travel may all tip the balance toward earlier empirical antiinfective therapy. If the PPD skin test is positive or if granulomatous hepatitis or other granulomatous disease is present with anergy (and sarcoid seems unlikely), then a therapeutic trial with isoniazid and rifampin (and possibly a third drug) should be undertaken, with treatment usually continued for up to 6 weeks. A failure of the fever to respond over this period suggests an alternative diagnosis.

The response of rheumatic fever and Still's disease to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) may be dramatic. The effects of glucocorticoids on temporal arteritis, polymyalgia rheumatica, and granulomatous hepatitis are equally dramatic. Colchicine is highly effective in preventing attacks of familial Mediterranean fever but is of little use once an attack is well under way. The ability of glucocorticoids and NSAIDs to mask fever while permitting the spread of infection dictates that their use be avoided unless infection has been largely ruled out and unless inflammatory disease is both probable and debilitating or threatening.

When no underlying source of FUO is identified after prolonged observation (>6 months), the prognosis is generally good, however vexing the fever may be to the patient. Under such circumstances, debilitating symptoms are treated with NSAIDs, and glucocorticoids are the last resort. The initiation of empirical therapy does not mark the end of the diagnostic workup; rather, it commits the physician to continued thoughtful reexamination and evaluation. Patience, compassion, equanimity, and intellectual flexibility are indispensable attributes for the clinician in dealing successfully with FUO.

ACKNOWLEDGMENTS

20 Hypothermia and Frostbite

Daniel F. Danzl

HYPOTHERMIA

Accidental hypothermia occurs when there is an unintentional drop in the body's core temperature below 35°C (95°F). At this temperature, many of the compensatory physiologic mechanisms to conserve heat begin to fail. *Primary accidental hypothermia* is a result of the direct exposure of a previously healthy individual to the cold. The mortality rate is much higher for those patients who develop *secondary hypothermia* as a complication of a serious systemic disorder.

CAUSES

Primary accidental hypothermia is geographically and seasonally pervasive. Although most cases occur in the winter months and in colder climates, it is surprisingly common in warmer regions as well. Multiple variables make individuals at the extremes of age, the elderly and neonates, particularly vulnerable to hypothermia (Table 20-1). The elderly have diminished thermal perception and are more susceptible to immobility, malnutrition, and systemic illnesses that interfere with heat generation or conservation. Dementia, psychiatric illness, and socioeconomic factors often compound these problems by impeding adequate measures to prevent hypothermia. Neonates have high rates of heat loss because of their increased surface-to-mass ratio and their lack of effective shivering and adaptive behavioral responses. In addition, malnutrition can contribute to heat loss because of diminished subcutaneous fat and because of depleted energy stores used for thermogenesis.

Individuals whose occupations or hobbies entail extensive exposure to cold weather are at increased risk for hypothermia. Military history is replete with hypothermic tragedies. Hunters, sailors, skiers, and climbers also are at great risk of exposure, whether it involves injury, changes in weather, or lack of preparedness.

Ethanol causes vasodilatation (which increases heat loss), reduces thermogenesis and gluconeogenesis, and may impair judgment or lead to obtundation. Phenothiazines, barbiturates, benzodiazepines, cyclic antidepressants, and many other medications reduce centrally mediated vasoconstriction. Up to 25% of patients admitted to an intensive care unit because of drug overdose are hypothermic. Anesthetics can block the shivering responses; their effects are compounded when patients are not covered adequately in the operating or recovery rooms.

Several types of endocrine dysfunction can lead to hypothermia. Hypothyroidism—particularly when extreme, as in myxedema coma—reduces the metabolic rate and impairs thermogenesis and behavioral responses. Adrenal insufficiency and hypopituitarism also increase susceptibility to hypothermia. Hypoglycemia, most commonly caused by insulin or oral hypoglycemic drugs, is associated with hypothermia, in part the result of neuroglycopenic effects on hypothalamic function. Increased osmolality and metabolic derangements associated with uremia, diabetic ketoacidosis, and lactic acidosis can lead to altered hypothalamic thermoregulation.

Neurologic injury from trauma, cerebrovascular accident, subarachnoid hemorrhage, or hypothalamic lesions increases susceptibility to hypothermia. Agenesis of the corpus callosum, or Shapiro syndrome, is one cause of episodic hypothermia, characterized by profuse perspiration followed by a rapid fall in temperature. Acute spinal cord injury disrupts the autonomic pathways that lead to shivering and prevents cold-induced reflex vasoconstrictive responses.

Hypothermia associated with sepsis is a poor prognostic sign. Hepatic failure causes decreased glycogen stores and gluconeogenesis, as well as a diminished shivering response. In acute myocardial infarction associated with low cardiac output, hypothermia may be reversed after adequate resuscitation. With extensive burns, psoriasis, erythrodermas, and other skin diseases, increased peripheral blood flow leads to excessive heat loss.

TABLE 20-1 RISK FACTORS FOR HYPOTHERMIA

Age extremes	Endocrine-related
Elderly	Diabetes mellitus
Neonates	Hypoglycemia
Environmental exposure	Hypothyroidism
Occupational	Adrenal insufficiency
Sports-related	Hypopituitarism

Phenothiazines	Spinal cord injury
Barbiturates	Multisystem
Carcinomatosis	Trauma
Anesthetics	Sepsis
Neuromuscular blockers	Shock
Antidepressants	Hepatic or renal failure
Insufficient fuel	Burns and exfoliative dermatologic disorders
Malnutrition	Immobility or debilitation
Marasmus	
Kwashiorkor	

THERMOREGULATION

Heat loss occurs through five mechanisms: radiation (55–65% of heat loss), conduction (10–15% of heat loss, but much greater in cold water), convection (increased in the wind), respiration, and evaporation (which are affected by the ambient temperature and the relative humidity).

The preoptic anterior hypothalamus normally orchestrates thermoregulation (Chap. 17). The immediate defense of thermoneutrality is via the autonomic nervous system, whereas delayed control is mediated by the endocrine system. Autonomic nervous system responses include the release of norepinephrine, increased muscle tone, and shivering, leading to thermogenesis and an increase in the basal metabolic rate. Cutaneous cold thermoreception causes direct reflex vasoconstriction to conserve heat. Prolonged exposure to cold also stimulates the thyroid axis, leading to an increased metabolic rate.

CLINICAL PRESENTATION

In most cases of hypothermia, the history of exposure to environmental factors, such as prolonged exposure to the outdoors without adequate clothing, makes the diagnosis straightforward. In urban settings, however, the presentation is often more subtle and other disease processes, toxin exposures, or psychiatric diagnoses should be considered.

After initial stimulation by hypothermia, there is progressive depression of all organ systems. The timing of the appearance of these clinical manifestations varies widely (Table 20-2). Without knowing the core temperature, it can be difficult to interpret other vital signs. For example, a tachycardia disproportionate to the core temperature suggests secondary hypothermia resulting from hypoglycemia, hypovolemia, or a toxin overdose. Because carbon dioxide production declines progressively, the respiratory rate should be low; persistent hyperventilation suggests a central nervous system (CNS) lesion or one of the organic acidoses. A markedly depressed level of consciousness in a patient with mild hypothermia should raise suspicion of an overdose or CNS dysfunction due to infection or trauma.

Physical examination findings can also be altered by hypothermia. For instance, the assumption that areflexia is solely attributable to hypothermia can obscure and delay the diagnosis of a spinal cord lesion. Patients with hypothermia may be confused or combative; these symptoms abate more rapidly with rewarming than with the use of restraints. A classic example of maladaptive behavior in patients with hypothermia is paradoxical undressing, which involves the inappropriate removal of clothing in response to a cold stress. The cold-induced ileus and abdominal rectus spasm can mimic, or mask, the presentation of an acute abdomen (Chap. 14).

When a patient in hypothermic cardiac arrest is first discovered, cardiopulmonary resuscitation is indicated, unless (1) a do-not-resuscitate status is verified, (2) obviously lethal injuries are identified, or

TABLE 20-2 PHYSIOLOGIC CHANGES ASSOCIATED WITH ACCIDENTAL HYPOTHERMIA

Severity	Body Temperature	Central Nervous System	Cardiovascular	Respiratory	Renal and Endocrine	Neuromuscular
Mild	35°C (95°F)–32.2°C (90°F)	Linear depression of cerebral metabolism; amnesia; apathy; dysarthria; impaired judgment; maladaptive behavior	Tachycardia, then progressive bradycardia; cardiac-cycle prolongation; vasoconstriction; increase in cardiac output and blood pressure	Tachypnea, then progressive decrease in respiratory minute volume; declining oxygen consumption; bronchorrhea; bronchospasm	Diuresis; increase in catecholamines, adrenal steroids, triiodothyronine and thyroxine; increase in metabolism with shivering	Increased preshivering muscle tone, then fatiguing
Moderate	<32.2°C (90°F)–28°C (82.4°F)	EEG abnormalities; progressive depression of level of consciousness; pupillary dilatation; paradoxical undressing; hallucinations	Progressive decrease in pulse and cardiac output; increased atrial and ventricular arrhythmias; suggestive (J-wave) ECG changes	Hypoventilation; 50% decrease in carbon dioxide production per 8°C drop in temperature; absence of protective airway reflexes	50% increase in renal blood flow; renal autoregulation intact; impaired insulin action	Hyporeflexia; diminishing shivering-induced thermogenesis; rigidity
Severe	<28°C (82.4°F)	Loss of cerebrovascular autoregulation; decline in cerebral blood flow; coma; loss of ocular reflexes; progressive decrease in EEG	Progressive decrease in blood pressure, heart rate, and cardiac output; re-entrant dysrhythmias; maximum risk of ventricular fibrillation; asystole	Pulmonic congestion and edema; 75% decrease in oxygen consumption; apnea	Decrease in renal blood flow parallels decrease in cardiac output; extreme oliguria; poikilothermia; 80% decrease in basal metabolism	No motion; decreased nerve-conduction velocity; peripheral areflexia; no corneal or oculocephalic reflexes

Source: Modified from RR Kempainen, DD Brunette: Resp. Care 49:192, 2004.

(3) the depression of a frozen chest wall is not possible. As the resuscitation proceeds, the prognosis is grave if there is evidence of widespread cell lysis, as reflected by potassium levels > 10 mmol/L (10 meq/L). Other findings that may preclude continuing resuscitation include a core temperature < 10–12°C, a pH < 6.5, or evidence of intravascular thrombosis with a fibrinogen value < 0.5 g/L (<50 mg/dL). The decision to terminate resuscitation before rewarming the patient past 33°C should be predicated on the type and severity of the precipitants of hypothermia. There are no validated prognostic indicators for recovery from hypothermia. A history of asphyxia with secondary cooling is the most important negative predictor of survival.

DIAGNOSIS AND STABILIZATION

Hypothermia is confirmed by measuring the core temperature, preferably at two sites. Rectal probes should be placed to a depth of 15 cm and not adjacent to cold feces. A simultaneous esophageal probe should be placed 24 cm below the larynx; it may read falsely high during heated inhalation therapy. Relying solely on infrared tympanic thermography is not advisable.

After a diagnosis of hypothermia is established, cardiac monitoring should be instituted, along with attempts to limit further heat loss. If the patient is in ventricular fibrillation, one defibrillation attempt (2 J/kg) should be administered. If the rhythm does not convert, rewarm the patient to 30–32°C before repeating defibrillation attempts. Supplemental oxygenation is always warranted, since tissue oxygenation is adversely affected by the leftward shift of the oxyhemoglobin dissociation curve. Pulse oximetry may be unreliable in patients with vasoconstriction. If protective airway reflexes are absent, gentle endotracheal intubation should be performed. Adequate pre-oxygenation will prevent ventricular arrhythmias. Although cardiac pacing for hypothermic bradydysrhythmias is rarely indicated, the transthoracic technique is preferable.

Insertion of a gastric tube prevents dilatation secondary to decreased bowel motility. Indwelling bladder catheters facilitate monitoring of cold-induced diuresis. Dehydration is commonly encountered with chronic hypothermia, and most patients benefit from a bolus of crystalloid. Normal saline is preferable to lactated Ringer's solution, as the liver in hypothermic patients inefficiently metabolizes lactate. The placement of a pulmonary artery catheter risks perforation of the less compliant pulmonary artery. Insertion of a central venous catheter into the cold right atrium should be avoided, since this can precipitate arrhythmias.

Arterial blood gases should not be corrected for temperature (Chap. 48). An uncorrected pH of 7.42 and a P_{CO_2} of 40 mmHg reflects appropriate alveolar ventilation and acid-base balance at any core temperature. Acid-base imbalances should be corrected gradually, since the bicarbonate buffering system is inefficient. A common error is overzealous hyperventilation in the setting of depressed CO_2 production. When the P_{CO_2} decreases 10 mmHg at 28°C, it doubles the pH increase of 0.08 that occurs at 37°C.

The severity of anemia may be underestimated because the hematocrit increases 2% for each 1°C drop in temperature. White blood cell sequestration and bone marrow suppression are common, potentially masking an infection. Although hypokalemia is more common in chronic hypothermia, hyperkalemia also occurs; the expected electrocardiographic changes can be obscured by hypothermia. Patients with renal insufficiency, metabolic acidoses, or rhabdomyolysis are at greatest risk for electrolyte disturbances.

Coagulopathies are common because cold inhibits the enzymatic reactions required for activation of the intrinsic cascade. In addition, thromboxane B_2 production by platelets is temperature-dependent, and platelet function is impaired. The administration of platelets and fresh frozen plasma is, therefore, not effective. The prothrombin or partial thromboplastin times or INR (international normalized ratio) reported by the laboratory appear deceptively normal and contrast with the observed in vivo coagulopathy. This contradiction occurs because all coagulation tests are routinely performed at 37°C, and the enzymes are thus rewarmed.

REWARMING STRATEGIES

The key initial decision is whether to rewarm the patient passively or actively. *Passive external rewarming* simply involves covering and insulating the patient in a warm environment. With the head also covered, the rate of rewarming is usually 0.5° to 2.0°C per hour. This technique is ideal for previously healthy patients who develop acute, mild primary accidental hypothermia. The patient must have sufficient glycogen to support endogenous thermogenesis.

The application of heat directly to the extremities of patients with chronic severe hypothermia should be avoided because it can induce peripheral vasodilatation and precipitate core temperature "afterdrop"—a response characterized by a continual decline in the core temperature after removal of the patient from the cold. Truncal heat application reduces the risk of afterdrop.

Active rewarming is necessary under the following circumstances: core temperature < 32°C (poikilothermia), cardiovascular instability, age extremes, CNS dysfunction, hormone insufficiency, or suspicion of secondary hypothermia. *Active external rewarming* is best accomplished with forced-air heating blankets. Other options include radiant heat sources and hot packs. Monitoring a patient with hypothermia in a heated tub is extremely difficult. Electric blankets should be avoided because vasoconstricted skin is easily burned.

There are numerous widely available *active core rewarming* options. Airway rewarming with heated humidified oxygen (40°–45°C) is a convenient option via mask or endotracheal tube. Although airway rewarming provides less heat than some other forms of active core rewarming, it eliminates respiratory heat loss and adds 1°–2°C to the overall rewarming rate. Crystalloids should be heated to 40°–42°C, but the quantity of heat provided is significant only during massive volume resuscitation. The most efficient method for heating and delivering fluid or blood is with a countercurrent in-line heat exchanger. Heated irrigation of the gastrointestinal tract or bladder transfers minimal heat because of the limited available surface area. These methods should be reserved for patients in cardiac arrest and then used in combination with all available active rewarming techniques. Closed thoracic lavage is far more efficient in severely hypothermic patients with cardiac arrest. The hemithoraces are irrigated through two large-bore thoracostomy tubes that are inserted into the hemithoraces. Thoracostomy tubes should not be placed in the left chest of a spontaneously perfusing patient for purposes of rewarming. Peritoneal lavage with the dialysate at 40°–45°C efficiently transfers heat when delivered through two catheters with outflow suction. Like peritoneal dialysis, standard hemodialysis is especially useful for patients with electrolyte abnormalities, rhabdomyolysis, or toxin ingestions.

Extracorporeal blood rewarming options (Table 20-3) should be considered in severely hypothermic patients, especially those with *primary accidental hypothermia*. Cardiopulmonary bypass should be considered in nonperfusing patients without documented contraindications to resuscitation. Circulatory support may be the only effective option in patients with completely frozen extremities, or those with significant tissue destruction coupled with rhabdomyolysis. There is no evidence that extremely rapid rewarming improves survival in perfusing patients. The best strategy is usually a combination of passive, truncal active, and active core rewarming techniques.

TABLE 20-3 OPTIONS FOR EXTRACORPOREAL BLOOD REWARMING

Extracorporeal Rewarming (ECR) Technique	Considerations
Venovenous (VV)	Circuit—CV catheter to CV or peripheral catheter No oxygenator/circulatory support Flow rates 150–400 mL/min ROR 2°–3°C/h
Hemodialysis (HD)	Circuit—single or dual vessel cannulation Stabilizes electrolyte or toxicologic abnormalities Exchange cycle volumes 200–500 mL/min ROR 2°–3°C/h
Continuous arteriovenous rewarming (CAVR)	Circuit—percutaneous 8.5 Fr femoral catheters Requires BP 60 mmHg systolic No perfusionist/pump/anticoagulation Flow rates 225–375 mL/min ROR 3°–4°C/h
Cardiopulmonary bypass (CPB)	Circuit—full circulatory support with pump and oxygenator Perfusate-temperature gradient (5°–10°C) Flow rates 2–7 L/min (ave. 3–4) ROR up to 9.5°C/h

Note: BP, blood pressure; CV, central venous; ROR, rate of rewarming.

Rx HYPOTHERMIA

When a patient is hypothermic, target organs and the cardiovascular system respond minimally to most medications. Moreover, cumulative doses can cause toxicity during rewarming because of increased binding of drugs to proteins, and impaired metabolism and excretion. As an example, the administration of repeated doses of digoxin or insulin would be ineffective while the patient is hypothermic, and the residual drugs are potentially toxic during rewarming.

Achieving a mean arterial pressure of at least 60 mmHg should be an early objective. If the hypotension does not respond to crystalloid/colloid infusion and rewarming, low-dose dopamine (2–5 μg/kg per min) support should be considered. Perfusion of the vasoconstricted cardiovascular system may also be improved with low-dose IV nitroglycerin.

Atrial arrhythmias should initially be monitored without intervention, as the ventricular response will be slow, and unless preexistent, most will convert spontaneously during rewarming. The role of prophylaxis and treatment of ventricular arrhythmias is problematic. Preexisting ventricular ectopy may be suppressed by hypothermia and reappear during rewarming. None of the class I agents has proved to be safe and efficacious. When available, bretylium tosylate was the class III ventricular antiarrhythmic of choice. There is no evidence that amiodarone is safe.

Initiating empirical therapy for adrenal insufficiency is usually not warranted unless there is a history suggesting steroid dependence, hypoadrenalism, or a failure to rewarm with standard therapy. The administration of parenteral levothyroxine to euthyroid patients with hypothermia, however, is potentially hazardous. Because laboratory results can be delayed and confounded by the presence of the sick euthyroid syndrome (Chap. 335), historic clues or physical findings suggestive of hypothyroidism should be sought. When myxedema is the cause of hypothermia, the relaxation phase of the Achilles reflex is prolonged more than the contraction phase.

Hypothermia obscures most of the symptoms and signs of infection, notably fever and leukocytosis. Shaking rigors from infection may be mistaken for shivering. Except in mild cases, extensive cultures and repeated physical examinations are essential. Unless an infectious source is identified, empirical antibiotic prophylaxis is most warranted in the elderly, neonates, and immunocompromised patients.

Preventive measures should be discussed with high-risk individuals, such as the elderly or people whose work frequently exposes them to extreme cold. The importance of layered clothing and headgear, adequate shelter, increased caloric intake, and the avoidance of ethanol should be emphasized, along with access to rescue services.

FROSTBITE

Peripheral cold injuries include both freezing and nonfreezing injuries to tissue. Tissue freezes quickly when in contact with thermal conductors such as metal or volatile solutions. Other predisposing factors include constrictive clothing or boots, immobility, or vasoconstrictive medications. Frostbite occurs when the tissue temperature drops below 0°C. Ice crystal formation subsequently distorts and destroys the cellular architecture. Once the vascular endothelium is damaged, stasis progresses rapidly to microvascular thrombosis. After the tissue thaws, there is progressive dermal ischemia. The microvasculature begins to collapse, arteriovenous shunting increases tissue pressures, and edema forms. Finally, thrombosis, ischemia, and superficial necrosis appear. The development of mummification and demarcation may take weeks to months.

CLINICAL PRESENTATION

The initial presentation of frostbite can be deceptively benign. The symptoms always include a sensory deficiency affecting light touch, pain, and temperature perception. The acral areas and distal extremities are the most common insensate areas. Some patients complain of a clumsy or "chunk of wood" sensation in the extremity.

FIGURE 20-1 Frostbite with vesiculation, surrounded by edema and erythema.

Deep frostbitten tissue can appear waxy, mottled, yellow, or violaceous-white. Favorable presenting signs include some warmth or sensation with normal color. The injury is often superficial if the subcutaneous tissue is pliable or if the dermis can be rolled over boney prominences.

Clinically, it is most practical to classify frostbite as superficial or deep. Superficial does not entail tissue loss. Classically, frostbite is retrospectively graded like a burn. First-degree frostbite causes only anesthesia and erythema. The appearance of superficial vesiculation surrounded by edema and erythema is considered second degree (Fig. 20-1). Hemorrhagic vesicles reflect a serious injury to the microvasculature and indicate third-degree frostbite. Fourth-degree injuries damage subcuticular, muscular, and osseous tissues.

The two most common nonfreezing peripheral cold injuries are *chilblain (pernio)* and *immersion (trench) foot*. Chilblain results from neuronal and endothelial damage induced by repetitive exposure to dry cold. Young females, particularly those with a history of Raynaud's phenomenon, are at greatest risk. Persistent vasospasticity and vasculitis can cause erythema, mild edema, and pruritus. Eventually plaques, blue nodules, and ulcerations develop. These lesions typically involve the dorsa of the hands and feet. In contrast, immersion (trench) foot results from repetitive exposure to wet cold above the freezing point. The feet initially appear cyanotic, cold, and edematous. The subsequent development of bullae is often indistinguishable from frostbite. This vesiculation rapidly progresses to ulceration and liquefaction gangrene. Patients with milder cases complain of hyperhidrosis, cold sensitivity, and painful ambulation for many years.

Rx FROSTBITE

Frozen tissue should be rapidly and completely thawed by immersion in circulating water at 37°–40°C. Rapid rewarming often produces an initial hyperemia. The early formation of large clear distal blebs is more favorable than smaller proximal dark hemorrhagic blebs. A common error is the premature termination of thawing, since the reestablishment of perfusion is intensely painful. Parenteral narcotics will be necessary with deep frostbite. If cyanosis persists after rewarming, the tissue compartment pressures should be monitored carefully.

Numerous experimental antithrombotic and vasodilatory treatment regimens have been evaluated. There is no conclusive evidence that dextran, heparin, steroids, calcium channel blockers, hyperbaric oxygen, or prostaglandin inhibitors salvage tissue. A treatment protocol for frostbite is summarized in **Table 20-4**.

Unless infection develops, any decision regarding debridement or amputation should be deferred until there is clear evidence of demarcation, mummification, and sloughing. Magnetic resonance angiography may demonstrate the line of demarcation earlier than clinical demarcation. The most common symptomatic sequelae reflect neuronal injury and the persistently abnormal sympathetic tone, including paresthesias, thermal misperception, and hyperhidrosis. Delayed findings include nail deformities, cutaneous carcinomas, and epiphyseal damage in children.

Management of the chilblain syndrome is usually supportive. With refractory perniosis, alternatives include nifedipine, steroids, or limaprost, a prostaglandin E_1 analogue.

TABLE 20-4 TREATMENT FOR FROSTBITE

Before Thawing	During Thawing	After Thawing
Remove from environment	Consider parenteral analgesia and ketorolac	Gently dry and protect part; elevate; pledgets between toes, if macerated
Prevent partial thawing and refreezing	Administer ibuprofen, 400 mg PO	If clear vesicles are intact, aspirate sterilely; if broken, debride and dress with antibiotic or sterile aloe vera ointment
Stabilize core temperature and treat hypothermia	Immerse part in 37°–40°C (thermometer-monitored) circulating water containing an antiseptic soap until distal flush (10–45 min)	Leave hemorrhagic vesicles intact to prevent dessication and infection
Protect frozen part—no friction or massage	Encourage patient to gently move part	Continue ibuprofen 400 mg PO (12 mg/kg per day) q8–12h
Address medical or surgical conditions	If pain is refractory, reduce water temperature to 35°–37°C and administer parenteral narcotics	Consider tetanus and streptococcal prophylaxis; elevate part Hydrotherapy at 37°C Consider phenoxybenzamine in severe cases

SECTION 3 NERVOUS SYSTEM DYSFUNCTION

21 Syncope

Mark D. Carlson

Syncope, a transient loss of consciousness and postural tone due to reduced cerebral blood flow, is associated with spontaneous recovery. It may occur suddenly, without warning, or may be preceded by symptoms of faintness ("presyncope"). These symptoms include lightheadedness, dizziness, a feeling of warmth, diaphoresis, nausea, and visual blurring occasionally proceeding to transient blindness. Presyncopal symptoms vary in duration and may increase in severity until loss of consciousness occurs, or they may resolve prior to loss of consciousness if the cerebral ischemia is corrected. The differentiation of syncope from seizure is an important, sometimes difficult, diagnostic problem.

Syncope may be benign when it occurs as a result of normal cardiovascular reflex effects on heart rate and vascular tone, or serious when due to a life-threatening cardiac arrhythmia. Syncope may occur as a single event or may be recurrent. Recurrent, unexplained syncope, particularly in an individual with structural heart disease, is associated with a high risk of death (40% mortality within 2 years).

PATHOPHYSIOLOGY

Under normal circumstances systemic blood pressure is regulated by a complex process that includes the musculature, venous valves, autonomic nervous system, and renin-aldosterone-angiotensin system. Knowledge of these processes is important to understanding the pathophysiology of syncope. Approximately three-fourths of the systemic blood volume is contained in the venous bed, and any interference in venous return may lead to a reduction in cardiac output. Cerebral blood flow can be maintained if cardiac output and systemic arterial vasoconstriction compensate, but when these adjustments fail, hypotension with resultant cerebral underperfusion to less than half of normal results in syncope. Normally, the pooling of blood in the lower parts of the body is prevented by (1) pressor reflexes that induce constriction of peripheral arterioles and venules, (2) reflex acceleration of the heart by means of aortic and carotid reflexes, and (3) improvement of venous return to the heart by activity of the muscles of the limbs. Tilting a normal person upright on a tilt table causes some blood to accumulate in the lower limbs and diminishes cardiac output slightly; this may be followed by a slight transitory fall in systolic blood pressure. However, in a patient with defective vasomotor reflexes, upright tilt may produce an abrupt and sustained fall in blood pressure, precipitating a faint.

CAUSES OF SYNCOPE

Transiently decreased cerebral blood flow is usually due to one of three general mechanisms: disorders of vascular tone or blood volume, cardiovascular disorders including obstructive lesions and cardiac arrhythmias, or cerebrovascular disease (Table 21-1). Not infrequently, however, the cause of syncope is multifactorial.

DISORDERS OF VASCULAR TONE OR BLOOD VOLUME

Disorders of vascular tone or blood volume that can cause syncope include the reflex syncopes and a number of conditions resulting in orthostatic intolerance. The reflex syncopes—including neurocardiogenic syncope, situational syncope, and carotid sinus hypersensitivity—share common autonomic nervous system pathophysiologic mechanisms: a cardioinhibitory component (e.g., bradycardia due to increased vagal activity), a vasodepressor component (e.g., inappropriate vasodilatation due to sympathetic withdrawal), or both.

Neurocardiogenic (Vasovagal and Vasodepressor) Syncope The term *neurocardiogenic* is generally used to encompass both vasovagal and vasodepressor syncope. Strictly speaking, vasovagal syncope is associated with both sympathetic withdrawal (vasodilatation) and increased parasympathetic activity (bradycardia), whereas vasodepressor syncope is associated with sympathetic withdrawal alone.

These forms of syncope are the common faint that may be experienced by normal persons; they account for approximately half of all episodes of syncope. Neurocardiogenic syncope is frequently recurrent and commonly precipitated by a hot or crowded environment, alcohol, extreme fatigue, severe pain, hunger, prolonged standing, and emotional or stressful situations. Episodes are often preceded by a presyncopal prodrome lasting seconds to minutes, and rarely occur in the supine position. The individual is usually sitting or standing and experiences

TABLE 21-1 CAUSES OF SYNCOPE

- I. Disorders of Vascular Tone or Blood Volume
  - A. Reflex syncopes
    - 1. Neurocardiogenic
    - 2. Situational
      - Cough
      - Micturition
      - Defecation
      - Valsalva
      - Deglutition
    - 3. Carotid sinus hypersensitivity
  - B. Orthostatic hypotension
    - 1. Drug-induced (antihypertensive or vasodilator drugs)
    - 2. Pure autonomic failure (idiopathic orthostatic hypotension)
    - 3. Multisystem atrophies
    - 4. Peripheral neuropathy (diabetic, alcoholic, nutritional, amyloid)
    - 5. Physical deconditioning
    - 6. Sympathectomy
    - 7. Decreased blood volume
- II. Cardiovascular Disorders
  - A. Structural and obstructive causes
    - 1. Pulmonary embolism
    - 2. Pulmonary hypertension
    - 3. Atrial myxoma
    - 4. Mitral valvular stenosis
    - 5. Myocardial disease (massive acute myocardial infarction)
    - 6. Left ventricular myocardial restriction or constriction
    - 7. Pericardial constriction or tamponade
    - 8. Aortic outflow tract obstruction
    - 9. Aortic valvular stenosis
    - 10. Hypertrophic obstructive cardiomyopathy

  - B. Psychogenic
    - 1. Anxiety attacks
    - 2. Hysterical fainting
  - C. Seizures

weakness, nausea, diaphoresis, lightheadedness, blurred vision, and often a forceful heartbeat with tachycardia followed by cardiac slowing and decreasing blood pressure prior to loss of consciousness. The individual appears pale or ashen; in dark-skinned individuals, the pallor may only be notable in the conjunctivae and lips. Patients with a gradual onset of presyncopal symptoms have time to protect themselves against injury; in others, syncope occurs suddenly, without warning.

The depth and duration of unconsciousness vary. Sometimes the patient remains partly aware of the surroundings, or there may be complete unresponsiveness. The unconscious patient usually lies motionless, with skeletal muscles relaxed, but a few clonic jerks of the limbs and face may occur. Sphincter control is usually maintained, in contrast to a seizure. The pulse may be feeble or apparently absent, the blood pressure low or undetectable, and breathing may be almost imperceptible. The duration of unconsciousness is rarely longer than a few minutes if the conditions that provoke the episode are reversed. Once the patient is placed in a horizontal position, the strength of the pulse improves, color begins to return to the face, breathing becomes quicker and deeper, and consciousness is restored. Some patients may experience a sense of residual weakness after regaining consciousness, and rising too soon may precipitate another faint. Unconsciousness may be prolonged if an individual remains upright; thus, it is essential that individuals with vasovagal syncope assume a recumbent position as soon as possible. Although usually benign, neurocardiogenic syncope can be associated with prolonged asystole and hypotension, resulting in hypoxic-ischemic injury.

Neurocardiogenic syncope often occurs in the setting of increased peripheral sympathetic activity and venous pooling. Under these conditions, vigorous myocardial contraction of a relatively empty left ventricle is thought to activate myocardial mechanoreceptors and vagal afferent nerve fibers that inhibit sympathetic activity and increase parasympathetic activity. The resultant vasodilatation and bradycardia induce hypotension and syncope. Although the reflex involving myocardial mechanoreceptors is the mechanism usually accepted as responsible for neurocardiogenic syncope, other reflexes may also be operative. Patients with transplanted (denervated) hearts have experienced cardiovascular responses identical to those present during neurocardiogenic syncope. This should not be possible if the response depends solely on the reflex mechanisms described above, unless the transplanted heart has become reinnervated. Moreover, neurocardiogenic syncope often occurs in response to stimuli (fear, emotional stress, or pain) that may not be associated with venous pooling in the lower extremities, which suggests a cerebral component to the reflex.

As distinct from the peripheral mechanisms, the central nervous system (CNS) mechanisms responsible for neurocardiogenic syncope are uncertain, but a sudden surge in central serotonin levels may contribute to the sympathetic withdrawal. Endogenous opiates (endorphins) and adenosine are also putative participants in the pathogenesis.

Situational Syncope A variety of activities, including cough, deglutition, micturition, and defecation, are associated with syncope in susceptible individuals. Like neurocardiogenic syncope, these syndromes may involve a cardioinhibitory response, a vasodepressor response, or both. Cough, micturition, and defecation are associated with maneuvers (such as Valsalva's, straining, and coughing) that may contribute to hypotension and syncope by decreasing venous return. Increased intracranial pressure secondary to the increased intrathoracic pressure may also contribute by decreasing cerebral blood flow.

Cough syncope typically occurs in men with chronic bronchitis or chronic obstructive lung disease during or after prolonged coughing fits. Micturition syncope occurs predominantly in middle-aged and older men, particularly those with prostatic hypertrophy and obstruction of the bladder neck; loss of consciousness usually occurs at night during or immediately after voiding. Deglutition syncope and defecation syncope occur in men and women. Deglutition syncope may be associated with esophageal disorders, particularly esophageal spasm. In some individuals, particular foods and carbonated or cold beverages initiate episodes by activating esophageal sensory receptors that trigger reflex sinus bradycardia or atrioventricular (AV) block. Defecation syncope is probably secondary to Valsalva's maneuver in older individuals with constipation.

Carotid Sinus Hypersensitivity Syncope due to carotid sinus hypersensitivity is precipitated by pressure on the carotid sinus baroreceptors, which are located just cephalad to the bifurcation of the common carotid artery. This typically occurs in the setting of shaving, a tight collar, or turning the head to one side. Carotid sinus hypersensitivity occurs predominantly in men ≥50 years old. Activation of carotid sinus baroreceptors gives rise to impulses carried via the nerve of Hering, a branch of the glossopharyngeal nerve, to the medulla in the brainstem. These afferent impulses activate efferent sympathetic nerve fibers to the heart and blood vessels, cardiac vagal efferent nerve fibers, or both. In patients with carotid sinus hypersensitivity, these responses may cause sinus arrest or AV block (a cardioinhibitory response), vasodilatation (a vasodepressor response), or both (a mixed response). The underlying mechanisms responsible for the carotid sinus hypersensitivity are not clear, and validated diagnostic criteria do not exist.

Postural (Orthostatic) Hypotension Orthostatic intolerance can result from hypovolemia or from disturbances in vascular control. The latter may occur due to agents that affect the vasculature or due to primary or secondary abnormalities of autonomic control. Sudden rising from a recumbent position or standing quietly are precipitating circumstances. *Orthostatic hypotension may be the cause of syncope in up to 30% of the elderly; polypharmacy with antihypertensive or antidepressant drugs is often a contributor in these patients.*

Postural syncope may occur in otherwise normal persons with defective postural reflexes. Pure autonomic failure (formerly called *idiopathic postural hypotension*) is characterized by orthostatic hypotension, syncope and near syncope, neurocardiogenic bladder, constipation, heat intolerance, inability to sweat, and erectile dysfunction (Chap. 370). The disorder is more common in men than women and typically begins between the ages of 50 and 75 years.

Orthostatic hypotension, often accompanied by disturbances in sweating, impotence, and sphincter difficulties, is also a primary feature of a variety or other autonomic nervous system disorders (Chap. 370). Among the most common causes of neurogenic orthostatic hypotension are chronic diseases of the peripheral nervous system that involve postganglionic unmyelinated fibers (e.g., diabetic, nutritional, and amyloid polyneuropathy). Much less common are the multiple system atrophies; these are CNS disorders in which orthostatic hypotension is associated with (1) parkinsonism (Shy-Drager syndrome), (2) progressive cerebellar degeneration, or (3) a more variable parkinsonian and cerebellar syndrome (Chap. 366). A rare, acute postganglionic dysautonomia may represent a variant of Guillain-Barré syndrome (Chap. 380); a related disorder, autoimmune autonomic neuropathy, is associated with autoantibodies to the ganglionic acetylcholine receptor.

There are several additional causes of postural syncope: (1) after physical deconditioning (such as after prolonged illness with recumbency, especially in elderly individuals with reduced muscle tone) or after prolonged weightlessness, as in space flight; (2) after sympathectomy that has abolished vasopressor reflexes; and (3) in patients receiving antihypertensive or vasodilator drugs and those who are hypovolemic because of diuretics, excessive sweating, diarrhea, vomiting, hemorrhage, or adrenal insufficiency.

Glossopharyngeal Neuralgia Syncope due to glossopharyngeal neuralgia (Chap. 371) is preceded by pain in the oropharynx, tonsillar fossa, or tongue. Loss of consciousness is usually associated with asystole rather than vasodilatation. The mechanism is thought to involve activation of afferent impulses in the glossopharyngeal nerve that terminate in the nucleus solitarius of the medulla and, via collaterals, activate the dorsal motor nucleus of the vagus nerve.

CARDIOVASCULAR DISORDERS

Cardiac syncope results from a sudden reduction in cardiac output, caused most commonly by a cardiac arrhythmia. In normal individuals, heart rates between 30 and 180 beats/min do not reduce cerebral blood flow, especially if the person is in the supine position. As the heart rate

decreases, ventricular filling time and stroke volume increase to maintain normal cardiac output. At rates <30 beats/min, stroke volume can no longer increase to compensate adequately for the decreased heart rate. At rates greater than ~180 beats/min, ventricular filling time is inadequate to maintain adequate stroke volume. In either case, cerebral hypoperfusion and syncope may occur. Upright posture; cerebrovascular disease; anemia; loss of atrioventricular synchrony; and coronary, myocardial, or valvular disease all reduce the tolerance to alterations in rate.

Bradyarrhythmias (Chap. 225) may occur as a result of an abnormality of impulse generation (e.g., sinoatrial arrest) or impulse conduction (e.g., AV block). Either may cause syncope if the escape pacemaker rate is insufficient to maintain cardiac output. Syncope due to bradyarrhythmias may occur abruptly, without presyncopal symptoms, and recur several times daily. Patients with *sick sinus syndrome* may have sinus pauses (>3 s), and those with syncope due to high-degree AV block (*Stokes-Adams-Morgagni syndrome*) may have evidence of conduction system disease (e.g., prolonged PR interval, bundle branch block). However, the arrhythmia is often transitory, and the surface electrocardiogram or continuous electrocardiographic monitor (Holter monitor) taken later may not reveal the abnormality. The *bradycardia-tachycardia syndrome* is a common form of sinus node dysfunction in which syncope generally occurs as a result of marked sinus pauses, some following termination of paroxysms of atrial tachyarrhythmias. Drugs are a common cause for bradyarrhythmias, particularly in patients with underlying structural heart disease. Digoxin, β-adrenergic receptor antagonists, calcium channel blockers, and many antiarrhythmic drugs may suppress sinoatrial node impulse generation or slow AV nodal conduction.

Syncope due to a *tachyarrhythmia* (Chap. 226) is usually preceded by palpitation or lightheadedness but may occur abruptly with no warning symptoms. *Supraventricular tachyarrhythmias* are unlikely to cause syncope in individuals with structurally normal hearts but may do so if they occur in patients with (1) heart disease that also compromises cardiac output, (2) cerebrovascular disease, (3) a disorder of vascular tone or blood volume, or (4) a rapid ventricular rate. These tachycardias result most commonly from paroxysmal atrial flutter, atrial fibrillation, or reentry involving the AV node or accessory pathways that bypass part or all of the AV conduction system. Patients with *Wolff-Parkinson-White syndrome* may experience syncope when a very rapid ventricular rate occurs due to reentry across an accessory AV connection.

In patients with structural heart disease, ventricular tachycardia is a common cause of syncope, particularly in those with a prior myocardial infarction. Patients with aortic valvular stenosis and hypertrophic obstructive cardiomyopathy are also at risk for ventricular tachycardia. Individuals with abnormalities of ventricular repolarization (prolongation of the QT interval) are at risk to develop polymorphic ventricular tachycardia (torsades des pointes). Those with the inherited form of this syndrome often have a family history of sudden death in young individuals. Genetic markers can identify some patients with familial long-QT syndrome, but the clinical utility of these markers remains unproven. Drugs (i.e., certain antiarrhythmics and erythromycin) and electrolyte disorders (i.e., hypokalemia, hypocalcemia, hypomagnesemia) can prolong the QT interval and predispose to torsades des pointes. Antiarrhythmic medications may precipitate ventricular tachycardia, particularly in patients with structural heart disease.

In addition to arrhythmias, syncope may also occur with a variety of structural cardiovascular disorders. Episodes are usually precipitated when the cardiac output cannot increase to compensate adequately for peripheral vasodilatation. Peripheral vasodilatation may be appropriate, such as following exercise, or may occur due to inappropriate activation of left ventricular mechanoreceptor reflexes, as occurs in aortic outflow tract obstruction (aortic valvular stenosis or hypertrophic obstructive cardiomyopathy). Obstruction to forward flow is the most common reason that cardiac output cannot increase. Pericardial tamponade is a rare cause of syncope. Syncope occurs in up to 10% of patients with massive pulmonary embolism and may occur with exertion in patients with severe primary pulmonary hypertension. The cause is an inability of the right ventricle to provide appropriate cardiac output in the presence of obstruction or increased pulmonary vascular resistance. Loss of consciousness is usually accompanied by other symptoms such as chest pain and dyspnea. Atrial myxoma, a prosthetic valve thrombus, and, rarely, mitral stenosis may impair left ventricular filling, decrease cardiac output, and cause syncope.

CEREBROVASCULAR DISEASE

Cerebrovascular disease alone rarely causes syncope but may lower the threshold for syncope in patients with other causes. The vertebrobasilar arteries, which supply brainstem structures responsible for maintaining consciousness, are usually involved when cerebrovascular disease causes or contributes to syncope. An exception is the rare patient with tight bilateral carotid stenosis and recurrent syncope, often precipitated by standing or walking. Most patients who experience lightheadedness or syncope due to cerebrovascular disease also have symptoms of focal neurologic ischemia, such as arm or leg weakness, diplopia, ataxia, dysarthria, or sensory disturbances. Basilar artery migraine is a rare disorder that causes syncope in adolescents.

DIFFERENTIAL DIAGNOSIS

ANXIETY ATTACKS AND HYPERVENTILATION SYNDROME

Anxiety, such as occurs in panic attacks, is frequently interpreted as a feeling of faintness or dizziness resembling presyncope. However, the symptoms are not accompanied by facial pallor and are not relieved by recumbency. The diagnosis is made on the basis of the associated symptoms such as a feeling of impending doom, air hunger, palpitations, and tingling of the fingers and perioral region. Attacks can often be reproduced by hyperventilation, resulting in hypocapnia, alkalosis, increased cerebrovascular resistance, and decreased cerebral blood flow. The release of epinephrine also contributes to the symptoms.

SEIZURES

A seizure may be heralded by an aura, which is caused by a focal seizure discharge and hence has localizing significance (Chap. 363). The aura is usually followed by a rapid return to normal or by a loss of consciousness. Injury from falling is frequent in a seizure and rare in syncope, since only in generalized seizures are protective reflexes abolished instantaneously. Sustained tonic-clonic movements are characteristic of convulsive seizures, but brief clonic, or tonic-clonic, seizure-like activity can accompany fainting episodes. The period of unconsciousness in seizures tends to be longer than in syncope. Urinary incontinence is frequent in seizures and rare in syncope. The return of consciousness is prompt in syncope and slow after a seizure. Mental confusion, headache, and drowsiness are common sequelae of seizures, whereas physical weakness with a clear sensorium characterizes the postsyncopal state. Repeated spells of unconsciousness in a young person at a rate of several per day or month are more suggestive of epilepsy than syncope. See Table 363-7 for a comparison of seizures and syncope.

HYPOGLYCEMIA

Severe hypoglycemia is usually due to a serious disease such as a tumor of the islets of Langerhans or advanced adrenal, pituitary, or hepatic disease; or to excessive administration of insulin.

HYSTERICAL FAINTING

The attack is usually unattended by an outward display of anxiety. Lack of change in pulse and blood pressure or color of the skin and mucous membranes distinguish it from the vasodepressor faint.

APPROACH TO THE PATIENT: Syncope

The diagnosis of syncope is often challenging. The cause may only be apparent at the time of the event, leaving few, if any, clues when the patient is seen later by the physician. The physician should think first of those causes that constitute a therapeutic emergency, including massive internal hemorrhage or myocardial infarction, which may be painless, and cardiac arrhythmias. In elderly persons, a sudden faint, without obvious cause, should arouse the sus-

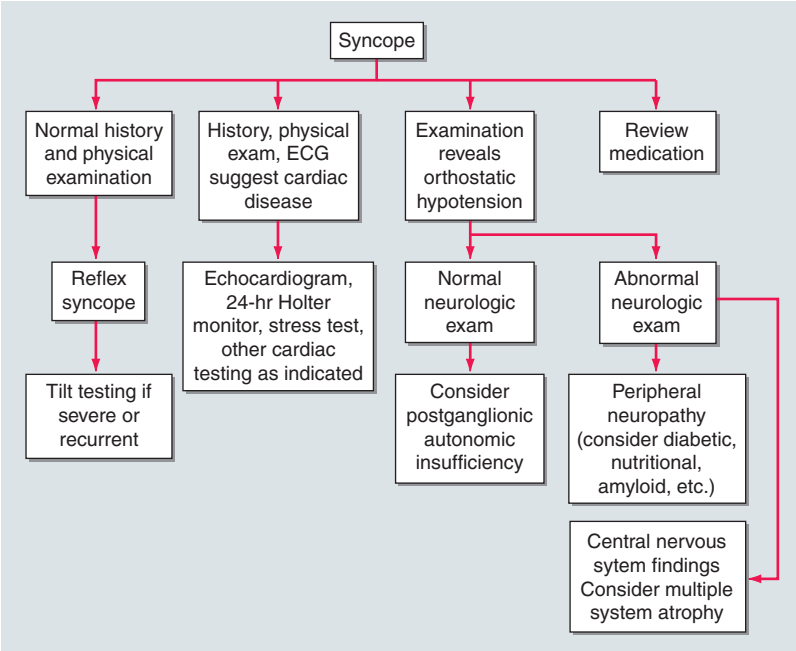

FIGURE 21-1 Approach to the patient with syncope.

picion of complete heart block or a tachyarrhythmia, even though all findings are negative when the patient is seen.

Figure 21-1 depicts an algorithmic approach to syncope. A careful history is the most important diagnostic tool, both to suggest the correct cause and to exclude important potential causes (Table 21-1). The nature of the events and their time course immediately prior to, during, and after an episode of syncope often provide valuable etiologic clues. Loss of consciousness in particular situations, such as during venipuncture or micturition or with volume depletion, suggests an abnormality of vascular tone. The position of the patient at the time of the syncopal episode is important; syncope in the supine position is unlikely to be vasovagal and suggests an arrhythmia or a seizure. Syncope due to carotid sinus syndrome may occur when the individual is wearing a shirt with a tight collar, turning the head (turning to look while driving in reverse), or manipulating the neck (as in shaving). The patient's medications must be noted, including nonprescription drugs or health store supplements, with particular attention to recent changes.

The physical examination should include evaluation of heart rate and blood pressure in the supine, sitting, and standing positions. In patients with unexplained recurrent syncope, an attempt to reproduce an attack may assist in diagnosis. Anxiety attacks induced by hyperventilation can be reproduced readily by having the patient breathe rapidly and deeply for 2–3 min. Cough syncope may be reproduced by inducing the Valsalva's maneuver. Carotid sinus massage should generally be avoided, unless carotid ultrasound is negative for atheroma, because its diagnostic specificity is unknown and it may provoke a transient ischemic attack (TIA) or stroke in individuals with carotid atheromas.

DIAGNOSTIC TESTS The choice of diagnostic tests should be guided by the history and the physical examination. Measurements of serum electrolytes, glucose, and the hematocrit are usually indicated. Cardiac enzymes should be evaluated if myocardial ischemia is suspected. Blood and urine toxicology screens may reveal the presence of alcohol or other drugs. In patients with possible adrenocortical insufficiency, plasma aldosterone and mineralocorticoid levels should be obtained.

Although the surface electrocardiogram is unlikely to provide a definitive diagnosis, it may provide clues to the cause of syncope *and should be performed in almost all patients*. The presence of conduction abnormalities (PR prolongation and bundle branch block) suggests a bradyarrhythmia, whereas pathologic Q waves or prolongation of the QT interval suggests a ventricular tachyarrhythmia. Inpatients should undergo continuous electrocardiographic monitoring; outpatients should wear a Holter monitor for 24–48 h. Whenever possible, symptoms should be correlated with the occurrence of arrhythmias. Continuous electrocardiographic monitoring may establish the cause of syncope in as many as 15% of patients. Cardiac event monitors may be useful in patients with infrequent symptoms, particularly in patients with presyncope. An implantable event monitor may be necessary for patients with extremely infrequent episodes. The presence of a late potential on a signal-averaged electrocardiogram is associated with increased risk for ventricular tachyarrhythmias in patients with a prior myocardial infarction. Low-voltage (visually inapparent) T wave alternans is also associated with development of sustained ventricular arrhythmias.

Invasive cardiac electrophysiologic testing provides diagnostic and prognostic information regarding sinus node function, AV conduction, and supraventricular and ventricular arrhythmias (Chaps. 225 and 226). Prolongation of the sinus node recovery time (>1500 ms) is a specific finding (85–100%) for diagnosis of sinus node dysfunction but has a low sensitivity; continuous electrocardiographic monitoring is usually more effective for diagnosing this abnormality. Prolongation of the HV interval and conduction block below the His bundle indicate that His-Purkinje disease may be responsible for syncope. Programmed stimulation for ventricular arrhythmias is most useful in patients who have experienced a myocardial infarction; the sensitivity and specificity of this technique is lower in patients with normal hearts or those with heart disease other than coronary artery disease.

Upright tilt table testing is indicated for recurrent syncope, a single syncopal episode that caused injury, or a single syncopal event in a "high-risk" setting (pilot, commercial vehicle driver, etc.), whether or not there is a history of preexisting heart disease or prior vasovagal episodes. In susceptible patients, upright tilt at an angle between 60° and 80° for 30–60 min induces a vasovagal episode. The protocol can be shortened if upright tilt is combined with administration of drugs that cause venous pooling or increase adrenergic stimulation (isoproterenol, nitroglycerin, edrophonium, or adenosine). The sensitivity and specificity of tilt-table testing is difficult to ascertain because of the lack of validated criteria. Moreover, the reflexes responsible for vasovagal syncope can be elicited in most, if not all, individuals given the appropriate stimulus. The specificity of tilt-table testing has been reported to be near 90%, but it is lower when pharmacologic provocation is employed. The reported sensitivity of the test ranges between 20 and 74%, the variability due to differences in populations studied, techniques used, and the absence of a true "gold standard" against which to compare test results. The reproducibility (in a time ranging from several hours to weeks) is 80–90% for an initially positive response, but may be less for an initially negative response (ranging from 30 to 90%).

A variety of other tests may be useful to determine the presence of structural heart disease that may cause syncope. The echocardiogram with Doppler examination detects valvular, myocardial, and pericardial abnormalities. The echocardiogram is the "gold standard" for the diagnosis of hypertrophic cardiomyopathy and atrial myxoma. Cardiac cine MRI provides an alternative noninvasive modality that may be useful for patients in whom diagnostic-quality echocardiographic images cannot be obtained. This test is also indicated for patients suspected of having arrhythmogenic right ventricular dysplasia or right ventricular outflow tract ventricular tachycardia. Both are associated with right ventricular structural abnormalities that are better visualized

on MR imaging than by echocardiogram. Exercise testing may detect ischemia or exercise-induced arrhythmias. In some patients, cardiac catheterization may be necessary to diagnose the presence or severity of coronary artery disease or valvular abnormalities. Ultrafast CT scan, ventilation-perfusion scan, or pulmonary angiography is indicated in patients in whom syncope may be due to pulmonary embolus.

In cases of possible cerebrovascular syncope, neuroimaging tests may be indicated, including Doppler ultrasound studies of the carotid and vertebrobasilar systems, MRI, magnetic resonance angiography, and x-ray angiography of the cerebral vasculature (Chap. 364). Electroencephalography is indicated if seizures are suspected.

℞ SYNCOPE

The treatment of syncope is directed at the underlying cause. This discussion will focus on disorders of autonomic control. **Arrhythmias are discussed in Chaps. 225 and 226, valvular heart diseases in Chap. 230, and cerebrovascular disorders in Chap. 364.**

Certain precautions should be taken regardless of the cause of syncope. At the first sign of symptoms, patients should make every effort to avoid injury should they lose consciousness. Patients with frequent episodes, or those who have experienced syncope without warning symptoms, should avoid situations in which sudden loss of consciousness might result in injury (e.g., climbing ladders, swimming alone, operating heavy machinery, driving). Patients should lower their head to the extent possible and preferably should lie down. Lowering the head by bending at the waist should be avoided because it may further compromise venous return to the heart. When appropriate, family members or other close contacts should be educated as to the problem. This will ensure appropriate therapy and may prevent delivery of inappropriate therapy (chest compressions associated with cardiopulmonary resuscitation) that may inflict trauma.

Patients who have lost consciousness should be placed in a position that maximizes cerebral blood flow, offers protection from trauma, and secures the airway. Whenever possible, the patient should be placed supine with the head turned to the side to prevent aspiration and the tongue from blocking the airway. Assessment of the pulse and direct cardiac auscultation may assist in determining if the episode is associated with a bradyarrhythmia or a tachyarrhythmia. Clothing that fits tightly around the neck or waist should be loosened. Peripheral stimulation, such as sprinkling cold water on the face, may be helpful. Patients should not be given anything by mouth or be permitted to rise until the sense of physical weakness has passed.

Patients with vasovagal syncope should be instructed to avoid situations or stimuli that have caused them to lose consciousness and to assume a recumbent position when premonitory symptoms occur. These behavioral modifications alone may be sufficient for patients with infrequent and relatively benign episodes of vasovagal syncope, particularly when loss of consciousness occurs in response to a specific stimulus. Tilt training (standing and leaning against a wall for progressively longer periods each day) has been used with limited success, particularly for patients with orthostatic intolerance. Episodes associated with intravascular volume depletion may be prevented by salt and fluid loading prior to provocative events.

Drug therapy may be necessary when vasovagal syncope is resistant to the above measures, when episodes occur frequently, or when syncope is associated with a significant risk for injury. β-Adrenergic receptor antagonists (metoprolol, 25–50 mg bid; atenolol, 25–50 mg qd; or nadolol, 10–20 mg bid; all starting doses), the most widely used agents, mitigate the increase in myocardial contractility that stimulates left ventricular mechanoreceptors and also block central serotonin receptors. Serotonin reuptake inhibitors (paroxetine, 20–40 mg qd; or sertraline, 25–50 mg qd), appear to be effective for some patients. Bupropion SR (150 mg qd), another antidepressant, has also been used with success. β-Adrenergic receptor antagonists and serotonin reuptake inhibitors are well tolerated and are often used as first-line agents for younger patients. Hydrofludrocortisone (0.1–0.2 mg qd), a mineralocorticoid, promotes sodium retention, volume expansion, and peripheral vasoconstriction by increasing β-receptor sensitivity to endogenous catecholamines. Hydrofludrocortisone is useful for patients with intravascular volume depletion and for those who also have postural hypotension. Proamatine (2.5–10 mg bid or tid), an α-agonist, has been used as a first-line agent for some patients. In a randomized controlled trial, proamatine was more effective than placebo in preventing syncope during an upright tilt-test. However, in some patients, proamatine and hydrofludrocortisone may increase resting supine systemic blood pressure, which may be problematic for those with hypertension.

Disopyramide (150 mg bid), a vagolytic antiarrhythmic drug with negative inotropic properties, and transdermal scopolamine, another vagolytic, have been used to treat vasovagal syncope, as have theophylline and ephedrine. Side effects associated with these drugs have limited their use for this indication. Disopyramide is a type 1A antiarrhythmic drug and should be used with great caution, if at all, in patients who are at risk for ventricular arrhythmias.

Although several clinical trials have suggested that pharmacologic therapy for neurocardiogenic syncope is effective, the few long-term prospective randomized controlled trials have yielded mixed results. In the Prevention of Syncope Trial (POST), metoprolol was ineffective in patients <42 years of age but decreased the incidence of syncope in patients >42, raising the possibility that there may be significant age-related differences in response to pharmacologic therapy.

Studies of permanent pacing for neurocardiogenic syncope have also yielded mixed results. Dual-chamber cardiac pacing may be effective for patients with frequent episodes of vasovagal syncope, particularly for those with prolonged asystole associated with vasovagal episodes. Pacemakers that can be programmed to transiently pace at a high rate (90–100 beats/min) after a profound drop in the patient's intrinsic heart rate are most effective.

Patients with orthostatic hypotension should be instructed to rise slowly and systematically (supine to seated, seated to standing) from the bed or a chair. Movement of the legs prior to rising facilitates venous return from the lower extremities. Whenever possible, medications that aggravate the problem (vasodilators, diuretics, etc.) should be discontinued. Elevation of the head of the bed [20–30 cm (8–12 in.)] and use of compression stockings may help.

Additional therapeutic modalities include salt loading and a variety of pharmacologic agents including sympathomimetic amines, monamine oxidase inhibitors, beta blockers, and levodopa. The treatment of orthostatic hypotension secondary to central or peripheral disorders of the autonomic nervous system is discussed in Chap. 370.

Glossopharyngeal neuralgia is treated with carbamazepine, which is effective for syncope as well as for pain. Patients with carotid sinus hypersensitivity should be instructed to avoid clothing and situations that stimulate carotid sinus baroreceptors. They should turn their entire body, rather than just their head, when looking to the side. Those with intractable syncope due to the cardioinhibitory response to carotid sinus stimulation should undergo permanent pacemaker implantation.

Patients with syncope should be hospitalized when there is a possibility that the episode may have resulted from a life-threatening abnormality or if recurrence with significant injury seems likely. These individuals should be admitted to a bed with continuous electrocardiographic monitoring. Patients who are known to have a normal heart and for whom the history strongly suggests vasovagal or situational syncope may be treated as outpatients if the episodes are neither frequent nor severe.

22 Dizziness and Vertigo

Robert B. Daroff

Dizziness is a common and often vexing symptom. Patients use the term to encompass a variety of sensations, including those that seem semantically appropriate (e.g., lightheadedness, faintness, spinning, giddiness) and those that are misleadingly inappropriate, such as mental confusion, blurred vision, headache, or tingling. Moreover, some individuals with gait disorders caused by peripheral neuropathy, myelopathy, spasticity, parkinsonism, or cerebellar ataxia complain of "dizziness" despite the absence of vertigo or other abnormal cephalic sensations. In this context, the term *dizziness* is being used to describe disturbed ambulation. There may be mild associated lightheadedness, particularly with impaired sensation from the feet or poor vision; this is known as *multiple-sensory-defect dizziness* and occurs in elderly individuals who complain of dizziness only when walking. Decreased position sense (secondary to neuropathy or myelopathy) and poor vision (from cataracts or retinal degeneration) create an overreliance on the aging vestibular apparatus. A less precise but sometimes comforting designation to patients is *benign dysequilibrium of aging*. Thus, a careful history is necessary to determine exactly what a patient who states, "Doctor, I'm dizzy," is experiencing. After eliminating the misleading symptoms or gait disturbance, "dizziness" usually means either *faintness* (presyncope) or *vertigo* (an illusory or hallucinatory sense of movement of the body or environment, most often a feeling of spinning). Operationally, after obtaining the history, dizziness may be classified into three categories: (1) faintness, (2) vertigo, and (3) miscellaneous head sensations.

FAINTNESS

Prior to an actual faint (syncope), there are often prodromal presyncopal symptoms (faintness) reflecting ischemia to a degree insufficient to impair consciousness. These include lightheadedness, "dizziness" without true vertigo, a feeling of warmth, diaphoresis, nausea, and visual blurring occasionally proceeding to blindness. Presyncopal symptoms vary in duration and may increase in severity until loss of consciousness occurs or may resolve prior to loss of consciousness if the cerebral ischemia is corrected. **Faintness and syncope are discussed in detail in Chap. 21.**

VERTIGO

Vertigo is usually due to a disturbance in the vestibular system. The end organs of this system, situated in the bony labyrinths of the inner ears, consist of the three semicircular canals and the otolithic apparatus (utricle and saccule) on each side. The canals transduce angular acceleration, while the otoliths transduce linear acceleration and the static gravitational forces that provide a sense of head position in space. The neural output of the end organs is conveyed to the vestibular nuclei in the brainstem via the eighth cranial nerves. The principal projections from the vestibular nuclei are to the nuclei of cranial nerves III, IV, and VI; spinal cord; cerebral cortex; and cerebellum. The vestibuloocular reflex (VOR) serves to maintain visual stability during head movement and depends on direct projections from the vestibular nuclei to the sixth cranial nerve (abducens) nuclei in the pons and, via the medial longitudinal fasciculus, to the third (oculomotor) and fourth (trochlear) cranial nerve nuclei in the midbrain. These connections account for the nystagmus (to-and-fro oscillation of the eyes) that is an almost invariable accompaniment of vestibular dysfunction. The vestibular nerves and nuclei project to areas of the cerebellum (primarily the flocculus and nodulus) that modulate the VOR. The vestibulospinal pathways assist in the maintenance of postural stability. Projections to the cerebral cortex, via the thalamus, provide conscious awareness of head position and movement.

The vestibular system is one of three sensory systems subserving spatial orientation and posture; the other two are the visual system (retina to occipital cortex) and the somatosensory system that conveys peripheral information from skin, joint, and muscle receptors. The three stabilizing systems overlap sufficiently to compensate (partially or completely) for each other's deficiencies. Vertigo may represent either physiologic stimulation or pathologic dysfunction in any of the three sensory systems.

Physiologic Vertigo This occurs in normal individuals when (1) the brain is confronted with an intersensory mismatch among the three stabilizing sensory systems; (2) the vestibular system is subjected to unfamiliar head movements to which it is unadapted, such as in seasickness; (3) unusual head/neck positions, such as the extreme extension when painting a ceiling; or (4) following a spin. Intersensory mismatch explains carsickness, height vertigo, and the visual vertigo most commonly experienced during motion picture chase scenes; in the latter, the visual sensation of environmental movement is unaccompanied by concomitant vestibular and somatosensory movement cues. *Space sickness*, a frequent transient effect of active head movement in the weightless zero-gravity environment, is another example of physiologic vertigo.

Pathologic Vertigo This results from lesions of the visual, somatosensory, or vestibular systems. Visual vertigo is caused by new or incorrect eyeglasses or by the sudden onset of an extraocular muscle paresis with diplopia; in either instance, central nervous system (CNS) compensation rapidly counteracts the vertigo. Somatosensory vertigo, rare in isolation, is usually due to a peripheral neuropathy or myelopathy that reduces the sensory input necessary for central compensation when there is dysfunction of the vestibular or visual systems.

The most common cause of pathologic vertigo is vestibular dysfunction involving either its end organ (labyrinth), nerve, or central connections. The vertigo is associated with jerk nystagmus and is frequently accompanied by nausea, postural unsteadiness, and gait ataxia. Since vertigo increases with rapid head movements, patients tend to hold their heads still.

LABYRINTHINE DYSFUNCTION This causes severe rotational or linear vertigo. When rotational, the hallucination of movement, whether of environment or self, is directed away from the side of the lesion. The fast phases of nystagmus beat away from the lesion side, and the tendency to fall is toward the side of the lesion, particularly in darkness or with the eyes closed.

Under normal circumstances, when the head is straight and immobile, the vestibular end organs generate a tonic resting firing frequency that is equal from the two sides. With any rotational acceleration, the anatomic positions of the semicircular canals on each side necessitate an increased firing rate from one and a commensurate decrease from the other. This change in neural activity is ultimately projected to the cerebral cortex, where it is summed with inputs from the visual and somatosensory systems to produce the appropriate conscious sense of rotational movement. After cessation of prolonged rotation, the firing frequencies of the two end organs reverse; the side with the initially increased rate decreases, and the other side increases. A sense of rotation in the opposite direction is experienced; since there is no actual head movement, this hallucinatory sensation is *physiologic postrotational vertigo*.

Any disease state that changes the firing frequency of an end organ, producing unequal neural input to the brainstem and ultimately the cerebral cortex, causes vertigo. The symptom can be conceptualized as the cortex inappropriately interpreting the abnormal neural input as indicating actual head rotation. Transient abnormalities produce short-lived symptoms. With a fixed unilateral deficit, central compensatory mechanisms ultimately diminish the vertigo. Since compensation depends on the plasticity of connections between the vestibular nuclei and the cerebellum, patients with brainstem or cerebellar disease have diminished adaptive capacity, and symptoms may persist indefinitely. Compensation is always inadequate for severe fixed bilateral lesions despite normal cerebellar connections; these patients are permanently symptomatic when they move their heads.

Acute unilateral labyrinthine dysfunction is caused by infection, trauma, and ischemia. Often, no specific etiology is uncovered, and the nonspecific terms *acute labyrinthitis*, *acute peripheral vestibulopathy*, or *vestibular neuritis* are used to describe the event. The vertiginous attacks are brief and leave the patient with mild vertigo for several days. Infection with herpes simplex virus type 1 has been implicated. It is impossible to predict whether a patient recovering from the first bout of vertigo will have recurrent episodes.

Labyrinthine ischemia, presumably due to occlusion of the labyrinthine branch of the internal auditory artery, may be the sole manifestation of vertebrobasilar insufficiency (Chap. 364); patients with this syndrome present with the abrupt onset of severe vertigo, nausea, and vomiting, but without tinnitus or hearing loss.

Acute bilateral labyrinthine dysfunction is usually the result of toxins such as drugs or alcohol. The most common offending drugs are the aminoglycoside antibiotics that damage the hair cells of the vestibular end organs and may cause a permanent disorder of equilibrium.

Recurrent unilateral labyrinthine dysfunction, in association with signs and symptoms of cochlear disease (progressive hearing loss and tinnitus), is usually due to Ménière's disease (Chap. 30). When auditory manifestations are absent, the term *vestibular neuronitis* denotes recurrent monosymptomatic vertigo. Transient ischemic attacks of the posterior cerebral circulation (vertebrobasilar insufficiency) only infrequently cause recurrent vertigo without concomitant motor, sensory, visual, cranial nerve, or cerebellar signs (Chap. 364).

Positional vertigo is precipitated by a recumbent head position, either to the right or to the left. Benign paroxysmal positional (or positioning) vertigo (BPPV) of the posterior semicircular canal is particularly common. Although the condition may be due to head trauma, usually no precipitating factors are identified. It generally abates spontaneously after weeks or months. The vertigo and accompanying nystagmus have a distinct pattern of latency, fatigability, and habituation that differs from the less common central positional vertigo (Table 22-1) due to lesions in and around the fourth ventricle. Moreover, the pattern of nystagmus in posterior canal BPPV is distinctive. When supine, with the head turned to the side of the offending ear (bad ear down), the lower eye displays a large-amplitude torsional nystagmus, and the upper eye has a lesser degree of torsion combined with upbeating nystagmus. If the eyes are directed to the upper ear, the vertical nystagmus in the upper eye increases in amplitude. Mild dysequilibrium when upright may also be present.

A *perilymphatic fistula* should be suspected when episodic vertigo is precipitated by Valsalva or exertion, particularly upon a background of a stepwise progressive sensory-neural hearing loss. The condition is usually caused by head trauma or barotrauma or occurs after middle ear surgery.

TABLE 22-1 BENIGN PAROXYSMAL POSITIONAL VERTIGO AND CENTRAL POSITIONAL VERTIGO

Features	BPPV	Central
Latency[a]	3–40 s	None: immediate vertigo and nystagmus
Fatigability[b]	Yes	No
Habituation[c]	Yes	No
Intensity of vertigo	Severe	Mild
Reproducibility[d]	Variable	Good

[a]Time between attaining head position and onset of symptoms.
[b]Disappearance of symptoms with maintenance of offending position.
[c]Lessening of symptoms with repeated trials.
[d]Likelihood of symptom production during any examination session.

TABLE 22-2 FEATURES OF PERIPHERAL AND CENTRAL VERTIGO

Sign or Symptom	Peripheral (Labyrinth)	Central (Brainstem or Cerebellum)
Direction of associated nystagmus	Unidirectional; fast phase opposite lesion[a]	Bidirectional or unidirectional
Purely horizontal nystagmus without torsional component	Uncommon	Common
Vertical or purely torsional nystagmus	Never present	May be present
Visual fixation	Inhibits nystagmus and vertigo	No inhibition
Severity of vertigo	Marked	Often mild
Direction of spin	Toward fast phase	Variable
Direction of fall	Toward slow phase	Variable
Duration of symptoms	Finite (minutes, days, weeks) but recurrent	May be chronic
Tinnitus and/or deafness	Often present	Usually absent
Associated CNS abnormalities	None	Extremely common (e.g., diplopia, hiccups, cranial neuropathies, dysarthria)
Common causes	BPPV, infection (labyrinthitis), Ménière's, neuronitis, ischemia, trauma, toxin	Vascular, demyelinating, neoplasm

[a]In Ménière's disease, the direction of the fast phase is variable.

VERTIGO OF VESTIBULAR NERVE ORIGIN This occurs with diseases that involve the nerve in the petrous bone or the cerebellopontine angle. Although less severe and less frequently paroxysmal, it has many of the characteristics of labyrinthine vertigo. The adjacent auditory division of the eighth cranial nerve is usually affected, which explains the frequent association of vertigo with unilateral tinnitus and hearing loss. The most common cause of eighth cranial nerve dysfunction is a tumor, usually a schwannoma (*acoustic neuroma*) or a meningioma. These tumors grow slowly and produce such a gradual reduction of labyrinthine output that central compensatory mechanisms can prevent or minimize the vertigo; auditory symptoms are the most common manifestations.

CENTRAL VERTIGO Lesions of the brainstem or cerebellum can cause acute vertigo, but associated signs and symptoms usually permit distinction from a labyrinthine etiology (Table 22-2). Occasionally, an acute lesion of the vestibulocerebellum may present with monosymptomatic vertigo indistinguishable from a labyrinthopathy.

Vertigo may be a manifestation of a migraine aura (Chap. 15), but some patients with migraine have episodes of vertigo unassociated with their headaches. Antimigrainous treatment should be considered in such patients with otherwise enigmatic vertiginous episodes.

Vestibular epilepsy, vertigo secondary to temporal lobe epileptic activity, is rare and almost always intermixed with other epileptic manifestations.

PSYCHOGENIC VERTIGO This is sometimes called phobic postural vertigo and is usually a concomitant of panic attacks (Chap. 386) or agoraphobia (fear of large open spaces, crowds, or leaving the safety of home). It should be suspected in patients so "incapacitated" by their symptoms that they adopt a prolonged housebound status. Most patients with organic vertigo attempt to function despite their discomfort. Organic vertigo is accompanied by nystagmus; a psychogenic etiology is almost certain when nystagmus is absent during a vertiginous episode. The symptoms often develop after an episode of acute labyrinthine dysfunction.

MISCELLANEOUS HEAD SENSATIONS

This designation is used, primarily for purposes of initial classification, to describe dizziness that is neither faintness nor vertigo. Cephal-

ic ischemia or vestibular dysfunction may be of such low intensity that the usual symptomatology is not clearly identified. For example, a small decrease in blood pressure or a slight vestibular imbalance may cause sensations different from distinct faintness or vertigo but that may be identified properly by provocative testing techniques (see below). Other causes of dizziness in this category are hyperventilation syndrome, hypoglycemia, and the somatic symptoms of a clinical depression; these patients should all have normal neurologic examinations and vestibular function tests. Depressed patients often insist that the depression is "secondary" to the dizziness.

APPROACH TO THE PATIENT: Dizziness and Vertigo

The most important diagnostic tool is a detailed history focused on the meaning of "dizziness" to the patient. Is it faintness (presyncope)? Is there a sensation of spinning? If either of these is affirmed and the neurologic examination is normal, appropriate investigations for the multiple causes of cephalic ischemia, presyncope (Chap. 21), or vestibular dysfunction are undertaken.

When the meaning of "dizziness" is uncertain, provocative tests may be helpful. These office procedures simulate either cephalic ischemia or vestibular dysfunction. Cephalic ischemia is obvious if the dizziness is duplicated during maneuvers that produce orthostatic hypotension. Further provocation involves the Valsalva maneuver, which decreases cerebral blood flow and should reproduce ischemic symptoms.

Hyperventilation is the cause of dizziness in many anxious individuals; tingling of the hands and face may be absent. Forced hyperventilation for 1 min is indicated for patients with enigmatic dizziness and normal neurologic examinations.

The simplest provocative test for vestibular dysfunction is rapid rotation and abrupt cessation of movement in a swivel chair. This always induces vertigo that the patients can compare with their symptomatic dizziness. The intense induced vertigo may be unlike the spontaneous symptoms, but shortly thereafter, when the vertigo has all but subsided, a lightheadedness supervenes that may be identified as "my dizziness." When this occurs, the dizzy patient, originally classified as suffering from "miscellaneous head sensations," is now properly diagnosed as having mild vertigo secondary to a vestibulopathy.

Patients with symptoms of positional vertigo should be appropriately tested (Table 22-1). A final provocative and diagnostic vestibular test, requiring the use of Frenzel eyeglasses (self-illuminated goggles with convex lenses that blur out the patient's vision, but allow the examiner to see the eyes greatly magnified), is vigorous head shaking in the horizontal plane for about 10 s. If nystagmus develops after the shaking stops, even in the absence of vertigo, vestibular dysfunction is demonstrated. The maneuver can then be repeated in the vertical plane. If the provocative tests establish the dizziness as a vestibular symptom, an evaluation of vestibular vertigo is undertaken.

EVALUATION OF PATIENTS WITH PATHOLOGIC VESTIBULAR VERTIGO

The evaluation depends on whether a central etiology is suspected (Table 22-2). If so, MRI of the head is mandatory. Such an examination is rarely helpful in cases of recurrent monosymptomatic vertigo with a normal neurologic examination. Typical BPPV requires no investigation after the diagnosis is made (Table 22-1).

Vestibular function tests serve to (1) demonstrate an abnormality when the distinction between organic and psychogenic is uncertain, (2) establish the side of the abnormality, and (3) distinguish between peripheral and central etiologies. The standard test is electronystagmography (calorics), where warm and cold water (or air) are applied, in a prescribed fashion, to the tympanic membranes, and the slow-phase velocities of the resultant nystagmus from the two are compared. A velocity decrease from one side indicates hypofunction ("canal paresis"). An inability to induce nystagmus with ice water denotes a "dead labyrinth." Some institutions have the capability of quantitatively determining various aspects of the VOR using computer-driven rotational chairs and precise oculographic recording of the eye movements.

TABLE 22-3 TREATMENT OF VERTIGO

Agent[a]	Dose[b]
Antihistamines	
Meclizine	25–50 mg 3 times/day
Dimenhydrinate	50 mg 1–2 times/day
Promethazine[c]	25–50-mg suppository or IM
Benzodiazepines	
Diazepam	2.5 mg 1–3 times/day
Clonazepam	0.25 mg 1–3 times/day
Phenothiazines	
Prochlorperazine[c]	5 mg IM or 25 mg suppository
Anticholinergic[d]	
Scopolamine transdermal	Patch
Sympathomimetics[d]	
Ephedrine	25 mg/d
Combination preparations[d]	
Ephedrine and promethazine	25 mg/d of each
Exercise therapy	
Repositioning maneuvers[e]	
Vestibular rehabilitation[f]	
Other	
Diuretics or low-salt (1 g/d) diet[g]	
Antimigrainous drugs[h]	
Inner ear surgery[i]	
Glucocorticoids[c]	100 mg/d for 3 days, tapered by 20 mg every 3 days

[a]All listed drugs are U.S. Food and Drug Administration approved, but most are not approved for the treatment of vertigo.
[b]Usual oral (unless otherwise stated) starting dose in adults; maintenance dose can be reached by a gradual increase.
[c]For acute vertigo only.
[d]For motion sickness only.
[e]For benign paroxysmal positional vertigo.
[f]For vertigo other than Ménière's and positional.
[g]For Ménière's disease.
[h]For migraine-associated vertigo (see Chap. 15 for a listing of prophylactic antimigrainous drugs).
[i]For perilymphatic fistula and refractory cases of Ménière's disease.

CNS disease can produce dizzy sensations of all types. Consequently, a neurologic examination is always required even if the history or provocative tests suggest a cardiac, peripheral vestibular, or psychogenic etiology. Any abnormality on the neurologic examination should prompt appropriate neurodiagnostic studies.

Rx VERTIGO

Treatment of acute vertigo consists of bed rest (1–2 days maximum) and vestibular suppressant drugs such as antihistaminics (meclizine, dimenhydrinate, promethazine), tranquilizers with GABA-ergic effects (diazepam, clonazepam), phenothiazines (prochlorperazine), or glucocorticoids **(Table 22-3)**. If the vertigo persists beyond a few days, most authorities advise ambulation in an attempt to induce central compensatory mechanisms, despite the short-term discomfort to the patient. Chronic vertigo of labyrinthine origin may be treated with a systematized vestibular rehabilitation program to facilitate central compensation.

Posterior semicircular canal BPPV, the most common type, is often self-limited but, when persistent, may respond dramatically to specific repositioning exercise programs designed to empty particulate debris from the canal. One of these exercises, the Epley procedure, is graphically demonstrated, in four languages, on a website for use in both physicians' offices and self-treatment (*www.charite.de/ch/neuro/vertigo.html*).

Prophylactic measures to prevent recurrent vertigo are variably effective. Antihistamines are commonly utilized but are of limited value. Ménière's disease may respond to a diuretic or, more effectively, to a very low salt diet (1 g/d). Recurrent episodes of migraine-associated vertigo should be treated with antimigrainous therapy (Chap. 15). There are a variety of inner ear surgical procedures for refractory Ménière's disease, but these are only rarely necessary.

Psychogenic ("phobic postural") vertigo is best treated with cognitive-behavioral therapy.

Helpful websites for both physicians and vertigo patients are: *www.iVertigo.net* and *www.tchain.com*.

Global Considerations There are no epidemiologic studies indicating an increased frequency of specific types of vertigo in different geographical areas. However, whereas BPPV of the posterior semicircular canal is overwhelmingly the most common form of positional vertigo in most countries, there seems to be an unusually large number of reports of horizontal (lateral) BPPV from Italy and Korea.

23 Weakness and Paralysis

Michael J. Aminoff

Normal motor function involves integrated muscle activity that is modulated by the activity of the cerebral cortex, basal ganglia, cerebellum, and spinal cord. Motor system dysfunction leads to weakness or paralysis, which is discussed in this chapter, or to ataxia (Chap. 368) or abnormal movements (Chap. 367). The mode of onset, distribution, and accompaniments of weakness help to suggest its cause.

Weakness is a reduction in the power that can be exerted by one or more muscles. Increased fatigability or limitation in function due to pain or articular stiffness is often confused with weakness by patients. *Increased fatigability* is the inability to sustain the performance of an activity that should be normal for a person of the same age, gender, and size. Increased time is sometimes required for full power to be exerted, and this *bradykinesia* may be misinterpreted as weakness. Severe proprioceptive sensory loss may also lead to complaints of weakness because adequate feedback information about the direction and power of movements is lacking. Finally, *apraxia,* a disorder of planning and initiating a skilled or learned movement unrelated to a significant motor or sensory deficit (Chap. 27), is sometimes mistaken for weakness by inexperienced medical staff.

Paralysis indicates weakness that is so severe that the muscle cannot be contracted at all, whereas *paresis* refers to weakness that is mild or moderate. The prefix "hemi-" refers to one half of the body, "para-" to both legs, and "quadri-" to all four limbs. The suffix "-plegia" signifies severe weakness or paralysis.

Weakness or paralysis is typically accompanied by other neurologic abnormalities that help to indicate the site of the responsible lesion. These include changes in tone, muscle bulk, muscle stretch reflexes, and cutaneous reflexes (Table 23-1).

Tone is the resistance of a muscle to passive stretch. Central nervous system (CNS) abnormalities that cause weakness generally produce *spasticity*, an increase in tone associated with disease of upper motor neurons. Spasticity is velocity-dependent, has a sudden release after reaching a maximum (the "clasp-knife" phenomenon), and predominantly affects the antigravity muscles (i.e., upper-limb flexors and lower-limb extensors). Spasticity is distinct from rigidity and paratonia, two other types of hypertonia. *Rigidity* is increased tone that is present throughout the range of motion (a "lead pipe" or "plastic" stiffness) and affects flexors and extensors equally; it sometimes has a cogwheel quality that is enhanced by voluntary movement of the contralateral limb (reinforcement). Rigidity occurs with certain extrapyramidal disorders such as Parkinson's disease. *Paratonia* (or *gegenhalten*) is increased tone that varies irregularly in a manner that may seem related to the degree of relaxation, is present throughout the range of motion, and affects flexors and extensors equally; it usually results from disease of the frontal lobes. Weakness with *decreased tone* (*flaccidity*) or normal tone occurs with disorders of *motor units.* A motor unit consists of a single lower motor neuron and all of the muscle fibers that it innervates.

Muscle bulk is generally unaffected in patients with upper motor neuron lesions, although mild disuse atrophy may eventually occur. By contrast, atrophy is often conspicuous when a lower motor neuron lesion is responsible for weakness and may also occur with advanced muscle disease.

Muscle stretch (tendon) reflexes are usually increased with upper motor neuron lesions, although they may be decreased or absent for a variable period immediately after onset of an acute lesion. This is usually—but not invariably—accompanied by abnormalities of *cutaneous reflexes* (such as superficial abdominals; Chap. 361) and, in particular, by an extensor plantar (Babinski) response. The muscle stretch reflexes are depressed in patients with lower motor neuron lesions when there is direct involvement of specific reflex arcs. The stretch reflexes are generally preserved in patients with myopathic weakness except in advanced stages, when they are sometimes attenuated. In disorders of the neuromuscular junction, the intensity of the reflexes may be affected by preceding voluntary activity of affected muscles—such activity may lead to enhancement of initially depressed reflexes in Lambert-Eaton myasthenic syndrome and, conversely, to depression of initially normal reflexes in myasthenia gravis (Chap. 381).

The distinction of *neuropathic* (lower motor neuron) from *myopathic* weakness is sometimes difficult clinically, although distal weakness is likely to be neuropathic and symmetric proximal weakness myopathic. *Fasciculations* (visible or palpable twitch within a muscle due to the spontaneous discharge of a motor unit) and early atrophy indicate that weakness is neuropathic.

TABLE 23-1 SIGNS THAT DISTINGUISH ORIGIN OF WEAKNESS

Sign	Upper Motor Neuron	Lower Motor Neuron	Myopathic
Atrophy	None	Severe	Mild
Fasciculations	None	Common	None
Tone	Spastic	Decreased	Normal/decreased
Distribution of weakness	Pyramidal/regional	Distal/segmental	Proximal
Tendon reflexes	Hyperactive	Hypoactive/absent	Normal/hypoactive
Babinski's sign	Present	Absent	Absent

PATHOGENESIS

Upper Motor Neuron Weakness This pattern of weakness results from disorders that affect the upper motor neurons or their axons in the cerebral cortex, subcortical white matter, internal capsule, brainstem, or spinal cord (Fig. 23-1). Such lesions produce weakness through decreased activation of the lower motor neurons. In general, distal muscle groups are affected more severely than proximal ones, and axial movements are spared unless the lesion is severe and bilateral. With corticobulbar involvement, weakness is usually observed only in the lower face and tongue; extraocular, upper facial, pharyngeal, and jaw muscles are almost always spared. With bilateral corticobulbar lesions, *pseudobulbar palsy* often develops: dysarthria, dysphagia, dysphonia, and emotional

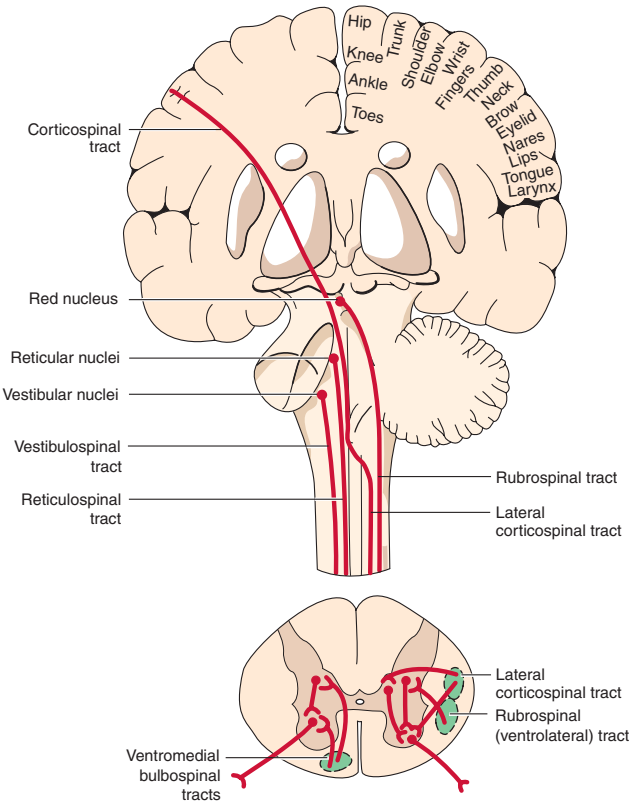

FIGURE 23-1 The corticospinal and bulbospinal upper motor neuron pathways. Upper motor neurons have their cell bodies in layer V of the primary motor cortex (the precentral gyrus, or Brodmann's area 4) and in the premotor and supplemental motor cortex (area 6). The upper motor neurons in the primary motor cortex are somatotopically organized as illustrated on the right side of the figure.

Axons of the upper motor neurons descend through the subcortical white matter and the posterior limb of the internal capsule. Axons of the *pyramidal* or *corticospinal system* descend through the brainstem in the cerebral peduncle of the midbrain, the basis pontis, and the medullary pyramids. At the cervicomedullary junction, most pyramidal axons decussate into the contralateral corticospinal tract of the lateral spinal cord, but 10–30% remain ipsilateral in the anterior spinal cord. Pyramidal neurons make direct monosynaptic connections with lower motor neurons. They innervate most densely the lower motor neurons of hand muscles and are involved in the execution of learned, fine movements. Corticobulbar neurons are similar to corticospinal neurons but innervate brainstem motor nuclei.

Bulbospinal upper motor neurons influence strength and tone but are not part of the pyramidal system. The descending *ventromedial bulbospinal pathways* originate in the tectum of the midbrain (tectospinal pathway), the vestibular nuclei (vestibulospinal pathway), and the reticular formation (reticulospinal pathway). These pathways influence axial and proximal muscles and are involved in the maintenance of posture and integrated movements of the limbs and trunk. The descending *ventrolateral bulbospinal pathways*, which originate predominantly in the red nucleus (rubrospinal pathway), facilitate distal limb muscles. The bulbospinal system is sometimes referred to as the *extrapyramidal upper motor neuron system*. In all figures, nerve cell bodies and axon terminals are shown, respectively, as closed circles and forks.

lability accompany bilateral facial weakness and a brisk jaw jerk. Spasticity accompanies upper motor neuron weakness but may not be present in the acute phase. Upper motor neuron lesions also affect the ability to perform rapid repetitive movements. Such movements are slow and coarse, but normal rhythmicity is maintained. Finger-nose-finger and heel-knee-shin maneuvers are performed slowly but adequately.

Lower Motor Neuron Weakness This pattern results from disorders of cell bodies of lower motor neurons in the brainstem motor nuclei and

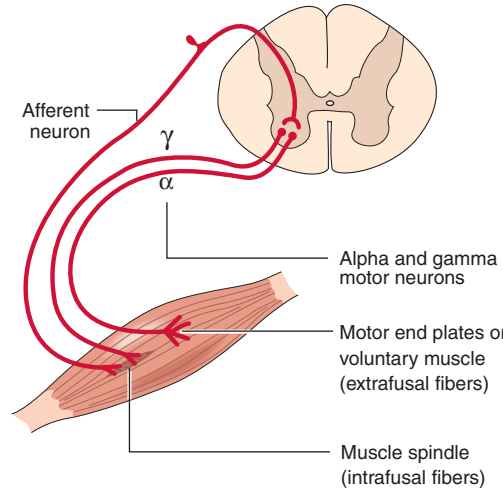

FIGURE 23-2 Lower motor neurons are divided into α and γ types. The larger α motor neurons are more numerous and innervate the extrafusal muscle fibers of the motor unit. Loss of α motor neurons or disruption of their axons produces lower motor neuron weakness. The smaller, less numerous γ motor neurons innervate the intrafusal muscle fibers of the muscle spindle and contribute to normal tone and stretch reflexes. The α motor neuron receives direct excitatory input from corticomotoneurons and primary muscle spindle afferents. The α and γ motor neurons also receive excitatory input from other descending upper motor neuron pathways, segmental sensory inputs, and interneurons. The α motor neurons receive direct inhibition from Renshaw cell interneurons, and other interneurons indirectly inhibit the α and γ motor neurons.

A tendon reflex requires the function of all illustrated structures. A tap on a tendon stretches muscle spindles (which are tonically activated by γ motor neurons) and activates the primary spindle afferent neurons. These stimulate the α motor neurons in the spinal cord, producing a brief muscle contraction, which is the familiar tendon reflex.

the anterior horn of the spinal cord, or from dysfunction of the axons of these neurons as they pass to skeletal muscle (Fig. 23-2). Weakness is due to a decrease in the number of muscle fibers that can be activated, through a loss of α motor neurons or disruption of their connections to muscle. Loss of γ motor neurons does not cause weakness but decreases tension on the muscle spindles, which decreases muscle tone and attenuates the stretch reflexes elicited on examination. An absent stretch reflex suggests involvement of spindle afferent fibers.

When a motor unit becomes diseased, especially in anterior horn cell diseases, it may spontaneously discharge, producing *fasciculations* that may be seen or felt clinically or recorded by electromyography (EMG). When α motor neurons or their axons degenerate, the denervated muscle fibers may also discharge spontaneously. These single muscle fiber discharges, or *fibrillation potentials*, cannot be seen or felt but can be recorded with EMG. If lower motor neuron weakness is present, recruitment of motor units is delayed or reduced, with fewer than normal activated at a given discharge frequency. This contrasts with weakness of upper motor neuron type, in which a normal number of motor units is activated at a given frequency but with a diminished maximal discharge frequency.

Myopathic Weakness Myopathic weakness is produced by disorders of the muscle fibers. Disorders of the neuromuscular junctions also produce weakness, but this is variable in degree and distribution and is influenced by preceding activity of the affected muscle. At a muscle fiber, if the nerve terminal releases a normal number of acetylcholine molecules presynaptically and a sufficient number of postsynaptic acetylcholine receptors are opened, the end plate reaches threshold and thereby generates an action potential that spreads across the muscle fiber membrane and into the transverse tubular system. This electrical excitation activates intracellular events that produce an energy-dependent contraction of the muscle fiber (excitation-contraction coupling).

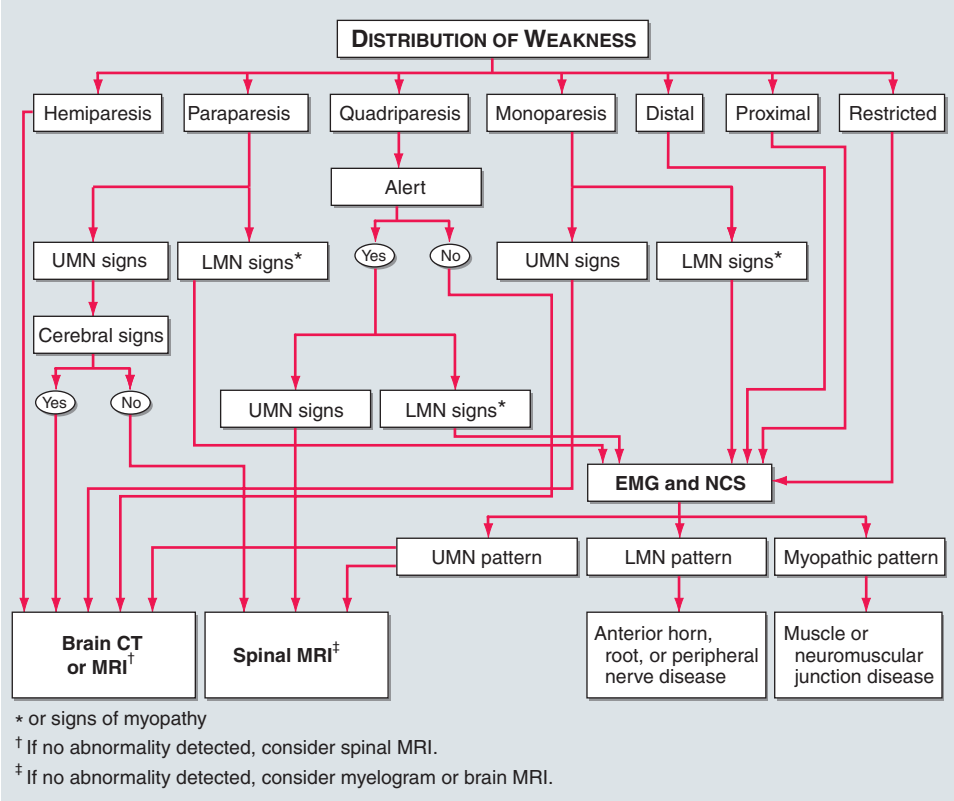

FIGURE 23-3 An algorithm for the initial workup of a patient with weakness. EMG, electromyography; LMN, lower motor neuron; NCS, nerve conduction studies; UMN, upper motor neuron.

Myopathic weakness is produced by a decrease in the number or contractile force of muscle fibers activated within motor units. With muscular dystrophies, inflammatory myopathies, or myopathies with muscle fiber necrosis, the number of muscle fibers is reduced within many motor units. On EMG, the size of each motor unit action potential is decreased, and motor units must be recruited more rapidly than normal to produce the desired power. Some myopathies produce weakness through loss of contractile force of muscle fibers or through relatively selective involvement of the type II (fast) fibers. These may not affect the size of individual motor unit action potentials and are detected by a discrepancy between the electrical activity and force of a muscle.

Diseases of the neuromuscular junction, such as myasthenia gravis, produce weakness in a similar manner, but the loss of muscle fibers is functional (due to inability to activate them) rather than related to muscle fiber loss. The number of muscle fibers that are activated varies over time, depending on the state of rest of the neuromuscular junctions. Thus, fatigable weakness is suggestive of myasthenia gravis or other disorders of the neuromuscular junction.

Hemiparesis Hemiparesis results from an upper motor neuron lesion above the midcervical spinal cord; most such lesions are above the foramen magnum. The presence of other neurologic deficits helps to localize the lesion. Thus, language disorders, cortical sensory disturbances, cognitive abnormalities, disorders of visual-spatial integration, apraxia, or seizures point to a cortical lesion. Homonymous visual field defects reflect either a cortical or a subcortical hemispheric lesion. A "pure motor" hemiparesis of the face, arm, or leg is often due to a small, discrete lesion in the posterior limb of the internal capsule, cerebral peduncle, or upper pons. Some brainstem lesions produce "crossed paralyses," consisting of ipsilateral cranial nerve signs and contralateral hemiparesis (Chap. 364). The absence of cranial nerve signs or facial weakness suggests that a hemiparesis is due to a lesion in the high cervical spinal cord, especially if associated with ipsilateral loss of proprioception and contralateral loss of pain and temperature sense (the Brown-Séquard syndrome).

Acute or episodic hemiparesis usually results from ischemic or hemorrhagic stroke, but may also relate to hemorrhage occurring into brain tumors or as a result of trauma; other causes include a focal structural lesion or inflammatory process as in multiple sclerosis, abscess, or sarcoidosis. Evaluation begins immediately with a CT scan of the brain (Fig. 23-3) and laboratory studies. If the CT is normal and an ischemic stroke is unlikely, MRI of the brain or cervical spine is performed.

Subacute hemiparesis that evolves over days or weeks has an extensive differential diagnosis. A common cause is subdural hematoma, especially in elderly or anticoagulated patients, even when there is no history of trauma. Infectious possibilities include cerebral abscess, fungal granuloma or meningitis, and parasitic infection. Weakness from primary and metastatic neoplasms may evolve over days to weeks. AIDS may present with subacute hemiparesis due to toxoplasmosis or primary CNS lymphoma. Noninfectious inflammatory processes, such as multiple sclerosis or, less commonly, sarcoidosis, merit consideration. If the brain MRI is normal and there are no cortical and hemispheric signs, MRI of the cervical spine should be undertaken.

Chronic hemiparesis that evolves over months is usually due to a neoplasm or vascular malformation, a chronic subdural hematoma, or a degenerative disease. If an MRI of the brain is normal, the possibility of a foramen magnum or high cervical spinal cord lesion should be considered.

Paraparesis An intraspinal lesion at or below the upper thoracic spinal cord level is most commonly responsible, but a paraparesis may also result from lesions at other locations that disturb upper motor neurons (especially parasagittal intracranial lesions) and lower motor neurons [anterior horn cell disorders, cauda equina syndromes due to involvement of nerve roots derived from the lower spinal cord (Chap. 372), and peripheral neuropathies].

Acute paraparesis may not be recognized as due to spinal cord disease at an early stage if the legs are flaccid and areflexic. Usually, however, there is sensory loss in the legs with an upper level on the trunk; a dissociated sensory loss suggestive of a central cord syndrome; or exaggerated stretch reflexes in the legs with normal reflexes in the arms. It is important to image the spinal cord (Fig. 23-3). Compressive lesions (particularly epidural tumor, abscess, or hematoma, but also a prolapsed intervertebral disk and vertebral involvement by malignancy or infection), spinal cord infarction (proprioception is usually spared), an arteriovenous fistula or other vascular anomaly, and transverse myelitis, are among the possible causes (Chap. 372).

Diseases of the cerebral hemispheres that produce acute paraparesis include anterior cerebral artery ischemia (shoulder shrug is also affected), superior sagittal sinus or cortical venous thrombosis, and acute hydrocephalus. If upper motor neuron signs are associated with drowsiness, confusion, seizures, or other hemispheric signs, MRI of the brain should be undertaken.

Paraparesis may result from a cauda equina syndrome, for example, following trauma to the low back, a midline disk herniation, or an intraspinal tumor; although sphincters are affected, hip flexion is often spared, as is sensation over the anterolateral thighs. Rarely, paraparesis is caused by a rapidly evolving anterior horn cell disease (such as po-

liovirus or West Nile virus infection), peripheral neuropathy (such as Guillain-Barré syndrome; Chap. 380) or myopathy (Chap. 382). In such cases, electrophysiologic studies are diagnostically helpful and refocus the subsequent evaluation.

Subacute or chronic paraparesis with spasticity is caused by upper motor neuron disease. When there is associated lower-limb sensory loss and sphincter involvement, a chronic spinal cord disorder is likely (Chap. 372). If an MRI of the spinal cord is normal, MRI of the brain may be indicated. If hemispheric signs are present, a parasagittal meningioma or chronic hydrocephalus is likely and MRI of the brain is the initial test. In the rare situation in which a longstanding paraparesis has a lower motor neuron or myopathic etiology, the localization is usually suspected on clinical grounds by the absence of spasticity and confirmed by EMG and nerve conduction tests.

Quadriparesis or Generalized Weakness Generalized weakness may be due to disorders of the CNS or of the motor unit. Although the terms *quadriparesis* and *generalized weakness* are often used interchangeably, quadriparesis is commonly used when an upper motor neuron cause is suspected, and generalized weakness when a disease of the motor unit is likely. Weakness from CNS disorders is usually associated with changes in consciousness or cognition, with spasticity and brisk stretch reflexes, and with alterations of sensation. Most neuromuscular causes of generalized weakness are associated with normal mental function, hypotonia, and hypoactive muscle stretch reflexes. The major causes of intermittent weakness are listed in Table 23-2. A patient with generalized fatigability without objective weakness may have the chronic fatigue syndrome (Chap. 384).

ACUTE QUADRIPARESIS Acute quadriparesis with onset over minutes may result from disorders of upper motor neurons (e.g., anoxia, hypotension, brainstem or cervical cord ischemia, trauma, and systemic metabolic abnormalities) or muscle (electrolyte disturbances, certain inborn errors of muscle energy metabolism, toxins, or periodic paralyses). Onset over hours to weeks may, in addition to the above, be due to lower motor neuron disorders. Guillain-Barré syndrome (Chap. 380) is the most common lower motor neuron weakness that progresses over days to 4 weeks; the finding of an elevated protein level in the cerebrospinal fluid is helpful but may be absent early in the course.

In obtunded patients, evaluation begins with a CT scan of the brain. If upper motor neuron signs are present but the patient is alert, the initial test is usually an MRI of the cervical cord. If weakness is lower motor neuron, myopathic, or uncertain in origin, the clinical approach begins with blood studies to determine the level of muscle enzymes and electrolytes and an EMG and nerve conduction study.

SUBACUTE OR CHRONIC QUADRIPARESIS When quadriparesis due to upper motor neuron disease develops over weeks, months, or years, the distinction between disorders of the cerebral hemispheres, brainstem, and cervical spinal cord is usually possible clinically. An MRI is obtained of the clinically suspected site of pathology. EMG and nerve conduction studies help to distinguish lower motor neuron disease (which usually presents with weakness that is most profound distally) from myopathic weakness, which is typically proximal.

TABLE 23-2 CAUSES OF EPISODIC GENERALIZED WEAKNESS

1. Electrolyte disturbances, e.g., hypokalemia, hyperkalemia, hypercalcemia, hypernatremia, hyponatremia, hypophosphatemia, hypermagnesemia
2. Muscle disorders
   a. Channelopathies (periodic paralyses)
   b. Metabolic defects of muscle (impaired carbohydrate or fatty acid utilization; abnormal mitochondrial function)
3. Neuromuscular junction disorders
   a. Myasthenia gravis
   b. Lambert-Eaton myasthenic syndrome
4. Central nervous system disorders
   a. Transient ischemic attacks of the brainstem
   b. Transient global cerebral ischemia
   c. Multiple sclerosis

Monoparesis This is usually due to lower motor neuron disease, with or without associated sensory involvement. Upper motor neuron weakness occasionally presents as a monoparesis of distal and nonantigravity muscles. Myopathic weakness is rarely limited to one limb.

ACUTE MONOPARESIS If the weakness is predominantly in distal and nonantigravity muscles and not associated with sensory impairment or pain, focal cortical ischemia is likely (Chap. 364); diagnostic possibilities are similar to those for acute hemiparesis. Sensory loss and pain usually accompany acute lower motor neuron weakness; the weakness is commonly localized to a single nerve root or peripheral nerve within the limb but occasionally reflects plexus involvement. If lower motor neuron weakness is suspected, or the pattern of weakness is uncertain, the clinical approach begins with an EMG and nerve conduction study.

SUBACUTE OR CHRONIC MONOPARESIS Weakness and atrophy that develop over weeks or months are usually of lower motor neuron origin. If they are associated with sensory symptoms, a peripheral cause (nerve, root, or plexus) is likely; in the absence of such symptoms, anterior horn cell disease should be considered. In either case, an electrodiagnostic study is indicated. If weakness is of upper motor neuron type, a discrete cortical (precentral gyrus) or cord lesion may be responsible, and an imaging study is performed of the appropriate site.

Distal Weakness Involvement of two or more limbs distally suggests lower motor neuron or peripheral nerve disease. Acute distal lower limb weakness occurs occasionally from an acute toxic polyneuropathy or cauda equina syndrome. Distal symmetric weakness usually develops over weeks, months, or years and, when associated with numbness, is due to metabolic, toxic, hereditary, degenerative, or inflammatory diseases of peripheral nerves (Chap. 379). Anterior horn cell disease may begin distally but is typically asymmetric and without accompanying numbness (Chap. 369). Rarely, myopathies present with distal weakness (Chap. 382). Electrodiagnostic studies help to localize the disorder (Fig. 23-3).

Proximal Weakness Myopathy often produces symmetric weakness of the pelvic or shoulder girdle muscles (Chap. 382). Diseases of the neuromuscular junction [such as myasthenia gravis (Chap. 381)], may present with symmetric proximal weakness often associated with ptosis, diplopia, or bulbar weakness and fluctuating in severity during the day. Extreme fatigability present in some cases of myasthenia gravis may even suggest episodic weakness, but strength rarely returns fully to normal. In anterior horn cell disease proximal weakness is usually asymmetric, but may be symmetric if familial. Numbness does not occur with any of these diseases. The evaluation usually begins with determination of the serum creatine kinase level and electrophysiologic studies.

Weakness in a Restricted Distribution Weakness may not fit any of the above patterns, being limited, for example, to the extraocular, hemifacial, bulbar, or respiratory muscles. If unilateral, restricted weakness is usually due to lower motor neuron or peripheral nerve disease, such as in a facial palsy (Chap. 379) or an isolated superior oblique muscle paresis (Chap. 382). Weakness of part of a limb is usually due to a peripheral nerve lesion such as carpal tunnel syndrome or another entrapment neuropathy. Relatively symmetric weakness of extraocular or bulbar muscles is usually due to a myopathy (Chap. 382) or neuromuscular junction disorder (Chap. 381). Bilateral facial palsy with areflexia suggests Guillain-Barré syndrome (Chap. 380). Worsening of relatively symmetric weakness with fatigue is characteristic of neuromuscular junction disorders. Asymmetric bulbar weakness is usually due to motor neuron disease. Weakness limited to respiratory muscles is uncommon and is usually due to motor neuron disease, myasthenia gravis, or polymyositis/dermatomyositis (Chap. 383).

ACKNOWLEDGMENT

Richard K. Olney, MD, was the author of this chapter in previous editions, and his contributions in the last three editions of Harrison's are appreciated.

24 Gait and Balance Disorders

Lewis Sudarsky

PREVALENCE, MORBIDITY, AND MORTALITY

Gait and balance problems are common in the elderly and contribute to the risk of falls and injury. Gait disorders have been described in 15% of individuals over the age of 65. By age 80, one person in four will use a mechanical aid to assist ambulation. Among those 85 and older, the prevalence of gait abnormality approaches 40%. In epidemiologic studies, gait disorders are consistently identified as a major risk factor for falls and injury.

A substantial number of older persons report insecure balance and experience falls and fear of falling. Prospective studies indicate that 20–30% of those over age 65 fall each year, and the proportion is even higher in hospitalized elderly and nursing home patients. Each year 8% of individuals >75 suffer a serious fall-related injury. Hip fractures often result in hospitalization and nursing home admission. For each person who is physically disabled, there are others whose functional independence is constrained by anxiety and fear of falling. Nearly one in five of elderly individuals voluntarily limit their activity because of fear of falling. With loss of ambulation, there is a diminished quality of life and increased morbidity and mortality.

ANATOMY AND PHYSIOLOGY

Upright bipedal gait depends on the successful integration of postural control and locomotion. These functions are widely distributed in the central nervous system. The biomechanics of bipedal walking are complex, and the performance is easily compromised by injury at any level. Command and control centers in the brainstem, cerebellum, and forebrain modify the action of spinal pattern generators to promote stepping. While a form of "fictive locomotion" can be elicited from quadrupedal animals after spinal transection, this capacity is limited in primates. Step generation in primates is dependent on locomotor centers in the pontine tegmentum, midbrain, and subthalamic region. Locomotor synergies are executed through the reticular formation and descending pathways in the ventromedial spinal cord. Cerebral control provides a goal and purpose for walking and is involved in avoidance of obstacles and adaptation of locomotor programs to context and terrain.

Postural control requires the maintenance of the center of mass over the base of support through the gait cycle. Unconscious postural adjustments maintain standing balance: long latency responses are measurable in the leg muscles, beginning 110 ms after a perturbation. Forward motion of the center of mass provides propulsive force for stepping, but failure to maintain the center of mass within stability limits results in falls. The anatomic substrate for dynamic balance has not been well defined, but the vestibular nucleus and midline cerebellum contribute to balance control in animals. Human patients with damage to these structures have impaired balance with standing and walking.

Standing balance depends on good quality sensory information about the position of the body center with respect to the environment, support surface, and gravitational forces. Sensory information for postural control is primarily generated by the visual system, the vestibular system, and by proprioceptive receptors in the muscle spindles and joints. A healthy redundancy of sensory afferent information is generally available, but loss of two of the three pathways is sufficient to compromise standing balance. Balance disorders in older individuals sometimes result from multiple insults in the peripheral sensory systems (e.g., visual loss, vestibular deficit, peripheral neuropathy), critically degrading the quality of afferent information needed for balance stability.

Older patients with mental status abnormalities and dementia from neurodegenerative diseases appear to be particularly prone to falls and injury. Frailty, muscle weakness, and deconditioning undoubtedly contribute to the risk. There is a growing literature on the use of attentional resources to manage locomotion. The ability to walk while attending to a cognitive task (dual tasking) may be particularly compromised in older adults with a history of falls. Walking is generally considered to be unconscious and automatic, but older patients with deficits in executive function may be unable to manage the attention needed for dynamic balance when distracted.

DISORDERS OF GAIT

The heterogeneity of gait disorders observed in clinical practice reflects the large network of neural systems involved in the task. There is the potential for abnormalities to develop, and walking is vulnerable to neurologic disease at every level. Gait disorders have been classified descriptively, based on the abnormal physiology and biomechanics. One problem with this approach is that many failing gaits look fundamentally similar. This overlap reflects common patterns of adaptation to threatened balance stability and declining performance. *The gait disorder observed clinically must be viewed as the product of a neurologic deficit and a functional adaptation.* Unique features of the failing gait are often overwhelmed by the adaptive response. Some of the common patterns of abnormal gait are summarized below. Gait disorders can also be classified by etiology, as listed in Table 24-1.

Cautious Gait The term *cautious gait* is used to describe the patient who walks with an abbreviated stride and lowered center of mass, as if walking on a slippery surface. This disorder is both common and nonspecific. It is, in essence, an adaptation to a perceived postural threat. A fear of falling may be associated. In one study, this disorder was observed in more than one-third of older patients with a higher level gait disturbance. Physical therapy often improves walking to the degree that follow-up observation may reveal a more specific underlying disorder.

Stiff-Legged Gait Spastic gait is characterized by stiffness in the legs, an imbalance of muscle tone, and a tendency to circumduct and scuff the feet. The disorder reflects compromise of corticospinal command and overactivity of spinal reflexes. The patient may walk on his or her toes. In extreme instances, the legs cross due to increased tone in the adductors. Upper motor neuron signs are present on physical examination. Shoes often reflect an uneven pattern of wear across the outside. The disorder may be cerebral or spinal in origin.

Myelopathy from cervical spondylosis is a common cause of spastic or spastic-ataxic gait. Demyelinating disease and trauma are the leading causes of myelopathy in younger patients. In a chronic progressive myelopathy of unknown cause, workup with laboratory and imaging tests may establish a diagnosis of multiple sclerosis. A family history should suggest hereditary spastic paraplegia (HSP). Genetic testing is now available for some of the common HSP mutations. Tropical spastic paraparesis related to the retrovirus HTLV-I is endemic in parts of the Caribbean and South America. A structural lesion, such as tumor or spinal vascular malformation, should be excluded with appropriate testing. Spinal cord disorders are discussed in detail in Chap. 372.

With cerebral spasticity asymmetry is common, involvement of the upper extremities is usually observed, and dysarthria is often an associated feature. Common causes include vascular disease (stroke), multiple sclerosis, and perinatal injury to the nervous system (cerebral palsy).

Other stiff-legged gaits include dystonia (Chap. 382) and stiff-person syndrome. Dystonia is a disorder characterized by sustained muscle con-

tractions, resulting in repetitive twisting movements and abnormal posture. It often has a genetic basis. Dystonic spasms produce plantar flexion and inversion of the feet, sometimes with torsion of the trunk. In autoimmune stiff-person syndrome, there is exaggerated lordosis of the lumbar spine and overactivation of antagonist muscles, which restricts trunk and lower limb movement and results in a wooden or fixed posture.

Parkinsonism and Freezing Gait Parkinson's disease (Chap. 366) is common, affecting 1% of the population >55. The stooped posture and shuffling gait are characteristic and distinctive features. Patients sometimes accelerate (festinate) with walking or display retropulsion. There may be difficulty with gait initiation (freezing) and a tendency to turn en bloc. Imbalance and falls may develop as the disease progresses over years. Other progressive neurodegenerative disorders may also involve a freezing gait; these include progressive supranuclear palsy, multiple system atrophy, corticobasal degeneration, and primary pallidal degeneration. Such patients with atypical parkinsonian syndromes frequently present with axial stiffness, postural instability, and a shuffling gait but tend to lack the characteristic pill-rolling tremor of Parkinson's disease. Falls within the first year suggest the possibility of progressive supranuclear palsy.

Hyperkinetic movement disorders also produce characteristic and recognizable disturbances in gait. In Huntington's disease (Chap. 367), the unpredictable occurrence of choreic movements gives the gait a dancing quality. Tardive dyskinesia is the cause of many odd, stereotypic gait disorders seen in chronic psychiatric patients.

Frontal Gait Disorder Frontal gait disorder, sometimes known as "gait apraxia," is common in the elderly and has a variety of causes. Typical features include a wide base of support, short stride, shuffling along the floor, and difficulty with starts and turns. Many patients exhibit difficulty with gait initiation, descriptively characterized as the "slipping clutch" syndrome or "gait ignition failure." The term *lower body parkinsonism* is also used to describe such patients. Strength is generally preserved, and patients are able to make stepping movements when not standing and maintaining balance at the same time. This disorder is a higher level motor control disorder, as opposed to an apraxia.

The most common cause of frontal gait disorder is vascular disease, particularly subcortical small-vessel disease. Lesions are frequently found in the deep frontal white matter and centrum ovale. Gait disorder may be the salient feature in hypertensive patients with ischemic lesions of the deep hemisphere white matter (Binswanger's disease). The clinical syndrome includes mental change (variable in degree), dysarthria, pseudobulbar affect (emotional disinhibition), increased tone, and hyperreflexia in the lower limbs.

Communicating hydrocephalus in the adult also presents with a gait disorder of this type. Other features of the diagnostic triad (mental change, incontinence) may be absent in the initial stages. MRI demonstrates ventricular enlargement, an enlarged flow void about the aqueduct, and a variable degree of periventricular white matter change. A lumbar puncture or dynamic test is necessary to confirm the presence of hydrocephalus.

Cerebellar Gait Ataxia Disorders of the cerebellum have a dramatic impact on gait and balance. Cerebellar gait ataxia is characterized by a wide base of support, lateral instability of the trunk, erratic foot placement, and decompensation of balance when attempting to walk tandem. Difficulty maintaining balance when turning is often an early feature. Patients are unable to walk tandem heel to toe, and display truncal sway in narrow-based or tandem stance. They show considerable variation in their tendency to fall in daily life.

Causes of cerebellar ataxia in older patients include stroke, trauma, tumor, and neurodegenerative disease, including multiple system atrophy (Chaps. 366 and 370) and various forms of hereditary cerebellar degeneration (Chap. 368). MRI demonstrates the extent and topography of cerebellar atrophy. A short expansion at the site of the fragile X mutation (fragile X pre-mutation) has been associated with gait ataxia in older men. Alcoholic cerebellar degeneration can be screened by history and often confirmed by MRI.

Sensory Ataxia As reviewed above, balance depends on high-quality afferent information from the visual and the vestibular systems and proprioception. When this information is lost or degraded, balance during locomotion is impaired and instability results. The sensory ataxia of tabetic neurosyphilis is a classic example. The contemporary equivalent is the patient with neuropathy affecting large fibers. Vitamin B_{12} deficiency is a treatable cause of large-fiber sensory loss in the spinal cord and peripheral nervous system. Joint position and vibration sense are diminished in the lower limbs. The stance in such patients is destabilized by eye closure; they often look down at their feet when walking and do poorly in the dark. Patients have been described with imbalance from bilateral vestibular loss, caused by disease or by exposure to ototoxic drugs. Table 24-2 compares sensory ataxia with cerebellar ataxia and frontal gait disorder. Some patients exhibit a syndrome of imbalance from the combined effect of multiple sensory deficits. Such patients, often elderly and diabetic, have disturbances in proprioception, vision, and vestibular sense that impair postural support.

Neuromuscular Disease Patients with neuromuscular disease often have an abnormal gait, occasionally as a presenting feature. With distal weakness (peripheral neuropathy) the step height is increased to compensate for foot drop, and the sole of the foot may slap on the floor during weight acceptance. Neuropathy may be associated with a degree of sensory imbalance, as described above. Patients with myopathy or muscular dystrophy more typically exhibit proximal weakness. Weakness of the hip girdle may result in a degree of excess pelvic sway during locomotion.

Toxic and Metabolic Disorders Alcohol intoxication is the most common cause of acute walking difficulty. Chronic toxicity from medications and metabolic disturbances can impair motor function and gait. Mental status changes may be present, and examination may reveal asterixis or myoclonus. Static equilibrium is disturbed, and such patients are easily thrown off balance. Disequilibrium is particularly evident in patients with chronic renal disease and those with hepatic failure, in whom asterixis may impair postural support. Sedative drugs, especially neuroleptics and long-acting benzodiazepines, affect postural control and increase the risk for falls. These disorders are important to recognize because they are often treatable.

Psychogenic Gait Disorder Psychogenic disorders are common in outpatient practice, and the presentation often involves gait. Some patients with extreme anxiety or phobia walk with exaggerated caution with abduction of the arms, as if walking on ice. This inappropriately overcautious gait differs in degree from the gait of the patient who is insecure and making adjustments for imbalance. Depressed patients exhibit primarily slowness, a manifestation of psychomotor retardation, and lack of purpose in their stride. Hysterical gait disorders are among the most spectacular encountered. Odd gyrations of posture with wastage of muscular energy (astasia-abasia), extreme slow mo-

TABLE 24-2 FEATURES OF CEREBELLAR ATAXIA, SENSORY ATAXIA, AND FRONTAL GAIT DISORDERS

	Cerebellar Ataxia	Sensory Ataxia	Frontal Gait
Base of support	Wide-based	Narrow base, looks down	Wide-based
Velocity	Variable	Slow	Very slow
Stride	Irregular, lurching	Regular with path deviation	Short, shuffling
Romberg	+/–	Unsteady, falls	+/–
Heel→ shin	Abnormal	+/–	Normal
Initiation	Normal	Normal	Hesitant
Turns	Unsteady	+/–	Hesitant, multistep
Postural instability	+	+++	++++
Falls	Late event	Frequent	Poor postural synergies getting up from a chair Frequent

tion, and dramatic fluctuations over time may be observed in patients with somatoform disorders and conversion reaction.

APPROACH TO THE PATIENT: Slowly Progressive Disorder of Gait

When reviewing the history it is helpful to inquire about the onset and progression of disability. Initial awareness of an unsteady gait often follows a fall. Stepwise evolution or sudden progression suggest vascular disease. Gait disorder may be associated with urinary urgency and incontinence, particularly in patients with cervical spine disease or hydrocephalus. It is always important to review the use of alcohol and medications that affect gait and balance. Information on localization derived from the neurologic examination can be helpful to narrow the list of possible diagnoses.

Gait observation provides an immediate sense of the patient's degree of disability. Characteristic patterns of abnormality are sometimes observed, though failing gaits often look fundamentally similar. Cadence (steps/min), velocity, and stride length can be recorded by timing a patient over a fixed distance. Watching the patient get out of a chair provides a good functional assessment of balance.

Brain imaging studies may be informative in patients with an undiagnosed disorder of gait. MRI is sensitive for cerebral lesions of vascular or demyelinating disease and is a good screening test for occult hydrocephalus. Patients with recurrent falls are at risk for subdural hematoma. Many elderly patients with gait and balance difficulty have white matter abnormalities in the periventricular region and centrum semiovale. While these lesions may be an incidental finding, a substantial burden of white matter disease will ultimately impact cerebral control of locomotion.

DISORDERS OF BALANCE

Balance is the ability to maintain equilibrium: a state in which opposing physical forces cancel. In physiology, this is taken to mean the ability of the organism to control the center of mass with respect to gravity and the support surface. In reality, no one is aware of what or where the center of mass is, but everyone, including gymnasts, figure skaters, and platform divers, move so as to manage it. Imbalance implies a disturbance of equilibrium. Disorders of balance present with difficulty maintaining posture standing and walking and with a subjective sense of disequilibrium, a form of dizziness.

The cerebellum and vestibular system organize antigravity responses needed to maintain the upright posture. As reviewed above, these responses are physiologically complex, and the anatomic representation is not well understood. Failure, resulting in disequilibrium, can occur at several levels: cerebellar, vestibular, somatosensory, and higher level disequilibrium. Patients with hereditary ataxia or alcoholic cerebellar degeneration do not generally complain of dizziness, but balance is visibly impaired. Neurologic examination will reveal a variety of cerebellar signs. Postural compensation may prevent falls early on, but falls inevitably occur with disease progression. The progression of a neurodegenerative ataxia is often measured by the number of years to loss of stable ambulation. Vestibular disorders have symptoms and signs in three categories: vertigo, the subjective appreciation or illusion of movement; nystagmus, a vestibulo-oculomotor sign; and poor balance, an impairment of vestibulo-spinal function. Not every patient has all manifestations. Patients with vestibular deficits related to ototoxic drugs may lack vertigo or obvious nystagmus, but balance is impaired on standing and walking, and the patient cannot navigate in the dark. Laboratory testing is available to explore vestibulo-oculomotor and vestibulo-spinal deficits.

Somatosensory deficits also produce imbalance and falls. There is often a subjective sense of insecure balance and fear of falling. Postural control is compromised by eye closure (Romberg's sign); these patients also have difficulty navigating in the dark. A dramatic example is the patient with autoimmune subacute sensory neuropathy, sometimes a paraneoplastic disorder (Chap. 97). Compensatory strategies enable such patients to walk in the virtual absence of proprioception, but the task requires active visual monitoring. Patients with higher level disorders of equilibrium have difficulty maintaining balance in daily life and may present with falls. There may be reduced awareness of balance impairment. Classic examples include patients with progressive supranuclear palsy and normal pressure hydrocephalus. Patients on sedating medications are also in this category. In prospective studies, cognitive impairment and the use of sedative medications substantially increase the risk for falls.

TABLE 24-3 RISK FACTORS FOR FALLS, A META-ANALYSIS: SUMMARY OF SIXTEEN CONTROLLED STUDIES

Risk Factor	Mean RR (OR)	Range
Weakness	4.9	1.9–10.3
Balance deficit	3.2	1.6–5.4
Gait disorder	3.0	1.7–4.8
Visual deficit	2.8	1.1–7.4
Mobility limitation	2.5	1.0–5.3
Cognitive impairment	2.4	2.0–4.7
Impaired functional status	2.0	1.0–3.1
Postural hypotension	1.9	1.0–3.4

Note: RR, relative risks from prospective studies; OR, odds ratios from retrospective studies.

FALLS

Falls are a common event, particularly among the elderly. Modest changes in balance function have been described in fit older subjects as a result of normal aging. Subtle deficits in sensory systems, attention, and motor reaction time contribute to the risk, and environmental hazards abound. Epidemiologic studies have identified a number of risk factors for falls, summarized in Table 24-3. A fall is not a neurologic problem, nor reason for referral to a specialist, but there are circumstances in which neurologic evaluation is appropriate. In a classic study, 90% of fall events occurred among 10% of individuals, a group known as *recurrent fallers*. Some of these are frail older persons with chronic diseases. Recurrent falls sometimes indicate the presence of serious balance impairment. Syncope, seizure, or falls related to loss of consciousness require appropriate evaluation and treatment (Chaps. 21 and 363).

The descriptive classification of falls is as difficult as the classification of gait disorders, for many of the same reasons. Postural control systems are widely distributed, and a number of disease-related abnormalities occur. Unlike gait problems that are apparent on observation, falls are rarely observed in the office. The patient and family may have limited information about what triggered the fall. Injuries can complicate the physical examination. While there is no standard nosology of falls, common patterns can be identified.

Slipping, Tripping, and "Mechanical Falls" Slipping on icy pavement, tripping on obstacles, and falls related to obvious environmental factors are often termed *mechanical falls*. They occasionally occur in healthy individuals with good balance compensation. Frequent tripping falls raise suspicion about an underlying neurologic deficit. Patients with spasticity, leg weakness, or foot drop experience tripping falls.

Weakness and Frailty Patients who lack strength in antigravity muscles have difficulty rising from a chair, fatigue easily when walking, and have difficulty maintaining their balance after a perturbation. These patients are often unable to get up after a fall and may be on the floor for an hour or more before help arrives. Deconditioning of this sort is often treatable. Resistance strength training can increase muscle mass and leg strength in people in their 80s and 90s.

Drop Attacks and Collapsing Falls Drop attacks are sudden collapsing falls without loss of consciousness. Patients who collapse from lack of postural tone present a diagnostic challenge. The patient may report that his or her legs just gave out underneath; the family may describe the patient as "collapsing in a heap." Orthostatic hypotension may be a factor in some such falls. Asterixis or epilepsy may impair postural support. A colloid cyst of the third ventricle can present with intermittent obstruction

of the foramen of Monroe, resulting in a drop attack. While collapsing falls are more common in older patients with vascular risk factors, they should not be confused with vertebrobasilar ischemic attacks.

Toppling Falls Some patients maintain tone in antigravity muscles but fall over like a tree trunk, as if postural defenses had disengaged. There may be a consistent direction to such falls. The patient with cerebellar pathology may lean and topple over toward the side of the lesion. Patients with lesions of the vestibular system or its central pathways may experience lateral pulsion and toppling falls. Patients with progressive supranuclear palsy often fall over backwards. Falls of this nature occur in patients with advanced Parkinson's disease once postural instability has developed.

Gait Freezing Another fall pattern in Parkinson's disease and related disorders is the fall due to freezing of gait. The feet stick to the floor and the center of mass keeps moving, resulting in a disequilibrium from which the patient cannot recover. This can result in a forward fall. Gait freezing can also occur as the patient attempts to turn and change direction. Similarly, the patient with Parkinson's disease and festinating gait may find his feet unable to keep up, resulting in a forward fall.

Falls Related to Sensory Deficit Patients with somatosensory, visual, or vestibular deficits are prone to falls. These patients have particular difficulty dealing with poor illumination or walking on uneven ground. These patients often express subjective imbalance, apprehension, and fear of falling. Deficits in joint position and vibration sense are apparent on physical examination.

Rx INTERVENTIONS TO REDUCE THE RISK OF FALLS AND INJURY

Efforts should be made to define the etiology of the gait disorder and mechanism of the falls. Standing blood pressure should be recorded. Specific treatment may be possible, once a diagnosis is established. Therapeutic intervention is often recommended for older patients at substantial risk for falls, even if no neurologic disease is identified. A home visit to look for environmental hazards can be helpful. A variety of modifications may be recommended to improve safety, including improved lighting and the installation of grab bars and nonslip surfaces.

Rehabilitation interventions attempt to improve muscle strength and balance stability and to make the patient more resistant to injury. High-intensity resistance strength training with weights and machines is useful to improve muscle mass, even in frail older patients. Improvements are realized in posture and gait, which should translate to reduced risk of falls and injury. The goal of sensory balance training is to improve balance stability. Measurable gains can be achieved in a few weeks of training, and benefits can be maintained over 6 months by a 10- to 20-min home exercise program. This strategy is particularly successful in patients with vestibular and somatosensory balance disorders. The Yale Health and Aging study used a strategy of targeted, multiple risk factor abatement to reduce falls in the elderly. Prescription medications were adjusted, and home-based exercise programs were tailored to the patient's need, based on an initial geriatric assessment. The program realized a 44% reduction in falls, compared with a control group of patients who had periodic social visits.

25 Numbness, Tingling, and Sensory Loss

Michael J. Aminoff, Arthur K. Asbury

Normal somatic sensation reflects a continuous monitoring process, little of which reaches consciousness under ordinary conditions. By contrast, disordered sensation, particularly when experienced as painful, is alarming and dominates the sufferer's attention. Physicians should be able to recognize abnormal sensations by how they are described, know their type and likely site of origin, and understand their implications.

POSITIVE AND NEGATIVE SYMPTOMS

Abnormal sensory symptoms may be divided into two categories, positive and negative. The prototypical positive symptom is tingling (pins-and-needles); other positive sensory phenomena include altered sensations that are described as pricking, bandlike, lightning-like shooting feelings (lancinations), aching, knifelike, twisting, drawing, pulling, tightening, burning, searing, electrical, or raw feelings. Such symptoms are often painful.

Positive phenomena usually result from trains of impulses generated at sites of lowered threshold or heightened excitability along a peripheral or central sensory pathway. The nature and severity of the abnormal sensation depend on the number, rate, timing, and distribution of ectopic impulses and the type and function of nervous tissue in which they arise. Because positive phenomena represent excessive activity in sensory pathways, they are not necessarily associated with a sensory deficit (loss) on examination.

Negative phenomena represent loss of sensory function and are characterized by diminished or absent feeling, often experienced as numbness, and by abnormal findings on sensory examination. In disorders affecting peripheral sensation, it is estimated that at least half the afferent axons innervating a given site are lost or functionless before a sensory deficit can be demonstrated by clinical examination. This threshold varies according to how rapidly function is lost in sensory nerve fibers. If the rate of loss is slow, lack of cutaneous feeling may be unnoticed by the patient and difficult to demonstrate on examination, even though few sensory fibers are functioning; if rapid, both positive and negative phenomena are usually conspicuous. Subclinical degrees of sensory dysfunction may be revealed by sensory nerve conduction studies or somatosensory evoked potentials (**Chap. e31**).

Whereas sensory symptoms may be either positive or negative, sensory signs on examination are always a measure of negative phenomena.

TERMINOLOGY

Words used to characterize sensory disturbance are descriptive and based on convention. Paresthesias and dysesthesias are general terms used to denote positive sensory symptoms. The term *paresthesias* typically refers to tingling or pins-and-needles sensations but may include a wide variety of other abnormal sensations, except pain; it sometimes implies that the abnormal sensations are perceived spontaneously. The more general term *dysesthesia*s denotes all types of abnormal sensations, including painful ones, regardless of whether a stimulus is evident.

Another set of terms refers to sensory abnormalities found on examination. *Hypesthesia* or *hypoesthesia* refers to a reduction of cutaneous sensation to a specific type of testing such as pressure, light touch, and warm or cold stimuli; *anesthesia,* to a complete absence of skin sensation to the same stimuli plus pinprick; and *hypalgesia* or *analgesia* to reduced or absent pain perception (nociception), such as perception of the pricking quality elicited by a pin. *Hyperesthesia* means pain or increased sensitivity in response to touch. Similarly, *allodynia* describes the situation in

which a nonpainful stimulus, once perceived, is experienced as painful, even excruciating. An example is elicitation of a painful sensation by application of a vibrating tuning fork. *Hyperalgesia* denotes severe pain in response to a mildly noxious stimulus, and *hyperpathia*, a broad term, encompasses all the phenomena described by hyperesthesia, allodynia, and hyperalgesia. With hyperpathia, the threshold for a sensory stimulus is increased and perception is delayed, but once felt, is unduly painful.

Disorders of deep sensation, arising from muscle spindles, tendons, and joints, affect proprioception (position sense). Manifestations include imbalance (particularly with eyes closed or in the dark), clumsiness of precision movements, and unsteadiness of gait, which are referred to collectively as *sensory ataxia*. Other findings on examination usually, but not invariably, include reduced or absent joint position and vibratory sensibility and absent deep tendon reflexes in the affected limbs. Romberg's sign is positive, which means that the patient sways markedly or topples when asked to stand with feet close together and eyes closed. In severe states of deafferentation involving deep sensation, the patient cannot walk or stand unaided or even sit unsupported. Continuous involuntary movements (*pseudoathetosis*) of the outstretched hands and fingers occur, particularly with eyes closed.

ANATOMY OF SENSATION

Cutaneous afferent innervation is conveyed by a rich variety of receptors, both naked nerve endings (nociceptors and thermoreceptors) and encapsulated terminals (mechanoreceptors). Each type of receptor has its own set of sensitivities to specific stimuli, size and distinctness of receptive fields, and adaptational qualities. Much of the knowledge about these receptors has come from the development of techniques to study single intact nerve fibers intraneurally in awake, unanesthetized human subjects. It is possible not only to record from but also to stimulate single fibers in isolation. A single impulse, whether elicited by a natural stimulus or evoked by electrical microstimulation in a large myelinated afferent fiber may be both perceived and localized.

Afferent fibers of all sizes in peripheral nerve trunks traverse the dorsal roots and enter the dorsal horn of the spinal cord (Fig. 25-1). From there the smaller fibers take a different route to the parietal cortex than the larger fibers. The polysynaptic projections of the smaller fibers (unmyelinated and small myelinated), which subserve mainly nociception, temperature sensibility, and touch, cross and ascend in the opposite anterior and lateral columns of the spinal cord, through the brainstem, to the ventral posterolateral (VPL) nucleus of the thalamus, and ultimately project to the postcentral gyrus of the parietal cortex (Chap. 12). This is the *spinothalamic pathway* or *anterolateral system*. The larger fibers, which subserve tactile and position sense and kinesthesia, project rostrally in the posterior column on the same side of the spinal cord and make their first synapse in the gracile or cuneate nucleus of the lower medulla. Axons of the second-order neuron decussate and ascend in the medial lemniscus located medially in the medulla and in the tegmentum of the pons and midbrain and synapse in the VPL nucleus; the third-order neurons project to parietal cortex. This large-fiber system is referred to as the *posterior column–medial lemniscal pathway* (lemniscal, for short). Note that although the lemniscal and the anterolateral pathways both project up the spinal cord to the thalamus, it is the (crossed) anterolateral pathway that is referred to as the *spinothalamic tract*, by convention.

Although the fiber types and functions that make up the spinothalamic and lemniscal systems are relatively well known, many other fibers, particularly those associated with touch, pressure, and position sense, ascend in a diffusely distributed pattern both ipsilaterally and contralaterally in the anterolateral quadrants of the spinal cord. This explains why a complete lesion of the posterior columns of the spinal cord may be associated with little sensory deficit on examination.

EXAMINATION OF SENSATION

The main components of the sensory examination are tests of primary sensation (pain, touch, vibration, joint position, and thermal sensation; Table 25-1).

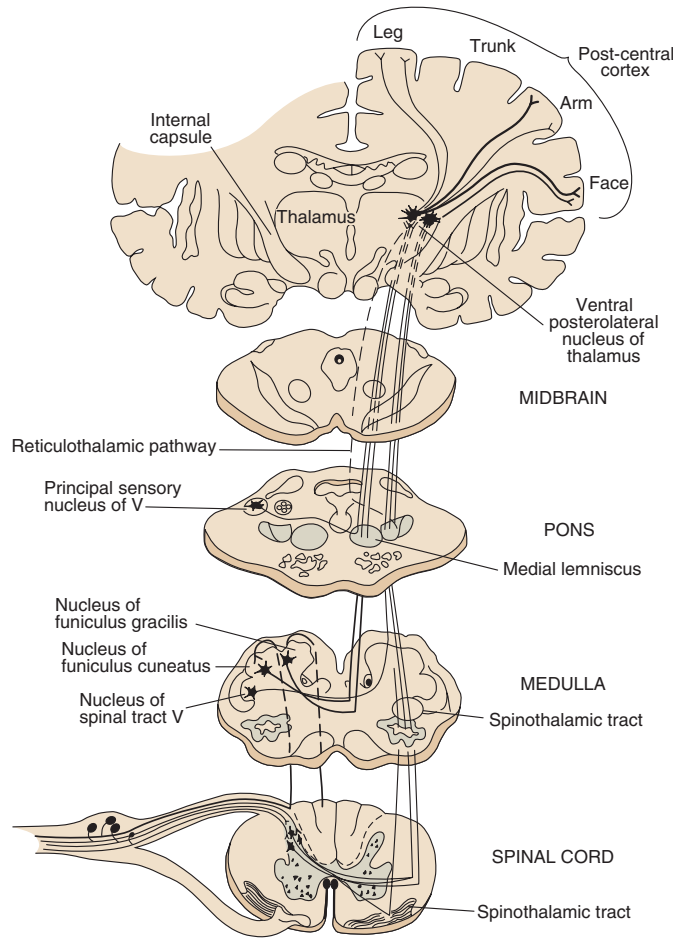

FIGURE 25-1 The main somatosensory pathways. The spinothalamic tract (pain, thermal sense) and the posterior column–lemniscal system (touch, pressure, joint position) are shown. Offshoots from the ascending anterolateral fasciculus (spinothalamic tract) to nuclei in the medulla, pons, and mesencephalon and nuclear terminations of the tract are indicated. *(From AH Ropper, RH Brown, in Adams and Victor's Principles of Neurology, 8th ed. New York, McGraw-Hill, 2007.)*

Some general principles pertain. The examiner must depend on patient responses, particularly when testing cutaneous sensation (pin, touch, warm, or cold), which complicates interpretation. Further, examination may be limited in some patients. In a stuporous patient, for example, sensory examination is reduced to observing the briskness of withdrawal in response to a pinch or other noxious stimulus. Comparison of response on one side of the body to the other is essential. In the alert but uncooperative patient, it may not be possible to examine cutaneous sensation, but some idea of proprioceptive function may be gained by noting the patient's best performance of movements requiring balance and precision. Frequently, patients present with sensory symptoms that do not fit an anatomic localization and that are accompanied by either no abnormalities or gross inconsistencies on examination. The examiner should then consider whether the sensory symptoms are a disguised request for help with psychological or situational problems. Discretion must be used in pursuing this possibility. Finally, sensory examination of a patient who has no neurologic complaints can be brief and consist of pinprick, touch, and vibration testing in the hands and feet plus evaluation of stance and gait, including the Romberg maneuver. Evaluation of stance and gait also tests the integrity of motor and cerebellar systems.

Primary Sensation (See Table 25-1) The sense of pain is usually tested with a clean pin, asking the patient to focus on the pricking or unpleasant quality of the stimulus and not just the pressure or touch sensation elicited. Areas of hypalgesia should be mapped by proceeding radially from the most hypalgesic site (Figs. 25-2 and 25-3).

TABLE 25-1 TESTING PRIMARY SENSATION

Sense	Test Device	Endings Activated	Fiber Size Mediating	Central Pathway
Pain	Pinprick	Cutaneous nociceptors	Small	SpTh, also D
Temperature, heat	Warm metal object	Cutaneous thermoreceptors for hot	Small	SpTh
Temperature, cold	Cold metal object	Cutaneous thermoreceptors for cold	Small	SpTh
Touch	Cotton wisp, fine brush	Cutaneous mechanoreceptors, also naked endings	Large and small	Lem, also D and SpTh
Vibration	Tuning fork, 128 Hz	Mechanoreceptors, especially pacinian corpuscles	Large	Lem, also D
Joint position	Passive movement of specific joints	Joint capsule and tendon endings, muscle spindles	Large	Lem, also D

Note: D, diffuse ascending projections in ipsilateral and contralateral anterolateral columns; SpTh, spinothalamic projection, contralateral; Lem, posterior column and lemniscal projection, ipsilateral.

Temperature sensation, to both hot and cold, is best tested with small containers filled with water of the desired temperature. This is impractical in most settings. An alternative way to test cold sensation is to touch a metal object, such as a tuning fork at room temperature, to the skin. For testing warm temperatures, the tuning fork or other metal object may be held under warm water of the desired temperature and then used. The appreciation of both cold and warmth should be tested because different receptors respond to each.

Touch is usually tested with a wisp of cotton or a fine camelhair brush. In general, it is better to avoid testing touch on hairy skin because of the profusion of sensory endings that surround each hair follicle.

Joint position testing is a measure of proprioception, one of the most important functions of the sensory system. With the patient's eyes closed, joint position is tested in the distal interphalangeal joint of the great toe and fingers. If errors are made in recognizing the direction of passive movements, more proximal joints are tested. A test of proximal joint position sense, primarily at the shoulder, is performed by asking the patient to bring the two index fingers together with arms extended and eyes closed. Normal individuals can do this accurately, with errors of 1 cm or less.

The sense of vibration is tested with a tuning fork that vibrates at 128 Hz. Vibration is usually tested over bony points, beginning distally; in the feet, it is tested over the dorsal surface of the distal phalanx of the big toes and at the malleoli of the ankles, and in the hands dorsally at the distal phalanx of the fingers. If abnormalities are found, more proximal sites can be examined. Vibratory thresholds at the same site in the patient and the examiner may be compared for control purposes.

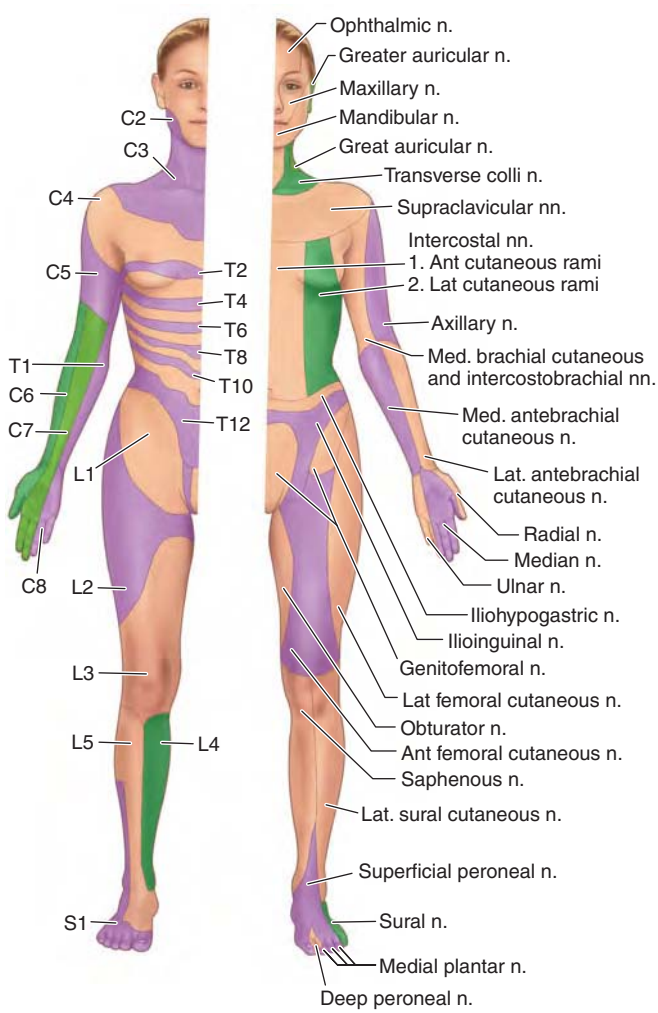

FIGURE 25-2 Anterior view of dermatomes (*left*) and cutaneous areas (*right*) supplied by individual peripheral nerves. *(Modified from MB Carpenter and J Sutin, in Human Neuroanatomy, 8th ed, Baltimore, Williams & Wilkins, 1983.)*

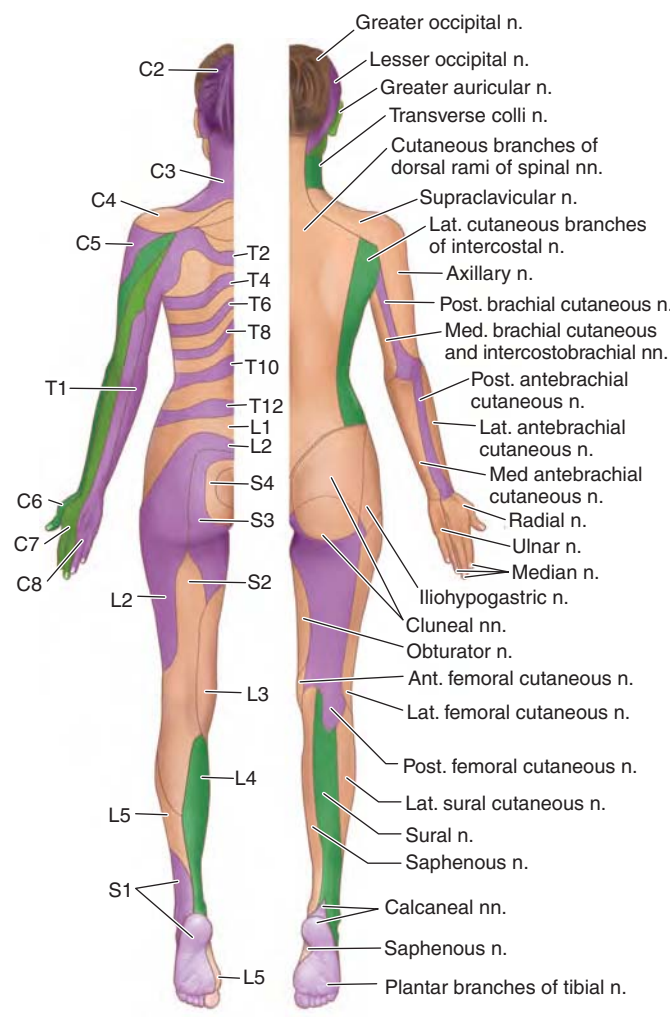

FIGURE 25-3 Posterior view of dermatomes (*left*) and cutaneous areas (*right*) supplied by individual peripheral nerves. *(Modified from MB Carpenter and J Sutin, in Human Neuroanatomy, 8th ed, Baltimore, Williams & Wilkins, 1983.)*

Quantitative Sensory Testing Effective sensory testing devices are now available commercially. Quantitative sensory testing is particularly useful for serial evaluation of cutaneous sensation in clinical trials. Threshold testing for touch and vibratory and thermal sensation is the most widely used application.

Cortical Sensation The most commonly used tests of cortical function are two-point discrimination, touch localization, and bilateral simultaneous stimulation and tests for graphesthesia and stereognosis. Abnormalities of these sensory tests, in the presence of normal primary sensation in an alert cooperative patient, signify a lesion of the parietal cortex or thalamocortical projections to the parietal lobe. If primary sensation is altered, these cortical discriminative functions will usually be abnormal also. Comparisons should always be made between analogous sites on the two sides of the body because the deficit with a specific parietal lesion is likely to be unilateral. Interside comparisons are important for all cortical sensory testing.

Two-point discrimination is tested by special calipers, the points of which may be set from 2 mm to several centimeters apart and then applied simultaneously to the site to be tested. The pulp of the fingertips is a common site to test; a normal individual can distinguish about 3-mm separation of points there.

Touch localization is performed by light pressure for an instant with the examiner's fingertip or a wisp of cottonwool; the patient, whose eyes are closed, is required to identify the site of touch with the fingertip. *Bilateral simultaneous stimulation* at analogous sites (e.g., the dorsum of both hands) can be carried out to determine whether the perception of touch is extinguished consistently on one side or the other. The phenomenon is referred to as *extinction*. *Graphesthesia* means the capacity to recognize with eyes closed letters or numbers drawn by the examiner's fingertip on the palm of the hand. Once again, interside comparison is of prime importance. Inability to recognize numbers or letters is termed *agraphesthesia*.

Stereognosis refers to the ability to identify common objects by palpation, recognizing their shape, texture, and size. Common standard objects, such as a key, paper clip, or coins, are best used. Patients with normal stereognosis should be able to distinguish a dime from a penny and a nickel from a quarter without looking. Patients should only be allowed to feel the object with one hand at a time. If they are unable to identify it in one hand, it should be placed in the other for comparison. Individuals unable to identify common objects and coins in one hand and who can do so in the other are said to have *astereognosis* of the abnormal hand.

LOCALIZATION OF SENSORY ABNORMALITIES

Sensory symptoms and signs can result from lesions at almost any level of the nervous system from parietal cortex to the peripheral sensory receptor. Noting the distribution and nature of sensory symptoms and signs is the most important way to localize their source. Their extent, configuration, symmetry, quality, and severity are the key observations.

Dysesthesias without sensory findings by examination may be difficult to interpret. To illustrate, tingling dysesthesias in an acral distribution (hands and feet) can be systemic in origin, e.g., secondary to hyperventilation, or induced by a medication such as acetazolamide. Distal dysesthesias can also be an early event in an evolving polyneuropathy or may herald a myelopathy, such as from vitamin B_{12} deficiency. Sometimes distal dysesthesias have no definable basis. In contrast, dysesthesias that correspond to a particular peripheral nerve territory denote a lesion of that nerve trunk. For instance, dysesthesias restricted to the fifth digit and the adjacent one-half of the fourth finger on one hand reliably point to disorder of the ulnar nerve, most commonly at the elbow.

Nerve and Root In focal nerve trunk lesions severe enough to cause a deficit, sensory abnormalities are readily mapped and generally have discrete boundaries (Figs. 25-2 and 25-3). Root ("radicular") lesions are frequently accompanied by deep, aching pain along the course of the related nerve trunk. With compression of a fifth lumbar (L5) or first sacral (S1) root, as from a ruptured intervertebral disc, sciatica (radicular pain relating to the sciatic nerve trunk) is a frequent manifestation (Chap. 16). With a lesion affecting a single root, sensory deficits may be minimal or absent because adjacent root territories overlap extensively.

With polyneuropathies, sensory deficits are generally graded, distal, and symmetric in distribution (Chap. 379). Dysesthesias, followed by numbness, begin in the toes and ascend symmetrically. When dysesthesias reach the knees, they have usually also appeared in the fingertips. The process appears to be nerve length–dependent, and the deficit is often described as "stocking-glove" in type. Involvement of both hands and feet also occurs with lesions of the upper cervical cord or the brainstem, but an upper level of the sensory disturbance may then be found on the trunk and other evidence of a central lesion may be present, such as sphincter involvement or signs of an upper motor neuron lesion (Chap. 23). Although most polyneuropathies are pansensory and affect all modalities of sensation, selective sensory dysfunction according to nerve fiber size may occur. Small-fiber polyneuropathies are characterized by burning, painful dysesthesias with reduced pinprick and thermal sensation but sparing of proprioception, motor function, and deep tendon reflexes. Touch is involved variably; when spared, the sensory pattern is referred to as exhibiting *sensory dissociation*. Sensory dissociation may occur with spinal cord lesions as well as small-fiber neuropathies. Large-fiber polyneuropathies are characterized by vibration and position sense deficits, imbalance, absent tendon reflexes, and variable motor dysfunction but preservation of most cutaneous sensation. Dysesthesias, if present at all, tend to be tingling or bandlike in quality.

Spinal Cord (See also Chap. 372) If the spinal cord is transected, all sensation is lost below the level of transection. Bladder and bowel function are also lost, as is motor function. Hemisection of the spinal cord produces the Brown-Séquard syndrome, with absent pain and temperature sensation contralaterally and loss of proprioceptive sensation and power ipsilaterally below the lesion (see Figs. 25-1 and 372-1).

Numbness or paresthesias in both feet may arise from a spinal cord lesion; this is especially likely when the upper level of the sensory loss extends to the trunk. When all extremities are affected, the lesion is probably in the cervical region or brainstem unless a peripheral neuropathy is responsible. The presence of upper motor neuron signs (Chap. 23) supports a central lesion; a hyperesthetic band on the trunk may suggest the level of involvement.

A dissociated sensory loss can reflect spinothalamic tract involvement in the spinal cord, especially if the deficit is unilateral and has an upper level on the torso. Bilateral spinothalamic tract involvement occurs with lesions affecting the center of the spinal cord, such as in syringomyelia. There is a dissociated sensory loss with impairment of pinprick and temperature appreciation but relative preservation of light touch, position sense, and vibration appreciation.

Dysfunction of the posterior columns in the spinal cord or of the posterior root entry zone may lead to a bandlike sensation around the trunk or a feeling of tight pressure in one or more limbs. Flexion of the neck sometimes leads to an electric shock–like sensation that radiates down the back and into the legs (Lhermitte's sign) in patients with a cervical lesion affecting the posterior columns, such as from multiple sclerosis, cervical spondylosis, or recent irradiation to the cervical region.

Brainstem Crossed patterns of sensory disturbance, in which one side of the face and the opposite side of the body are affected, localize to the lateral medulla. Here a small lesion may damage both the ipsilateral descending trigeminal tract and ascending spinothalamic fibers subserving the opposite arm, leg, and hemitorso (see "Lateral medullary syndrome" in Fig. 364-10). A lesion in the tegmentum of the pons and midbrain, where the lemniscal and spinothalamic tracts merge, causes pansensory loss contralaterally.

Thalamus Hemisensory disturbance with tingling numbness from head to foot is often thalamic in origin but can also arise from the anterior parietal region. If abrupt in onset, the lesion is likely to be due to a small stroke (lacunar infarction), particularly if localized to the thalamus. Occasionally, with lesions affecting the VPL nucleus or adjacent white matter, a syndrome of thalamic pain, also called *Déjerine-Roussy*

syndrome, may ensue. The persistent, unrelenting unilateral pain is often described in dramatic terms.

Cortex With lesions of the parietal lobe involving either the cortex or subjacent white matter, the most prominent symptoms are contralateral hemineglect, hemi-inattention, and a tendency not to use the affected hand and arm. On cortical sensory testing (e.g., two-point discrimination, graphesthesia), abnormalities are often found but primary sensation is usually intact. Anterior parietal infarction may present as a pseudothalamic syndrome with contralateral loss of primary sensation from head to toe. Dysesthesias or a sense of numbness may also occur, and rarely, a painful state.

Focal Sensory Seizures These are generally due to lesions in the area of the postcentral or precentral gyrus. The principal symptom of focal sensory seizures is tingling, but additional, more complex sensations may occur, such as a rushing feeling, a sense of warmth, or a sense of movement without detectable motion. Symptoms typically are unilateral; commonly begin in the arm or hand, face, or foot; and often spread in a manner that reflects the cortical representation of different bodily parts, as in a Jacksonian march. Duration of seizures is variable; they may be transient, lasting only for seconds, or persist for an hour or more. Focal motor features may supervene, often becoming generalized with loss of consciousness and tonic-clonic jerking.

26 Confusion and Delirium

S. Andrew Josephson, Bruce L. Miller

Confusion, a mental and behavioral state of reduced comprehension, coherence, and capacity to reason, is one of the most common problems encountered in medicine, accounting for a large number of emergency department visits, hospital admissions, and inpatient consultations. *Delirium*, a term used to describe an acute confusional state, remains a major cause of morbidity and mortality, contributing billions of dollars yearly to health care costs in the United States alone. Delirium often goes unrecognized despite clear evidence that it is usually the cognitive manifestation of serious underlying medical or neurologic illness.

CLINICAL FEATURES OF DELIRIUM

A multitude of terms are used to describe delirium, including encephalopathy, acute brain failure, acute confusional state, and postoperative or intensive care unit (ICU) psychosis. Delirium has many clinical manifestations, but essentially it is defined as a relatively acute decline in cognition that fluctuates over hours or days. The hallmark of delirium is a deficit of attention, although all cognitive domains—including memory, executive function, visuospatial tasks, and language—are variably involved. Associated symptoms may include altered sleep-wake cycles, perceptual disturbances such as hallucinations or delusions, affect changes, and autonomic findings including heart rate and blood pressure instability.

Delirium is a clinical diagnosis that can only be made at the bedside. Two broad clinical categories of delirium have been described, hyperactive and hypoactive subtypes, based on differential psychomotor features. The cognitive syndrome associated with severe alcohol withdrawal remains the classic example of the hyperactive subtype, featuring prominent hallucinations, agitation, and hyperarousal, often accompanied by life-threatening autonomic instability. In striking contrast is the hypoactive subtype of delirium, exemplified by opiate intoxication, in which patients are withdrawn and quiet, with prominent apathy and psychomotor slowing.

This dichotomy between subtypes of delirium is a useful construct, but patients often fall somewhere along a spectrum between the hyperactive and hypoactive extremes, sometimes fluctuating from one to the other within minutes. Therefore, clinicians must recognize the broad range of presentations of delirium in order to identify all patients with this potentially reversible cognitive disturbance. Hyperactive patients, such as those with delirium tremens, are easily recognized by their characteristic severe agitation, tremor, hallucinations, and autonomic instability. Patients who are quietly disturbed are more often overlooked on the medical wards and in the ICU, yet multiple studies suggest that this under-recognized hypoactive subtype is associated with worse outcomes.

The reversibility of delirium is emphasized because many etiologies, such as systemic infection and medication effects, can be easily treated. However, the long-term cognitive effects of delirium remain largely unknown and understudied. Some episodes of delirium continue for weeks, months, or even years. The persistence of delirium in some patients and its high recurrence rate may be due to inadequate treatment of the underlying etiology for the syndrome. In some instances, delirium does not disappear because there is underlying permanent neuronal damage. Even after an episode of delirium resolves, there may still be lingering effects of the disorder. A patient's recall of events after delirium varies widely, ranging from complete amnesia to repeated reexperiencing of the frightening period of confusion in a disturbing manner, similar to what is seen in patients with posttraumatic stress disorder.

RISK FACTORS

An effective primary prevention strategy for delirium begins with identification of patients at highest risk, including those preparing for elective surgery or being admitted to the hospital. Although no single validated scoring system has been widely accepted as a screen for asymptomatic patients, there are multiple well-established risk factors for delirium.

The two most consistently identified risks are older age and baseline cognitive dysfunction. Individuals who are over age 65 or exhibit low scores on standardized tests of cognition develop delirium upon hospitalization at a rate approaching 50%. Whether age and baseline cognitive dysfunction are truly independent risk factors is uncertain. Other predisposing factors include sensory deprivation, such as preexisting hearing and visual impairment, as well as indices for poor overall health, including baseline immobility, malnutrition, and underlying medical or neurologic illness.

In-hospital risks for delirium include the use of bladder catheterization, physical restraints, sleep and sensory deprivation, and the addition of three or more new medications. Avoiding such risks remains a key component of delirium prevention as well as treatment. Surgical and anesthetic risk factors for the development of postoperative delirium include specific procedures such as those involving cardiopulmonary bypass and inadequate or excessive treatment of pain in the immediate postoperative period.

The relationship between delirium and dementia (Chap. 365) is complicated by significant overlap between these two conditions, and it is not always simple to distinguish between the two. Dementia and preexisting cognitive dysfunction serve as major risk factors for delirium, and at least two-thirds of cases of delirium occur in patients with coexisting underlying dementia. A form of dementia with parkinsonism, termed *dementia with Lewy bodies*, is characterized by a fluctuating course, prominent visual hallucinations, parkinsonism, and an attentional deficit that clinically resembles hyperactive delirium. Delirium in the elderly often reflects an insult to the brain that is vulnerable due to an underlying neurodegenerative condition. Therefore, the development of delirium sometimes heralds the onset of a previously unrecognized brain disorder.

EPIDEMIOLOGY

Delirium is a common disease, but its reported incidence has varied widely based on the criteria used to define the disorder. Estimates of delirium in hospitalized patients range from 14 to 56%, with higher rates reported for elderly patients and patients undergoing hip surgery. Older patients in the ICU have especially high rates of delirium ranging from 70 to 87%. The condition is not recognized in up to one-third of delirious inpatients, and the diagnosis is especially problematic in the ICU environment where cognitive dysfunction is often difficult to appreciate in the setting of serious systemic illness and sedation. Delirium in the ICU should be viewed as an important manifestation of organ dysfunction not unlike liver, kidney, or heart failure.

Outside of the acute hospital setting, delirium occurs in nearly two-thirds of patients in nursing homes and in over 80% of those at the end of life. These estimates emphasize the remarkably high frequency of this cognitive syndrome in older patients, a population expected to grow in the upcoming decade with the aging of the "baby boom" generation.

In previous decades an episode of delirium was viewed as a transient condition that carried a benign prognosis. Delirium has now been clearly associated with substantial morbidity and increased mortality, and is increasingly recognized as a sign of serious underlying illness. Recent estimates of in-hospital mortality among delirious patients have ranged from 25 to 33%, a rate that is similar to patients with sepsis. Patients with an in-hospital episode of delirium have a higher mortality in the months and years following their illness compared with age-matched nondelirious hospitalized patients. Delirious hospitalized patients have a longer length of stay, are more likely to be discharged to a nursing home, and are more likely to experience subsequent episodes of delirium; as a result, this condition has enormous economic implications.

PATHOGENESIS

The pathogenesis and anatomy of delirium are incompletely understood. The attentional deficit that serves as the neuropsychological hallmark of delirium appears to have a diffuse localization with the brainstem, thalamus, prefrontal cortex, thalamus, and parietal lobes. Rarely, focal lesions such as ischemic strokes have led to delirium in otherwise healthy persons; right parietal and medial dorsal thalamic lesions have been reported most commonly, stressing the relevance of these areas to delirium pathogenesis. In most cases, delirium results from widespread disturbances in cortical and subcortical regions, rather than a focal neuroanatomic cause. Electroencephalogram (EEG) data in persons with delirium usually show symmetric slowing, a nonspecific finding supporting diffuse cerebral dysfunction.

Deficiency of acetylcholine often plays a key role in delirium pathogenesis. Medications with anticholinergic properties can precipitate delirium in susceptible individuals, and therapies designed to boost cholinergic tone such as cholinesterase inhibitors have, in small trials, been shown to relieve symptoms of delirium. Dementia patients are susceptible to episodes of delirium, and those with Alzheimer's pathology are known to have a chronic cholinergic deficiency state due to degeneration of acetylcholine-producing neurons in the basal forebrain. Another common dementia associated with decreased acetylcholine levels, dementia with Lewy bodies, clinically mimics delirium in some patients. Other neurotransmitters are also likely involved in this diffuse cerebral disorder. For example, increases in dopamine can also lead to delirium. Patients with Parkinson's disease treated with dopaminergic medications can develop a delirious-like state that features visual hallucinations, fluctuations, and confusion. In contrast, reducing dopaminergic tone with dopamine antagonists such as typical and atypical antipsychotic medications has long been recognized as effective symptomatic treatment in patients with delirium.

Not all individuals exposed to the same insult will develop signs of delirium. A low dose of an anticholinergic medication may have no cognitive effects on a healthy young adult but may produce a florid delirium in an elderly person with known underlying dementia. However, an extremely high dose of the same anticholinergic medication may lead to delirium even in healthy young persons. This concept of delirium developing as the result of an insult in predisposed individuals is currently the most widely accepted pathogenic construct. Therefore, if a previously healthy individual with no known history of cognitive illness develops delirium in the setting of a relatively minor insult such as elective surgery or hospitalization, then an unrecognized underlying neurologic illness such as a neurodegenerative disease, multiple previous strokes, or another diffuse cerebral cause should be considered. In this context, delirium can be viewed as the symptom resulting from a "stress test for the brain" induced by the insult. Exposure to known inciting factors such as systemic infection or offending drugs can unmask a decreased cerebral reserve and herald a serious underlying and potentially treatable illness.

TABLE 26-1 THE CONFUSION ASSESSMENT METHOD (CAM) DIAGNOSTIC ALGORITHM

The diagnosis of delirium requires the presence of features 1 and 2 and of *either* 3 or 4.[a]

- Feature 1: Acute onset and fluctuating course
  - This feature is satisfied by positive responses to these questions: Is there evidence of an acute change in mental status from the patient's baseline? Did the (abnormal) behavior fluctuate during the day—that is, tend to come and go—or did it increase and decrease in severity?
- Feature 2: Inattention
  - This feature is satisfied by a positive response to this question: Did the patient have difficulty focusing attention—for example, was easily distractible—or have difficulty keeping track of what was being said?
- Feature 3: Disorganized thinking
  - This feature is satisfied by a positive response to this question: Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?
- Feature 4: Altered level of consciousness
  - This feature is satisfied by any answer other than "alert" to this question: Overall, how would you rate this patient's level of consciousness: alert (normal), vigilant (hyperalert), lethargic (drowsy, easily aroused), stupor (difficult to arouse), or coma (unarousable)?

[a]Information is usually obtained from a reliable reporter, such as a family member, caregiver, or nurse.

APPROACH TO THE PATIENT: Delirium

As the diagnosis of delirium is clinical and made at the bedside, a careful history and physical examination is necessary when evaluating patients with possible confusional states. Screening tools can aid physicians and nurses in identifying patients with delirium, including the Confusion Assessment Method (CAM) (Table 26-1); the Organic Brain Syndrome Scale; the Delirium Rating Scale; and, in the ICU, the Delirium Detection Score and the ICU version of the CAM. These scales are based on criteria from the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) or the World Health Organization's International Classification of Diseases (ICD). Unfortunately, these scales themselves do not identify the full spectrum of patients with delirium. All patients who are acutely confused should be presumed delirious regardless of their presentation due to the wide variety of possible clinical features. A course that fluctuates over hours or days and may worsen at night (termed *sundowning*) is typical but not essential for the diagnosis. Observation of the patient will usually reveal an altered level of consciousness or a deficit of attention. Other hallmark features that may be present in the delirious patient include alteration of sleep-wake cycles, thought disturbances such as hallucinations or delusions, autonomic instability, and changes in affect.

HISTORY It may be difficult to elicit an accurate history in delirious patients who have altered levels of consciousness or impaired attention. Information from a collateral source such as a spouse or other family member is therefore invaluable. The three most important pieces of history include the patient's baseline cognitive function, the time course of the present illness, and current medications.

Premorbid cognitive function can be assessed through the collateral source or, if needed, via a review of outpatient records. Delirium by definition represents a change that is relatively acute, usually over hours to days, from a cognitive baseline. As a result, an acute confusional state is nearly impossible to diagnose without some knowledge of baseline cognitive function. Without this information, many patients with dementia or depression may be mistaken as delirious during a single initial evaluation. Patients with a more hypoactive, apathetic presentation with psychomotor slowing may only be iden-

tified as being different from baseline through conversations with family members. A number of validated instruments have been shown to accurately diagnose cognitive dysfunction using a collateral source including the modified Blessed Dementia Rating Scale and Clinical Dementia Rating (CDR). Baseline cognitive impairment is common in patients with delirium. Even when no such history of cognitive impairment is elicited, there should still be a high suspicion for previously unrecognized underlying neurologic disorder.

Establishing the time course of cognitive change is important not only to make a diagnosis of delirium but also to correlate the onset of the illness with potentially treatable etiologies such as recent medication changes or symptoms of systemic infection.

Medications remain a common cause of delirium, especially those compounds with anticholinergic or sedative properties. It is estimated that nearly one-third of all cases of delirium are secondary to medications, especially in the elderly. Medication histories should include all prescription as well as over-the-counter and herbal substances taken by the patient and any recent changes in dosing or formulation, including substitution of generics for brand-name medications.

Other important elements of the history include screening for symptoms of organ failure or systemic infection, which often contributes to delirium in the elderly. A history of illicit drug use, alcoholism, or toxin exposure is common in younger delirious patients. Finally, asking the patient and collateral source about other symptoms that may accompany delirium, such as depression or hallucinations, may help identify potential therapeutic targets.

PHYSICAL EXAMINATION The general physical examination in a delirious patient should include a careful screening for signs of infection such as fever, tachypnea, pulmonary consolidation, heart murmur, or stiff neck. The patient's fluid status should be assessed; both dehydration and fluid overload with resultant hypoxia have been associated with delirium, and each is usually easily rectified. The appearance of the skin can be helpful, showing jaundice in hepatic encephalopathy, cyanosis in hypoxia, or needle tracks in patients using intravenous drugs.

The neurologic examination requires a careful assessment of mental status. Patients with delirium often present with a fluctuating course; therefore the diagnosis can be missed when relying on a single time point of evaluation. Some but not all patients exhibit the characteristic pattern of sundowning, a worsening of their condition in the evening. In these cases, assessment only during morning rounds may be falsely reassuring.

An altered level of consciousness ranging from hyperarousal to lethargy to coma is present in most patients with delirium and can be easily assessed at the bedside. In the patient with a relatively normal level of consciousness, a screen for an attentional deficit is in order, as this deficit is the classic neuropsychological hallmark of delirium. Attention can be assessed while taking a history from the patient. Tangential speech, a fragmentary flow of ideas, or inability to follow complex commands often signifies an attentional problem. Formal neuropsychological tests to assess attention exist, but a simple bedside test of digit span forward is quick and fairly sensitive. In this task, patients are asked to repeat successively longer random strings of digits beginning with two digits in a row. Average adults can repeat a string of between five to seven digits before faltering; a digit span of four or less usually indicates an attentional deficit unless hearing or language barriers are present.

More formal neuropsychological testing can be extraordinarily helpful in assessing the delirious patient, but it is usually too cumbersome and time-consuming in the inpatient setting. A simple Mini Mental Status Examination (MMSE) (see Table 365-5) can provide some information regarding orientation, language, and visuospatial skills; however, performance of some tasks on the MMSE such as spelling "world" backwards or serial subtraction of digits will be impaired by delirious patients' attentional deficits alone and are therefore unreliable.

The remainder of the screening neurologic examination should focus on identifying new focal neurologic deficits. Focal strokes or mass lesions in isolation are rarely the cause of delirium, but patients with underlying extensive cerebrovascular disease or neurodegenerative conditions may not be able to cognitively tolerate even relatively small new insults. Patients should also be screened for additional signs of neurodegenerative conditions such as parkinsonism, which is seen not only in idiopathic Parkinson's disease but also in other dementing conditions such as Alzheimer's disease, dementia with Lewy bodies, and progressive supranuclear palsy. The presence of multifocal myoclonus or asterixis on the motor examination is nonspecific but usually indicates a metabolic or toxic etiology of the delirium.

ETIOLOGY Some etiologies can be easily discerned through a careful history and physical examination, while others require confirmation with laboratory studies, imaging, or other ancillary tests. A large, diverse group of insults can lead to delirium, and the cause in many patients is often multifactorial. Common etiologies are listed in Table 26-2.

Prescribed, over-the-counter, and herbal medications are common precipitants of delirium. Drugs with anticholinergic properties, narcotics, and benzodiazepines are especially frequent offenders, but nearly any compound can lead to cognitive dysfunction in a predisposed patient. While an elderly patient with baseline dementia may become delirious upon exposure to a relatively low dose of a medication, other less-susceptible individuals may only become delirious with very high doses of the same medication. This observation emphasizes the importance of correlating the timing of recent medication changes, including dose and formulation, with the onset of cognitive dysfunction.

TABLE 26-2 COMMON ETIOLOGIES OF DELIRIUM

- Toxins
  - Prescription medications: especially those with anticholinergic properties, narcotics and benzodiazepines
  - Drugs of abuse: alcohol intoxication and alcohol withdrawal, opiates, ecstasy, LSD, GHB, PCP, ketamine, cocaine
  - Poisons: inhalants, carbon monoxide, ethylene glycol, pesticides
- Metabolic conditions
  - Electrolyte disturbances: hypoglycemia, hyperglycemia, hyponatremia, hypernatremia, hypercalcemia, hypocalcemia, hypomagnesemia
  - Hypothermia and hyperthermia
  - Pulmonary failure: hypoxemia and hypercarbia
  - Liver failure/hepatic encephalopathy
  - Renal failure/uremia
  - Cardiac failure
  - Vitamin deficiencies: B_{12}, thiamine, folate, niacin
  - Dehydration and malnutrition
  - Anemia
- Infections
  - Systemic infections: urinary tract infections, pneumonia, skin and soft tissue infections, sepsis
  - CNS infections: meningitis, encephalitis, brain abscess
- Endocrinologic conditions
  - Hyperthyroidism, hypothyroidism
  - Hyperparathyroidism
  - Adrenal insufficiency
- Cerebrovascular disorders
  - Global hypoperfusion states
  - Hypertensive encephalopathy
  - Focal ischemic strokes and hemorrhages: especially nondominant parietal and thalamic lesions
- Autoimmune disorders
  - CNS vasculitis
  - Cerebral lupus
- Seizure-related disorders
  - Nonconvulsive status epilepticus
  - Intermittent seizures with prolonged post-ictal states
- Neoplastic disorders
  - Diffuse metastases to the brain
  - Gliomatosis cerebri
  - Carcinomatous meningitis
- Hospitalization
- Terminal end of life delirium

Abbreviations: LSD, lysergic acid diethylamide; GHB, γ-hydroxybutyrate; PCP, phencyclidine; CNS, central nervous system.

In younger patients especially, illicit drugs and toxins are common causes of delirium. In addition to more classic drugs of abuse, the recent rise in availability of so-called club drugs, such as methylenedioxymethamphetamine (MDMA, ecstasy), γ-hydroxybutyrate (GHB), and the PCP-like agent ketamine, has led to an increase in delirious young persons presenting to acute care settings. Many common prescription drugs such as oral narcotics and benzodiazepines are now often abused and readily available on the street. Alcohol intoxication with high serum levels can cause confusion, but more commonly it is withdrawal from alcohol that leads to a classic hyperactive delirium. Alcohol and benzodiazepine withdrawal should be considered in all cases of delirium as even patients who drink only a few servings of alcohol every day can experience relatively severe withdrawal symptoms upon hospitalization.

Metabolic abnormalities such as electrolyte disturbances of sodium, calcium, magnesium, or glucose can cause delirium, and mild derangements can lead to substantial cognitive disturbances in susceptible individuals. Other common metabolic etiologies include liver and renal failure, hypercarbia and hypoxia, vitamin deficiencies of thiamine and B_{12}, autoimmune disorders including CNS vasculitis, and endocrinopathies such as thyroid and adrenal disorders.

Systemic infections often cause delirium, especially in the elderly. A common scenario involves the development of an acute cognitive decline in the setting of a urinary tract infection in a patient with baseline dementia. Pneumonia, skin infections such as cellulitis, and frank sepsis can also lead to delirium. This so-called septic encephalopathy, often seen in the ICU, is likely due to the release of proinflammatory cytokines and their diffuse cerebral effects. CNS infections such as meningitis, encephalitis, and abscess are less-common etiologies of delirium; however, given the high mortality associated with these conditions when not treated quickly, clinicians must always maintain a high index of suspicion.

In some susceptible individuals, exposure to the unfamiliar environment of a hospital can lead to delirium. This etiology usually occurs as part of a multifactorial delirium and should be considered a diagnosis of exclusion after all other causes have been thoroughly investigated. Many primary prevention and treatment strategies for delirium involve relatively simple methods to address those aspects of the inpatient setting that are most confusing.

Cerebrovascular etiologies are usually due to global hypoperfusion in the setting of systemic hypotension from heart failure, septic shock, dehydration, or anemia. Focal strokes in the right parietal lobe and medial dorsal thalamus can rarely lead to a delirious state. A more common scenario involves a new focal stroke or hemorrhage causing confusion in a patient who has decreased cerebral reserve. In these individuals, it is sometimes difficult to distinguish between cognitive dysfunction resulting from the new neurovascular insult itself and delirium due to the infectious, metabolic, and pharmacologic complications that can accompany hospitalization after stroke.

Because a fluctuating course is often seen in delirium, intermittent seizures may be overlooked when considering potential etiologies. Both nonconvulsive status epilepticus as well as recurrent focal or generalized seizures followed by post-ictal confusion can cause delirium; EEG remains essential for this diagnosis. Seizure activity spreading from an electrical focus in a mass or infarct can explain global cognitive dysfunction caused by relatively small lesions.

It is very common for patients to experience delirium at the end of life in palliative care settings. This condition, sometimes described as *terminal restlessness*, must be identified and treated aggressively as it is an important cause of patient and family discomfort at the end of life. It should be remembered that these patients may also be suffering from more common etiologies of delirium such as systemic infection.

LABORATORY AND DIAGNOSTIC EVALUATION A cost-effective approach to the diagnostic evaluation of delirium allows the history and physical examination to guide tests. No established algorithm for workup will fit all delirious patients due to the staggering number of potential etiologies, but one step-wise approach is detailed in Table 26-3. If a clear precipitant is identified early, such as an offending medication, then little further workup is required. If, however, no likely etiology is uncovered with initial evaluation, an aggressive search for an underlying cause should be initiated.

TABLE 26-3 STEP-WISE EVALUATION OF A PATIENT WITH DELIRIUM

- Initial evaluation
  - History with special attention to medications (including over-the-counter and herbals)
  - General physical examination and neurologic examination
  - Complete blood count
  - Electrolyte panel including calcium, magnesium, phosphorus
  - Liver function tests including albumin
  - Renal function tests
- First-tier further evaluation guided by initial evaluation
  - Systemic infection screen
    - Urinalysis and culture
    - Chest radiograph
    - Blood cultures
  - Electrocardiogram
  - Arterial blood gas
  - Serum and/or urine toxicology screen (perform earlier in young persons)
  - Brain imaging with MRI with diffusion and gadolinium (preferred) or CT
  - Suspected CNS infection: lumbar puncture following brain imaging
  - Suspected seizure-related etiology: electroencephalogram (EEG) (if high suspicion should be performed immediately)
- Second-tier further evaluation
  - Vitamin levels: B_{12}, folate, thiamine
  - Endocrinologic laboratories: thyroid-stimulating hormone (TSH) and free T4; cortisol
  - Serum ammonia
  - Sedimentation rate
  - Autoimmune serologies: antinuclear antibodies (ANA), complement levels; p-ANCA, c-ANCA
  - Infectious serologies: rapid plasmin reagin (RPR); fungal and viral serologies if high suspicion; HIV antibody
  - Lumbar puncture (if not already performed)
  - Brain MRI with and without gadolinium (if not already performed)

Note: p-ANCA, perinuclear antineutrophil cytoplasmic antibody; c-ANCA, cytoplasmic antineutrophil cytoplasmic antibody.

Basic screening labs, including a complete blood count, electrolyte panel, and tests of liver and renal function, should be obtained in all patients with delirium. In elderly patients, screening for systemic infection, including chest radiography, urinalysis and culture, and possibly blood cultures, is important. In younger individuals, serum and urine drug and toxicology screening may be appropriate early in the workup. Additional laboratory tests addressing other autoimmune, endocrinologic, metabolic, and infectious etiologies should be reserved for patients in whom the diagnosis remains unclear after initial testing.

Multiple studies have demonstrated that brain imaging in patients with delirium is often unhelpful. However, if the initial workup is unrevealing, most clinicians quickly move toward imaging of the brain in order to exclude structural causes. A noncontrast CT scan can identify large masses and hemorrhages but is otherwise relatively insensitive for discovering an etiology of delirium. The ability of MRI to identify most acute ischemic strokes as well as to provide neuroanatomic detail that gives clues to possible infectious, inflammatory, neurodegenerative, and neoplastic conditions makes it the test of choice. Since MRI techniques are limited by availability, speed of imaging, patient cooperation, and contraindications to magnetic exposure, many clinicians begin with CT scanning and proceed to MRI if the etiology of delirium remains elusive.

Lumbar puncture (LP) must be obtained immediately, after appropriate neuroimaging, in all patients in whom CNS infection is suspected. Spinal fluid examination can also be useful in identifying inflammatory and neoplastic conditions as well as in the diagnosis of hepatic encephalopathy through elevated CSF glutamine levels. As a result, LP should be considered in any delirious patient with a negative workup. EEG does not have a routine role in the workup of delirium, but it remains invaluable if seizure-related etiologies are considered.

Rx DELIRIUM

Management of delirium begins with treatment of the underlying inciting factor (e.g., patients with systemic infections should be given appropriate antibiotics and underlying electrolyte disturbances judiciously corrected). These treatments often lead to prompt resolution of delirium. Blindly targeting the symptoms of delirium pharmacologically only serves to prolong the time patients remain in the confused state and may mask important diagnostic information.

Relatively simple methods of supportive care can be highly effective in treating patients with delirium. Reorientation by the nursing staff and family combined with visible clocks, calendars, and outside-facing windows can reduce confusion. Sensory isolation should be prevented by providing glasses and hearing aids to those patients who need them. Sundowning can be addressed to a large extent through vigilance to appropriate sleep-wake cycles. During the day, a well-lit room should be accompanied by activities or exercises to prevent napping. At night, a quiet, dark environment with limited interruptions by staff can assure proper rest. These sleep-wake cycle interventions are especially important in the ICU setting as the usual constant 24-h activity commonly provokes delirium. Attempting to mimic the home environment as much as possible has also been shown to help treat and even prevent delirium. Visits from friends and family throughout the day minimize the anxiety associated with the constant flow of new faces of staff and physicians. Allowing hospitalized patients to have access to home bedding, clothing, and nightstand objects makes the hospital environment less foreign and therefore less confusing. Simple standard nursing practices such as maintaining proper nutrition and volume status as well as managing incontinence and skin breakdown also help to alleviate discomfort and resulting confusion.

In some instances, patients pose a threat to their own safety or to the safety of staff members, and acute management is required. Bed alarms and personal sitters are more effective and much less disorienting than physical restraints. Chemical restraints should be avoided, but, when necessary, very-low-dose typical or atypical antipsychotic medications administered on an as-needed basis are effective. The recent association of atypical antipsychotic use in the elderly with increased mortality underscores the importance of using these medications judiciously and only as a last resort. Benzodiazepines are not as effective as antipsychotics and often worsen confusion via their sedative properties. Although many clinicians still use benzodiazepines to treat acute confusion, their use should be limited only to cases in which delirium is caused by alcohol or benzodiazepine withdrawal.

PREVENTION

Given the high morbidity associated with delirium and the tremendously increased health care costs that accompany it, development of an effective strategy to prevent delirium in hospitalized patients is extremely important. Successful identification of high-risk patients is the first step, followed by initiation of appropriate interventions. One trial randomized more than 850 elderly inpatients to simple standardized protocols used to manage risk factors for delirium, including cognitive impairment, immobility, visual impairment, hearing impairment, sleep deprivation, and dehydration. Significant reductions in the number and duration of episodes of delirium were observed in the treatment group, but unfortunately delirium recurrence rates were unchanged. All hospitals and health care systems should work toward developing standardized protocols to address common risk factors with the goal of decreasing the incidence of delirium.

ACKNOWLEDGMENT

In the previous edition, Allan H. Ropper contributed to a section on acute confusional states that was incorporated into this current chapter.

27 Aphasia, Memory Loss, and Other Focal Cerebral Disorders

M.-Marsel Mesulam

The cerebral cortex of the human brain contains ~20 billion neurons spread over an area of 2.5 m^2. The *primary sensory* areas provide an obligatory portal for the entry of sensory information into cortical circuitry, whereas the *primary motor* areas provide final common pathways for coordinating complex motor acts. The primary sensory and motor areas constitute 10% of the cerebral cortex. The rest is subsumed by unimodal, heteromodal, paralimbic, and limbic areas, collectively known as the *association cortex* (Fig. 27-1). The association cortex mediates the integrative processes that subserve cognition, emotion, and behavior. A systematic testing of these mental functions is necessary for the effective clinical assessment of the association cortex and its diseases.

According to current thinking, there are no centers for "hearing words," "perceiving space," or "storing memories." Cognitive and behavioral functions (domains) are coordinated by intersecting *large-scale neural networks* that contain interconnected cortical and subcortical components. The network approach to higher cerebral function has at least four implications of clinical relevance: (1) a single domain such as language or memory can be disrupted by damage to any one of several areas, as long as these areas belong to the same network; (2) damage confined to a single area can give rise to multiple deficits, involving the functions of all networks that intersect in that region; (3) damage to a network component may give rise to minimal or transient deficits if other parts of the network undergo compensatory reorganization; and (4) individual anatomic sites within a network display a relative (but not absolute) specialization for different behavioral aspects of the relevant function. Five anatomically defined large-scale networks are most relevant to clinical practice: a perisylvian network for language; a parietofrontal network for spatial cognition; an occipitotemporal network for face and object recognition; a limbic network for retentive memory; and a prefrontal network for attention and behavior.

THE LEFT PERISYLVIAN NETWORK FOR LANGUAGE: APHASIAS AND RELATED CONDITIONS

Language allows the communication and elaboration of thoughts and experiences by linking them to arbitrary symbols known as words. The neural substrate of language is composed of a distributed network centered in the perisylvian region of the *left* hemisphere. The posterior pole of this network is located at the temporoparietal junction and includes a region known as *Wernicke's area*. An essential function of Wernicke's area is to transform sensory inputs into their lexical representations so that these can establish the distributed associations that give the word its meaning. The anterior pole of the language network is located in the inferior frontal gyrus and includes a region known as *Broca's area*. An essential function of this area is to transform lexical representations into their articulatory sequences so that the words can be uttered in the form of spoken language. The sequencing function of Broca's area also appears to involve the ordering of words into sentences that contain a meaning-appropriate *syntax* (grammar). Wernicke's and Broca's areas are interconnected with each other and with additional perisylvian, temporal, prefrontal, and posterior parietal regions, making up a neural network subserving the various aspects of lan-

e6 Memory Loss

Thomas D. Bird, Bruce L. Miller

Memory allows us to store, retain, and retrieve information. These three processes influence and are modified by the type of information that is to be remembered, the duration of time over which it must be retained, and the way in which the brain will use the information in the future. The neural circuits underlying these processes are dynamic, reflecting the flexibility of memory itself. To delineate the neural circuitry underlying it, it is helpful to break down memory into simpler components. This categorization, however, need not lead to the assumption that memory is not a unitary phenomenon.

LONG-TERM MEMORY

In an effort to explain why focal brain damage affects some aspects of memory but not others, a fundamental distinction has been made between *declarative memory*, which refers to the conscious memory for facts and events, and *nondeclarative memory*, which refers to memory for skills, habits, or other manifestations of learning that can be expressed without awareness of what was learned (Fig. e6-1). Patients with bilateral medial temporal lobe (MTL) damage show declarative memory deficits in the face of intact nondeclarative memory. For example, such a patient may learn to play the piano, over time, without remembering a single practice session or even recognizing the teacher who patiently works with him everyday.

DECLARATIVE MEMORY

Within the declarative memory system, *episodic* and *semantic* memory can be distinguished. *Episodic memory* allows the recollection of unique personal experiences. With episodic memory, the person reexperiences the sights, sounds, smells, and other details of a specific event. Many episodic memories are kept for minutes and hours but soon discarded. Others remain for the course of a lifetime. This temporal difference in storage probably reflects different physiologic processes at work (see below). *Semantic memory*, in contrast, refers to knowledge about the world; generic information that is acquired across many different contexts and accessed without accompanying details of the time when the words or facts were remembered. One's vocabulary and knowledge of the associations between verbal concepts make up the bulk of semantic memory. This fractionation of declarative memory is supported by evidence that episodic and semantic memory have distinctive anatomic substrates.

Episodic Memory In the MTL, the hippocampal formation receives processed sensory information from association areas in the frontal, parietal, and occipital lobes via the parahippocampal cortex. Given these multiple cortical neuroanatomical connections, the hippocampus is well placed to create associations between simultaneously occurring stimuli in our sensory world. Key structures involved with episodic memory include the hippocampus, entorhinal cortex, mammillary bodies, and thalamus. Alterations of episodic memory can be devastating. Overly intense or painful episodic memories can result in posttraumatic stress disorder, a devastating illness in which patients repeatedly reexperience unpleasant episodes from their lives. By contrast, loss of episodic memories, as in Alzheimer's disease (AD), will prevent the individual from learning new things about the world and will eventually strip away the old memories that constitute a life biography.

Given its anatomic placement and architecture, the hippocampus has the unique ability to bind together "what happened," "when it happened," and "where it happened." The architecture of the hippocampus includes a circular pathway of neurons from the entorhinal cortex to the dentate gyrus and CA3 and CA1 neurons of the hippocampus to the subiculum and back to the entorhinal cortex. This pathway is heavily damaged in AD. Individual elements of episodic memories are permanently stored within the same neocortical regions that are involved in initial processing and analyzing of sensory information (neocortex). Each different cortical region makes a unique contribution to the storage of a given memory, and all regions participate together in the creation of a complete memory representation. The hippocampal formation, then, is saddled with the task of binding together these different regional contributions into a coherent memory trace. The connections within the hippocampal formation and between the MTL and neocortical regions are formed more rapidly than are the connections between disparate cortical regions. Therefore, when a particular cue in the environment or the mental state of the person activates cells in the cortical regions, the MTL network that is associated with that cue is reactivated and the entire neocortical representation is strengthened. As multiple reactivations occur, the connections between the relevant neocortical regions are slowly strengthened until the memory trace no longer depends on the MTL's activity but is instead entirely represented in the cortex.

While the MTL learns quickly and has a limited capacity for storage, the neocortex learns slowly and has a very large storage capacity. In both regions, learning occurs via Hebbian synapses, whereby "cells that fire together, wire together." With repeated activations, memories become "consolidated" in the neocortex and, therefore, independent of the MTL. This process, by which the burden of long-term (permanent) memory storage is gradually assumed by the neocortex, ensures that the MTL system is constantly available for the acquisition of new information. Recent evidence, however, points to the hippocampus as serving a critical function in the retrieval of detailed episodic memories, regardless of the age of the memory.

Injury anywhere along this septohippocampal pathway can lead to severe loss of episodic memory. Patients with injury to this system will exhibit anterograde amnesia, an inability to commit new information to memory. Memories that were established before the injury (remote memories) tend to be relatively preserved, although a retrograde amnesia, going back anywhere from minutes to years, is usually evident. Larger lesions cause a more extensive retrograde memory deficit. Also, as brain injury improves over time, the retrograde memory impairment tends to diminish, and the temporal gradient for memory loss shrinks.

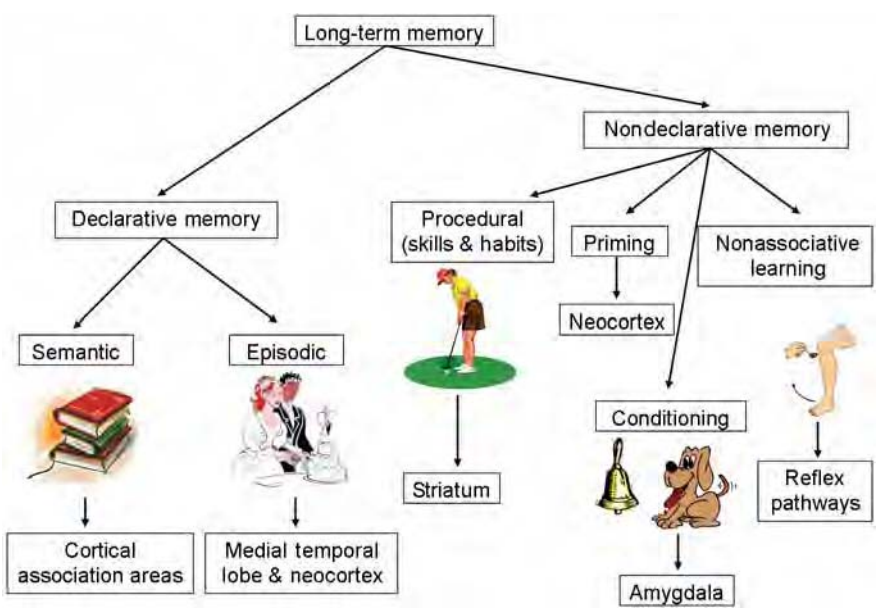

FIGURE e6-1 Fractionation of long-term memory. *(Adapted from LR Squire, SM Zola: Proc Natl Acad Sci U S A, 24: 13515, 1996.)*

The most common cause for entorhinal dysfunction is AD, which begins in the entorhinal cortex and then spreads to the hippocampus. A common mechanism for hippocampal dysfunction is traumatic injury because the hippocampi sit adjacent to, and are easily pushed against, bone in the middle cranial fossa. The hippocampus, particularly the CA1 and subicular region, is very sensitive to metabolic insults, including hypoxia, hypoglycemia, and prolonged seizures. Vascular infarction can occur with occlusion of the hippocampal branches off the posterior cerebral arteries. Infections, in particular herpes simplex encephalitis, can selectively attack the medial temporal regions, leading to severe and permanent deficits in episodic memory.

Additionally, severe loss of episodic memory can also be due to dysfunction in the mammillothalamic memory system. The amnesia of Korsakoff's syndrome is due to injury from hemorrhage into the mammillary bodies and dorsomedial nuclei of the thalamus. Furthermore, recent studies of patients with stroke in the left dorsomedial nucleus of the thalamus suggest that injury here alone will precipitate a severe amnesia. Finally, tumors can injure the septum, fornix, or medial temporal lobes, leading to amnesia.

Emotion plays a key role in enhancing the ability to remember personal episodes and other information encoded in a particular affective state. Emotionally charged events are more easily remembered than emotionally neutral episodes, and highly vivid "flashbulb" memories are often laid down during traumatic or emotional events; sometimes during positive but often during negative events. In humans, the amygdala modulates memory processes during emotional experiences.

One simple way to test episodic memory is to ask the patient to recall recent events such as what he did on the last big holiday, what is going on in the news, or what she had for breakfast. With regard to personal episodic memories, it is always necessary to have a historian who can verify that the recent memories are correct (not confabulated).

Semantic Memory Unlike episodic memory, the recall of semantic memory does not lead to the retrieval of details of when, or where, the information was acquired. For example, we remember that a fork is a utensil that is used for eating food without remembering when we learned the word *fork* or when we discovered its use. Semantic memory is composed of a complex hierarchy of knowledge about the world. Knowing that a fork is generally used for eating depends on understanding that in certain social situations, eating with only our hands is inappropriate, and that some foods are more easily eaten with a fork than another available utensil, such as a spoon. While a fork may be useful in many different situations, our semantic hierarchy reminds us that its main function is to facilitate eating. These ideas are held together in the semantic memory system, which spans across the association areas of the neocortex. Therefore, if we are in a situation that requires using a fork as a tool in a novel manner, we can still call upon our semantic memory system to aid us in solving the problem.

Evidence that semantic memories are independent of the septohippocampal and mamillothalamic memory systems comes from humans with injury to these systems who maintain access to semantic knowledge despite profound deficits in episodic memory. In contrast, patients with primarily anterior and lateral temporal lobe damage show intact episodic memory but impaired semantic memory. The finding that children born with hippocampal sclerosis and lifelong episodic memory impairments can still function fairly well in school suggests that semantic memories are not wholly dependent upon intact episodic memory.

In semantic dementia, a syndrome associated with neurodegenerative disease that begins in the anterior temporal lobes, both the simple labeling process (naming) and knowledge about the identity of people and objects are lost. Patients with semantic dementia classify objects into increasingly superordinate categories, having lost access to specific exemplars. Hence, a hawk becomes a "hunting bird," then a "bird," then an "animal," and then a "thing" as the disease worsens. Eventually all objects are classified with a series of simple stereotyped phrases. Bilateral anterior temporal dysfunction is the anatomic substrate of semantic dementia, a subtype of the frontotemporal lobar degenerations. Aside from semantic dementia, the other disorders that lead to this syndrome include limbic encephalitis, associated with viral or paraneoplastic processes, and herpes simplex encephalitis.

Bedside assessment of semantic memory is difficult, but the gravest deficits may be seen if the patient is unable to name common objects such as a pen or watch or less common objects such as a stethoscope or a fluorescent bulb.

NONDECLARATIVE MEMORY

Nondeclarative memory is an umbrella term for a heterogeneous collection of nonconscious memory abilities that involve multiple distinct neural regions, including the amygdala, basal ganglia, cerebellum, and sensory cortex (Fig. e6-1). *Procedural memory* is one type of nondeclarative memory. The difference between declarative memory and procedural memory is the difference between "knowing that" and "knowing how." *Procedural learning* describes the formation of skills and habits. Because it requires extensive practice, it is a slow and inflexible learning system that eventually takes on an automatic or reflexive quality. It is, however, long-lasting and reliable: even after years of absence from a bicycle, a bike rider does not lose the skill entirely.

Procedural memory involves motor, perceptual, and cognitive processes. For example, flipping pancakes is a motor skill, a parent's attentiveness to his or her baby's cry in a distant room involves perceptual learning, and increasing alacrity in solving Sudoku puzzles with practice requires cognitive skills. While declarative memory can, in some cases, enhance or hasten the acquisition of skills and habits, conscious awareness of learning is not necessary; once the information is acquired, it often becomes difficult to verbalize how it was learned. Cognitive psychologists have shown that in some cases, declarative memory processes can hinder nondeclarative learning, suggesting that there are times when the two memory "systems" may compete for cognitive resources.

The forms of perceptual and motor learning that can occur without conscious recollections are mediated in part by contractions and expansions of representations in the sensory and motor cortex. One study, for example, has shown that the cortical representation of the fingers of the left hand of musical string players is larger than that in nonmusicians, suggesting that the representation of different parts of the body in the primary somatosensory cortex of humans depends on use and changes to conform to the current needs and experiences of the individual. Discrete cortical regions exist in the anterior temporal lobes in which object knowledge (such as words related to color, animals, tools, or action) is organized as a distributed system. Here the attributes of an object are stored close to the regions of the cortex that mediate perception of those attributes.

Recent research now points to the basal ganglia as fundamental in motor skill learning, while the cerebellum is involved in the association of a visual cue with a motor action. Parkinson's disease (PD) causes damage to the basal ganglia and is associated with impairments in habit learning but spares declarative memory. The basal ganglia project to and receive projections from the frontal cortex, and this corticostriatal loop has been implicated in the learning of skills and habits. Furthermore, recent functional MRI work suggests that the MTL-based declarative memory and the corticostriatal procedural memory systems operate independently from each other and may in fact compete for cognitive resources. That is, basal ganglia activity is negatively correlated with MTL activity when both systems are engaged by a particular task.

Bedside testing of nondeclarative memory is outside the realm of the generalist, but deficits may be reported by patients or their families.

MOLECULAR AND NEUROCHEMICAL BASIS OF LONG-TERM MEMORY

Long-term potentiation (LTP), which refers to a long-lasting enhancement of synaptic transmission resulting from repetitive stimulation of excitatory synapses, is presumed to be involved in episodic memory acquisition and storage. LTP occurs in the hippocampus and is mediated by *N*-methyl-D-aspartate (NMDA) receptors as well as the cyclic AMP–responsive element-binding (CREB) protein. Animal experiments have

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

shown that the formation of new episodic memories leads to physiologic changes in the synapse, while longer-term memory requires new protein synthesis and leads to physical changes at neuronal synapses.

The cholinergic system also plays an important role in memory, and anticholinergic agents such as atropine and scopolamine interfere with memory. Choline acetyltransferase (the enzyme catalyzing the formation of acetylcholine) is known to be deficient in the cortex of patients with AD. The brains of AD patients show severe neuronal loss in the nucleus basalis of Meynert, the major source of cholinergic input to the cerebral cortex. These findings form the basis for the use of cholinesterase inhibitors in the treatment of AD, with benefits thought to arise from increased levels of available acetylcholine. Behavior and mood are modulated by noradrenergic, serotonergic, and dopaminergic pathways, and norepinephrine has been shown to be reduced in the brainstem locus coeruleus in AD. Also, neurotrophins are postulated to play a role in memory in part by preserving cholinergic neurons. GABA agonists including the benzodiazepines are associated with reversible but sometimes severe episodes of amnesia. Working memory (see below) is strongly modulated by dopamine.

SHORT-TERM MEMORY

WORKING MEMORY

While the fractionation of memory into declarative and nondeclarative systems has provided a reasonable framework for understanding many aspects of memory's neurologic underpinnings, another major division of memory has used time as the distinguishing characteristic. While some information is retained for only a few seconds—enough time to hear, remember and dial a phone number—other memories are seemingly remembered throughout a life span. This brief type of memory differs from long-term memory, not only in terms of duration of retention but also with regard to its function and neuroanatomy.

Working memory stores items only as long as the information is in consciousness and is either being rehearsed (subvocally) or manipulated in some other fashion (i.e., rotated or integrated with existing information in semantic memory). The capacity of working memory is limited by attention. Normal individuals can hold about seven (plus or minus two) "bits" of information in working memory; these bits can be manipulated and either discarded or associated and transferred into long-term memory. Working memory is highly vulnerable to distraction and sometimes is even called *working attention* to emphasize the conscious and effortful processes that it entails. In the most widely accepted conceptualization of working memory, there are four main components: (1) a central executive that keeps track of and gathers information; (2) a visual system called the *visuospatial scratchpad*, which holds visual representations of objects; (3) a phonologic "system" that holds verbal information; and (4) an episodic buffer that is capable of binding together information from different modalities into a coherent trace.

Lesions that disrupt the structure or function of the dorsolateral frontal or posterior parietal regions decimate working memory. These deficits in working memory have a profound effect on the organism by disrupting the learning process downstream to working memory, or by affecting activities that directly depend on an intact working memory. In the classic amnesic syndrome, patients have intact working memory but cannot transfer information from working memory into long-term store.

Single-cell recordings have uncovered a network of neurons in the posterior parietal and dorsolateral frontal lobes where activity is high only during periods when information is being held in memory for use over just a few seconds. These neurons appear to provide an important functional basis for working memory. Similarly, functional imaging studies from humans show that the dorsolateral frontal lobes, particularly Brodmann area 46, are critical for working memory.

TESTING MEMORY AT THE BEDSIDE

Testing of memory should be performed in anyone in whom memory deficits are a concern, whether these concerns are raised by the patient, family, or health care workers. If the deficits are subtle, the testing may require a comprehensive consultation with a neuropsychologist, neuropsychiatrist, or behavioral neurologist. However, memory testing can be an extremely valuable component of the neurologic examination and performed effectively at the bedside. There are a wide variety of brief standardized screens of cognition, but the most commonly used test is the Mini Mental Status Examination (Table 365-5), a 30-point test that is strongly dependent on working (spell "world" backwards) and episodic memory (orientation and three-word recall). Testing semantic and procedural memory is usually outside the realm of the generalist, but if deficits in these systems are suspected, further tests are warranted.

Of all the memory processes, working memory is perhaps the easiest to assess at the bedside. The most common bedside test of working memory involves asking patients to repeat a series of digits orally, with the clinician gradually increasing the number of to-be-retained digits. There are two ways of administering the test. Asking the patient to repeat the digits in the same order as they were delivered is called *digit span forward*. In contrast, the clinician may also ask the patient to repeat the digits in reverse order, called *digit span backward*. Digit span forward is a test of attention, while digit span backward is a simple probe of working memory. The capacity for digit span forward is typically six numbers, while normal adults can generally repeat five digits backward.

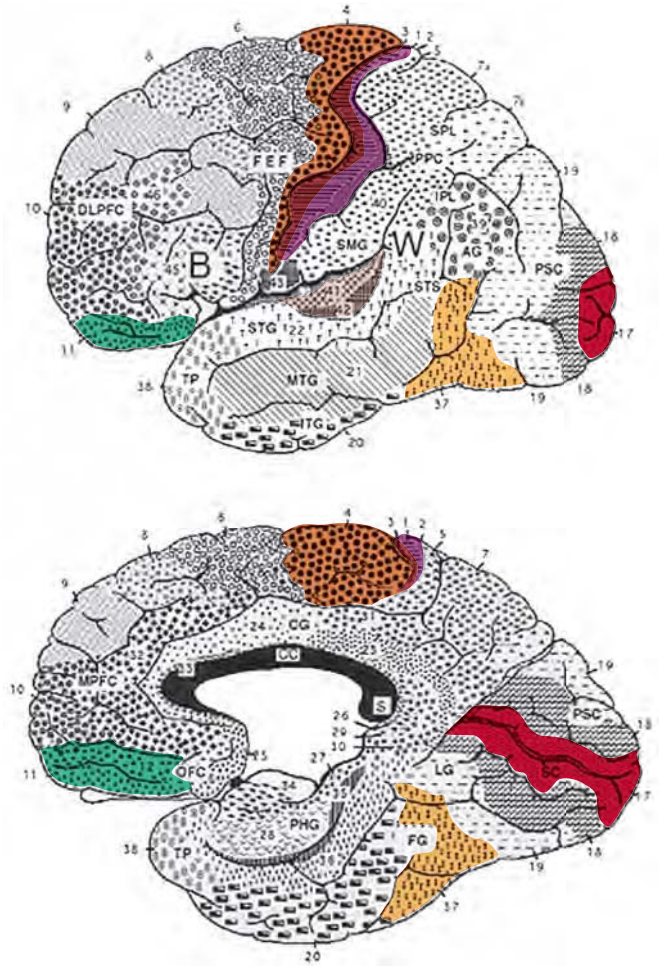

FIGURE 27-1 Lateral (*top*) and medial (*bottom*) views of the cerebral hemispheres. The numbers refer to the Brodmann cytoarchitectonic designations. Area 17 corresponds to the primary visual cortex, 41–42 to the primary auditory cortex, 1–3 to the primary somatosensory cortex, and 4 to the primary motor cortex. The rest of the cerebral cortex contains association areas. AG, angular gyrus; B, Broca's area; CC, corpus callosum; CG, cingulate gyrus; DLPFC, dorsolateral prefrontal cortex; FEF, frontal eye fields (premotor cortex); FG, fusiform gyrus; IPL, inferior parietal lobule; ITG, inferior temporal gyrus; LG, lingual gyrus; MPFC, medial prefrontal cortex; MTG, middle temporal gyrus; OFC, orbitofrontal cortex; PHG, parahippocampal gyrus; PPC, posterior parietal cortex; PSC, peristriate cortex; SC, striate cortex; SMG, supramarginal gyrus; SPL, superior parietal lobule; STG, superior temporal gyrus; STS, superior temporal sulcus; TP, temporopolar cortex; W, Wernicke's area.

guage function. Damage to any one of these components or to their interconnections can give rise to language disturbances (*aphasia*). Aphasia should be diagnosed only when there are deficits in the formal aspects of language such as naming, word choice, comprehension, spelling, and syntax. Dysarthria and mutism do not, by themselves, lead to a diagnosis of aphasia. The language network shows a left hemisphere dominance pattern in the vast majority of the population. In ~90% of right handers and 60% of left handers, aphasia occurs only after lesions of the left hemisphere. In some individuals no hemispheric dominance for language can be discerned, and in some others (including a small minority of right handers) there is a right hemisphere dominance for language. A language disturbance occurring after a right hemisphere lesion in a right hander is called *crossed aphasia*.

CLINICAL EXAMINATION

The clinical examination of language should include the assessment of naming, spontaneous speech, comprehension, repetition, reading, and writing. A deficit of naming (*anomia*) is the single most common finding in aphasic patients. When asked to name common objects (pencil or wristwatch), the patient may fail to come up with the appropriate word, may provide a circumlocutious description of the object ("the thing for writing"), or may come up with the wrong word (*paraphasia*). If the patient offers an incorrect but legitimate word ("pen" for "pencil"), the naming error is known as a *semantic paraphasia*; if the word approximates the correct answer but is phonetically inaccurate ("plentil" for "pencil"), it is known as a *phonemic paraphasia*. Asking the patient to name body parts, geometric shapes, and component parts of objects (lapel of coat, cap of pen) can elicit mild forms of anomia in patients who can otherwise name common objects. In most anomias, the patient cannot retrieve the appropriate name when shown an object but can point to the appropriate object when the name is provided by the examiner. This is known as a one-way (or retrieval-based) naming deficit. A two-way naming deficit exists if the patient can neither provide nor recognize the correct name, indicating the presence of a language comprehension impairment. *Spontaneous speech* is described as "fluent" if it maintains appropriate output volume, phrase length, and melody or as "nonfluent" if it is sparse, halting, and average utterance length is below four words. The examiner should also note if the speech is paraphasic or circumlocutious; if it shows a relative paucity of substantive nouns and action verbs versus function words (prepositions, conjunctions); and if word order, tenses, suffixes, prefixes, plurals, and possessives are appropriate. *Comprehension* can be tested by assessing the patient's ability to follow conversation, by asking yes-no questions ("Can a dog fly?", "Does it snow in summer?") or asking the patient to point to appropriate objects ("Where is the source of illumination in this room?"). Statements with embedded clauses or passive voice construction ("If a tiger is eaten by a lion, which animal stays alive?") help to assess the ability to comprehend complex syntactic structure. Commands to close or open the eyes, stand up, sit down, or roll over should not be used to assess overall comprehension since appropriate responses aimed at such axial movements can be preserved in patients who otherwise have profound comprehension deficits.

Repetition is assessed by asking the patient to repeat single words, short sentences, or strings of words such as "No ifs, ands, or buts." The testing of repetition with tongue-twisters such as "hippopotamus" or "Irish constabulary" provides a better assessment of dysarthria and palilalia than aphasia. Aphasic patients may have little difficulty with tongue-twisters but have a particularly hard time repeating a string of function words. It is important to make sure that the number of words does not exceed the patient's attention span. Otherwise, the failure of repetition becomes a reflection of the narrowed attention span rather than an indication of an aphasic deficit. *Reading* should be assessed for deficits in reading aloud as well as comprehension. *Writing* is assessed for spelling errors, word order, and grammar. *Alexia* describes an inability to either read aloud or comprehend single words and simple sentences; *agraphia* (or dysgraphia) is used to describe an acquired deficit in the spelling or grammar of written language.

The correspondence between individual deficits of language function and lesion location does not display a rigid one-to-one relationship and should be conceptualized within the context of the distributed network model. Nonetheless, the classification of aphasias of acute onset into specific clinical syndromes helps to determine the most likely anatomic distribution of the underlying neurologic disease and has implications for etiology and prognosis (Table 27-1). The syndromes listed in Table 27-1 are most applicable to aphasias caused by cerebrovascular accidents (CVA). They can be divided into "central" syndromes, which result from damage to the two epicenters of the language network (Broca's and Wernicke's areas), and "disconnection" syndromes, which arise from lesions that interrupt the functional connectivity of these centers with each other and with the other components of the language network. The syndromes outlined below are idealizations; pure syndromes occur rarely.

Wernicke's Aphasia Comprehension is impaired for spoken and written language. Language output is fluent but is highly paraphasic and circumlocutious. The tendency for paraphasic errors may be so pronounced that it leads to strings of neologisms, which form the basis of what is known as "jargon aphasia." Speech contains large

numbers of function words (e.g., prepositions, conjunctions) but few substantive nouns or verbs that refer to specific actions. The output is therefore voluminous but uninformative. For example, a patient attempts to describe how his wife accidentally threw away something important, perhaps his dentures: "We don't need it anymore, she says. And with it when that was downstairs was my teeth-tick . . . a . . . den . . . dentith . . . my dentist. And they happened to be in that bag . . . see? How could this have happened? How could a thing like this happen…So she says we won't need it anymore…I didn't think we'd use it. And now if I have any problems anybody coming a month from now, 4 months from now, or 6 months from now, I have a new dentist. Where my two . . . two little pieces of dentist that I use . . . that I . . . all gone. If she throws the whole thing away . . . visit some friends of hers and she can't throw them away."

TABLE 27-1 CLINICAL FEATURES OF APHASIAS AND RELATED CONDITIONS

	Comprehension	Repetition of Spoken Language	Naming	Fluency
Wernicke's	Impaired	Impaired	Impaired	Preserved or increased
Broca's	Preserved (except grammar)	Impaired	Impaired	Decreased
Global	Impaired	Impaired	Impaired	Decreased
Conduction	Preserved	Impaired	Impaired	Preserved
Nonfluent (motor) transcortical	Preserved	Preserved	Impaired	Impaired
Fluent (sensory) transcortical	Impaired	Preserved	Impaired	Preserved
Isolation	Impaired	Echolalia	Impaired	No purposeful speech
Anomic	Preserved	Preserved	Impaired	Preserved except for word-finding pauses
Pure word deafness	Impaired only for spoken language	Impaired	Preserved	Preserved
Pure alexia	Impaired only for reading	Preserved	Preserved	Preserved

Gestures and pantomime do not improve communication. The patient does not seem to realize that his or her language is incomprehensible and may appear angry and impatient when the examiner fails to decipher the meaning of a severely paraphasic statement. In some patients this type of aphasia can be associated with severe agitation and paranoid behaviors. One area of comprehension that may be preserved is the ability to follow commands aimed at axial musculature. The dissociation between the failure to understand simple questions ("What is your name?") in a patient who rapidly closes his or her eyes, sits up, or rolls over when asked to do so is characteristic of Wernicke's aphasia and helps to differentiate it from deafness, psychiatric disease, or malingering. Patients with Wernicke's aphasia cannot express their thoughts in meaning-appropriate words and cannot decode the meaning of words in any modality of input. This aphasia therefore has expressive as well as receptive components. Repetition, naming, reading, and writing are also impaired.

The lesion site most commonly associated with Wernicke's aphasia is the posterior portion of the language network and tends to involve at least parts of Wernicke's area. An embolus to the inferior division of the middle cerebral artery, and to the posterior temporal or angular branches in particular, is the most common etiology (Chap. 364). Intracerebral hemorrhage, severe head trauma, or neoplasm are other causes. A coexisting right hemi- or superior quadrantanopia is common, and mild right nasolabial flattening may be found, but otherwise the examination is often unrevealing. The paraphasic, neologistic speech in an agitated patient with an otherwise unremarkable neurologic examination may lead to the suspicion of a primary psychiatric disorder such as schizophrenia or mania, but the other components characteristic of acquired aphasia and the absence of prior psychiatric disease usually settle the issue. Some patients with Wernicke's aphasia due to intracerebral hemorrhage or head trauma may improve as the hemorrhage or the injury heals. In most other patients, prognosis for recovery is guarded.

Broca's Aphasia Speech is nonfluent, labored, interrupted by many word-finding pauses, and usually dysarthric. It is impoverished in function words but enriched in meaning-appropriate nouns and verbs. Abnormal word order and the inappropriate deployment of *bound morphemes* (word endings used to denote tenses, possessives, or plurals) lead to a characteristic agrammatism. Speech is telegraphic and pithy but quite informative. In the following passage, a patient with Broca's aphasia describes his medical history: "I see . . . the dotor, dotor sent me . . . Bosson. Go to hospital. Dotor . . . kept me beside. Two, tee days, doctor send me home."

Output may be reduced to a grunt or single word ("yes" or "no"), which is emitted with different intonations in an attempt to express approval or disapproval. In addition to fluency, naming and repetition are also impaired. Comprehension of spoken language is intact, except for syntactically difficult sentences with passive voice structure or embedded clauses. Reading comprehension is also preserved, with the occasional exception of a specific inability to read small grammatical words such as conjunctions and pronouns. The last two features indicate that Broca's aphasia is not just an "expressive" or "motor" disorder and that it may also involve a comprehension deficit for function words and syntax. Patients with Broca's aphasia can be tearful, easily frustrated, and profoundly depressed. Insight into their condition is preserved, in contrast to Wernicke's aphasia. Even when spontaneous speech is severely dysarthric, the patient may be able to display a relatively normal articulation of words when singing. This dissociation has been used to develop specific therapeutic approaches (melodic intonation therapy) for Broca's aphasia. Additional neurologic deficits usually include right facial weakness, hemiparesis or hemiplegia, and a buccofacial apraxia characterized by an inability to carry out motor commands involving oropharyngeal and facial musculature (e.g., patients are unable to demonstrate how to blow out a match or suck through a straw). Visual fields are intact. The cause is most often infarction of Broca's area (the inferior frontal convolution; "B" in Fig. 27-1) and surrounding anterior perisylvian and insular cortex, due to occlusion of the superior division of the middle cerebral artery (Chap. 364). Mass lesions including tumor, intracerebral hemorrhage, or abscess may also be responsible. Small lesions confined to the posterior part of Broca's area may lead to a nonaphasic and often reversible deficit of speech articulation, usually accompanied by mild right facial weakness. When the cause of Broca's aphasia is stroke, recovery of language function generally peaks within 2–6 months, after which time further progress is limited.

Global Aphasia Speech output is nonfluent, and comprehension of spoken language is severely impaired. Naming, repetition, reading, and writing are also impaired. This syndrome represents the combined dysfunction of Broca's and Wernicke's areas and usually results from strokes that involve the entire middle cerebral artery distribution in the left hemisphere. Most patients are initially mute or say a few words, such as "hi" or "yes." Related signs include right hemiplegia, hemisensory loss, and homonymous hemianopia. Occasionally, a patient with a lesion in Wernicke's area will present with a global aphasia that soon resolves into Wernicke's aphasia.

Conduction Aphasia Speech output is fluent but paraphasic, comprehension of spoken language is intact, and repetition is severely impaired. Naming and writing are also impaired. Reading aloud is impaired, but reading comprehension is preserved. The lesion sites spare Broca's and Wernicke's areas but may induce a functional disconnection between the two so that lexical representations formed in Wernicke's area and adjacent regions cannot be conveyed to Broca's area for assembly into corresponding articulatory patterns. Occasionally, a Wernicke's area lesion gives rise to a transient Wernicke's aphasia

that rapidly resolves into a conduction aphasia. The paraphasic output in conduction aphasia interferes with the ability to express meaning, but this deficit is not nearly as severe as the one displayed by patients with Wernicke's aphasia. Associated neurologic signs in conduction aphasia vary according to the primary lesion site.

Nonfluent Transcortical Aphasia (Transcortical Motor Aphasia) The features are similar to Broca's aphasia, but repetition is intact and agrammatism may be less pronounced. The neurologic examination may be otherwise intact, but a right hemiparesis can also exist. The lesion site disconnects the intact language network from prefrontal areas of the brain and usually involves the anterior watershed zone between anterior and middle cerebral artery territories or the supplementary motor cortex in the territory of the anterior cerebral artery.

Fluent Transcortical Aphasia (Transcortical Sensory Aphasia) Clinical features are similar to those of Wernicke's aphasia, but repetition is intact. The lesion site disconnects the intact core of the language network from other temporoparietal association areas. Associated neurologic findings may include hemianopia. Cerebrovascular lesions (e.g., infarctions in the posterior watershed zone) or neoplasms that involve the temporoparietal cortex posterior to Wernicke's area are the most common causes.

Isolation Aphasia This rare syndrome represents a combination of the two transcortical aphasias. Comprehension is severely impaired, and there is no purposeful speech output. The patient may parrot fragments of heard conversations (*echolalia*), indicating that the neural mechanisms for repetition are at least partially intact. This condition represents the pathologic function of the language network when it is isolated from other regions of the brain. Broca's and Wernicke's areas tend to be spared, but there is damage to the surrounding frontal, parietal, and temporal cortex. Lesions are patchy and can be associated with anoxia, carbon monoxide poisoning, or complete watershed zone infarctions.

Anomic Aphasia This form of aphasia may be considered the "minimal dysfunction" syndrome of the language network. Articulation, comprehension, and repetition are intact, but confrontation naming, word finding, and spelling are impaired. Speech is enriched in function words but impoverished in substantive nouns and verbs denoting specific actions. Language output is fluent but paraphasic, circumlocutious, and uninformative. The lesion sites can be anywhere within the left hemisphere language network, including the middle and inferior temporal gyri. *Anomic aphasia is the single most common language disturbance seen in head trauma, metabolic encephalopathy, and Alzheimer's disease.*

Pure Word Deafness The most common causes are either bilateral or left-sided middle cerebral artery strokes affecting the superior temporal gyrus. The net effect of the underlying lesion is to interrupt the flow of information from the unimodal auditory association cortex to Wernicke's area. Patients have no difficulty understanding written language and can express themselves well in spoken or written language. They have no difficulty interpreting and reacting to environmental sounds since primary auditory cortex and subcortical auditory relays are intact. Since auditory information cannot be conveyed to the language network, however, it cannot be decoded into lexical representations and the patient reacts to speech as if it were in an alien tongue that cannot be deciphered. Patients cannot repeat spoken language but have no difficulty naming objects. In time, patients with pure word deafness teach themselves lip reading and may appear to have improved. There may be no additional neurologic findings, but agitated paranoid reactions are frequent in the acute stages. Cerebrovascular lesions are the most frequent cause.

Pure Alexia without Agraphia This is the visual equivalent of pure word deafness. The lesions (usually a combination of damage to the left occipital cortex and to a posterior sector of the corpus callosum—the splenium) interrupt the flow of visual input into the language network. There is usually a right hemianopia, but the core language network remains unaffected. The patient can understand and produce spoken language, name objects in the left visual hemifield, repeat, and write. However, the patient acts as if illiterate when asked to read even the simplest sentence because the visual information from the written words (presented to the intact left visual hemifield) cannot reach the language network. Objects in the left hemifield may be named accurately because they activate nonvisual associations in the right hemisphere, which, in turn, can access the language network through transcallosal pathways anterior to the splenium. Patients with this syndrome may also lose the ability to name colors, although they can match colors. This is known as a *color anomia*. The most common etiology of pure alexia is a vascular lesion in the territory of the posterior cerebral artery or an infiltrating neoplasm in the left occipital cortex that involves the optic radiations as well as the crossing fibers of the splenium. Since the posterior cerebral artery also supplies medial temporal components of the limbic system, the patient with pure alexia may also experience an amnesia, but this is usually transient because the limbic lesion is unilateral.

Aphemia There is an acute onset of severely impaired fluency (often mutism), which cannot be accounted for by corticobulbar, cerebellar, or extrapyramidal dysfunction. Recovery is the rule and involves an intermediate stage of hoarse whispering. Writing, reading, and comprehension are intact, so this is not a true aphasic syndrome. Partial lesions of Broca's area or subcortical lesions that undercut its connections with other parts of the brain may be present. Occasionally, the lesion site is on the medial aspects of the frontal lobes and may involve the supplementary motor cortex of the left hemisphere.

Apraxia This generic term designates a complex motor deficit that cannot be attributed to pyramidal, extrapyramidal, cerebellar, or sensory dysfunction and that does not arise from the patient's failure to understand the nature of the task. The form that is most frequently encountered in clinical practice is known as *ideomotor apraxia*. Commands to perform a specific motor act ("cough," "blow out a match") or to pantomime the use of a common tool (a comb, hammer, straw, or toothbrush) in the absence of the real object cannot be followed. The patient's ability to comprehend the command is ascertained by demonstrating multiple movements and establishing that the correct one can be recognized. Some patients with this type of apraxia can imitate the appropriate movement (when it is demonstrated by the examiner) and show no impairment when handed the real object, indicating that the sensorimotor mechanisms necessary for the movement are intact. Some forms of ideomotor apraxia represent a disconnection of the language network from pyramidal motor systems: commands to execute complex movements are understood but cannot be conveyed to the appropriate motor areas, even though the relevant motor mechanisms are intact. *Buccofacial apraxia* involves apraxic deficits in movements of the face and mouth. *Limb apraxia* encompasses apraxic deficits in movements of the arms and legs. Ideomotor apraxia is almost always caused by lesions in the left hemisphere and is commonly associated with aphasic syndromes, especially Broca's aphasia and conduction aphasia. Its presence cannot be ascertained in patients with language comprehension deficits. The ability to follow commands aimed at axial musculature ("close the eyes," "stand up") is subserved by different pathways and may be intact in otherwise severely aphasic and apraxic patients. Patients with lesions of the anterior corpus callosum can display a special type of ideomotor apraxia confined to the left side of the body. Since the handling of real objects is not impaired, ideomotor apraxia, by itself, causes no major limitation of daily living activities.

Ideational apraxia refers to a deficit in the execution of a goal-directed sequence of movements in patients who have no difficulty executing the individual components of the sequence. For example, when asked to pick up a pen and write, the sequence of uncapping the pen, placing the cap at the opposite end, turning the point toward the writing surface, and writing may be disrupted, and the patient may be seen trying to write with the wrong end of the pen or even with the removed cap. These motor sequencing problems are usually seen in the context of confusional states

and dementias rather than focal lesions associated with aphasic conditions. *Limb-kinetic apraxia* involves a clumsiness in the actual use of tools that cannot be attributed to sensory, pyramidal, extrapyramidal, or cerebellar dysfunction. This condition can emerge in the context of focal premotor cortex lesions or *corticobasal ganglionic degeneration*.

Gerstmann's Syndrome The combination of *acalculia* (impairment of simple arithmetic), *dysgraphia* (impaired writing), *finger anomia* (an inability to name individual fingers such as the index or thumb), and *right-left confusion* (an inability to tell whether a hand, foot, or arm of the patient or examiner is on the right or left side of the body) is known as Gerstmann's syndrome. In making this diagnosis it is important to establish that the finger and left-right naming deficits are not part of a more generalized anomia and that the patient is not otherwise aphasic. When Gerstmann's syndrome is seen in isolation, it is commonly associated with damage to the inferior parietal lobule (especially the angular gyrus) in the left hemisphere.

Aprosodia Variations of melodic stress and intonation influence the meaning and impact of spoken language. For example, the two statements "He *is* clever." and "He is *clever*?" contain an identical word choice and syntax but convey vastly different messages because of differences in the intonation and stress with which the statements are uttered. This aspect of language is known as *prosody*. Damage to perisylvian areas in the right hemisphere can interfere with speech prosody and can lead to syndromes of aprosodia. Damage to right hemisphere regions corresponding to Wernicke's area can selectively impair decoding of speech prosody, whereas damage to right hemisphere regions corresponding to Broca's area yields a greater impairment in the ability to introduce meaning-appropriate prosody into spoken language. The latter deficit is the most common type of aprosodia identified in clinical practice—the patient produces grammatically correct language with accurate word choice but the statements are uttered in a monotone that interferes with the ability to convey the intended stress and affect. Patients with this type of aprosodia give the mistaken impression of being depressed or indifferent.

Subcortical Aphasia Damage to subcortical components of the language network (e.g., the striatum and thalamus of the left hemisphere) can also lead to aphasia. The resulting syndromes contain combinations of deficits in the various aspects of language but rarely fit the specific patterns described in Table 27-1. In a patient with a CVA, an anomic aphasia accompanied by dysarthria or a fluent aphasia with hemiparesis should raise the suspicion of a subcortical lesion site.

Progressive Aphasias In clinical practice, acquired aphasias are most commonly encountered in one of two contexts: CVAs and degenerative diseases. Aphasias caused by CVAs start suddenly and display maximal deficits at the onset. The underlying lesion is relatively circumscribed and associated with a total loss of neural function at the lesion site. These are the "classic" aphasias described above where relatively reproducible relationships between lesion site and aphasia pattern can be discerned. Aphasias caused by neurodegenerative diseases have an insidious onset and relentless progression so that the symptomatology changes over time. Since the neuronal loss within the areas encompassed by the neurodegeneration is partial and since it tends to include multiple components of the language network, distinctive clinical patterns and clinico-anatomic correlations are less obvious.

Dementia is a generic term used to designate a neurodegenerative disease that impairs intellect and behavior to the point where customary daily living activities become compromised (Chap. 365). Alzheimer's disease is the single most common cause of dementia. The neuropathology of Alzheimer's disease causes the earliest and most profound neuronal loss in memory-related parts of the brain such as the entorhinal cortex and the hippocampus. This is why progressive forgetfulness for recent events and experiences is the cardinal feature of Alzheimer's disease. In time, the neuronal pathology in Alzheimer's disease spreads to the language network and a progressive aphasia, usually of the anomic type, becomes added to the progressive amnesia. There are other patterns of dementia, however, where neurodegeneration initially targets the language rather than memory network of the brain, leading to the emergence of a progressive aphasia that becomes the most prominent aspect of the clinical picture during the initial phases of the disease. Primary progressive aphasia (PPA) is the most widely recognized syndrome with this pattern of selective language impairment.

CLINICAL PRESENTATION AND DIAGNOSIS OF PPA The patient with PPA comes to medical attention because of word-finding difficulties, abnormal speech patterns, and spelling errors of recent onset. PPA is diagnosed when other mental faculties such as memory for daily events, visuospatial skills (assessed by tests of drawing and face recognition), and comportment (assessed by history obtained from a third party) remain relatively intact; when language is the major area of dysfunction for the first few years of the disease; and when structural brain imaging does not reveal a specific lesion, other than atrophy, to account for the language deficit. Impairments in other cognitive functions may also emerge, but the language dysfunction remains the most salient feature and deteriorates most rapidly throughout the illness.

LANGUAGE IN PPA The language impairment in PPA varies from patient to patient. Some patients cannot find the right words to express thoughts; others cannot understand the meaning of heard or seen words; still others cannot name objects in the environment. The language impairment can be fluent (that is, with normal articulation, flow, and number of words per utterance) or nonfluent. The single most common sign of primary progressive aphasia is anomia, manifested by an inability to come up with the right word during conversation and/or an inability to name objects shown by the examiner. Many patients remain in an anomic phase through most of the disease and experience a gradual intensification of word-finding deficits to the point of near-mutism. Others, however, proceed to develop distinct forms of agrammatism and/or word comprehension deficits. The agrammatism consists of inappropriate word order and misuse of small grammatical words. One patient, for example, sent the following e-mail to her daughter: "I will come my house in your car and drive my car into chicago. . . . You will back get your car and my car park in my driveway. Love, Mom." Comprehension deficits, if present, start with an occasional inability to understand single low-frequency words and gradually progress to encompass the comprehension of conversational speech.

The impairments of syntax, comprehension, naming, or writing in PPA are no different from those seen in aphasias of cerebrovascular causes. However, they form slightly different patterns. According to a classification proposed by Gorno-Tempini and colleagues, three variants of PPA can be recognized: an agrammatical variant characterized by poor fluency and impaired syntax, a semantic variant characterized by preserved fluency and syntax but poor single word comprehension, and a logopenic variant characterized by preserved syntax and comprehension but frequent word-finding pauses during spontaneous speech. The agrammatical variant is also known as *progressive nonfluent aphasia* and displays similarities to Broca's aphasia. However, dysarthria is usually absent. The semantic variant of PPA is also known as *semantic dementia* and displays similarities to Wernicke's aphasia, but the comprehension difficulty tends to be milder. The most obvious difference between aphasias caused by CVA and those caused by neurodegenerative disease is the post-stroke improvement in CVA-related aphasias, leading to a progressive crystallization of the subtypes listed in Table 27-1, versus the gradual deterioration that leads to a loss of syndromic specificity as the disease progresses.

PATHOPHYSIOLOGY Patients with PPA display progressive atrophy (indicative of neuronal loss), electroencephalographic slowing, decreased blood flow (measured by single photon emission CT) and decreased glucose utilization (measured by positron emission tomography) that are most pronounced within the language network of the brain. The abnormalities may remain confined to left hemisphere perisylvian and anterior temporal cortices for many years. The clinical focality of pri-

mary progressive aphasia is thus matched by the anatomic selectivity of the underlying pathologic process.

The three variants display overlapping distributions of neuronal loss but the agrammatical variant is most closely associated with atrophy in the anterior parts of the language network (where Broca's area is located), the semantic variant with atrophy in the temporal components of the language network, and the logopenic variant with atrophy in the temporoparietal component of the language network. The relationship between poor language comprehension and damage to Wernicke's area, which is a feature of CVA-related aphasias, is not present in PPA. Instead, poor comprehension is most closely associated with neuronal loss in the lateral and anterior temporal cortex.

NEUROPATHOLOGY Approximately 30% of patients have shown the microscopic pathology of Alzheimer's disease, presumably with an atypical distribution of lesions. In the majority of cases, the neuropathology falls within the family of frontotemporal lobar degenerations (FTLD) and displays various combinations of focal neuronal loss, gliosis, tau-positive inclusions, Pick bodies, and tau-negative ubiquitin inclusions (Chap. 365). Familial forms of PPA with tau-negative ubiquinated inclusions have recently been linked to mutations of the progranulin gene on chromosome 17. Apolipoprotein E and prion protein genotyping has shown differences between patients with typical clinical patterns of Alzheimer's disease and those with a diagnosis of PPA. The intriguing possibility has been raised that a personal or family history of dyslexia may be a risk factor for primary progressive aphasia, at least in some patients, suggesting that this disease may arise on a background of genetic or developmental vulnerability affecting language-related areas of the brain.

THE PARIETOFRONTAL NETWORK FOR SPATIAL ORIENTATION: NEGLECT AND RELATED CONDITIONS

HEMISPATIAL NEGLECT

Adaptive orientation to significant events within the extrapersonal space is subserved by a large-scale network containing three major cortical components. The *cingulate cortex* provides access to a limbic-motivational mapping of the extrapersonal space, the *posterior parietal cortex* to a sensorimotor representation of salient extrapersonal events, and the *frontal eye fields* to motor strategies for attentional behaviors (Fig. 27-2). Subcortical components of this network include the striatum and the thalamus. Contralesional hemispatial neglect represents one outcome of damage to any of the cortical or subcortical components of this network. *The traditional view that hemispatial neglect always denotes a parietal lobe lesion is inaccurate*. In keeping with this anatomic organization, the clinical manifestations of neglect display three behavioral components: sensory events (or their mental representations) within the neglected hemispace have a lesser impact on overall awareness; there is a paucity of exploratory and orienting acts directed toward the neglected hemispace; and the patient behaves as if the neglected hemispace was motivationally devalued.

According to one model of spatial cognition, the right hemisphere directs attention within the *entire* extrapersonal space, whereas the left hemisphere directs attention mostly within the contralateral right hemispace. Consequently, unilateral left hemisphere lesions do not give rise to much contralesional neglect since the global attentional mechanisms of the right hemisphere can compensate for the loss of the *contralaterally* directed attentional functions of the left hemisphere. Unilateral right hemisphere lesions, however, give rise to severe contralesional left hemispatial neglect because the unaffected left hemisphere does not contain ipsilateral attentional mechanisms. This model is consistent with clinical experience, which shows that contralesional neglect is more common, severe, and lasting after damage to the right hemisphere than after damage to the left hemisphere. Severe neglect for the right hemispace is rare, even in left handers with left hemisphere lesions.

Patients with severe neglect may fail to dress, shave, or groom the left side of the body; may fail to eat food placed on the left side of the tray; and may fail to read the left half of sentences. When the examiner

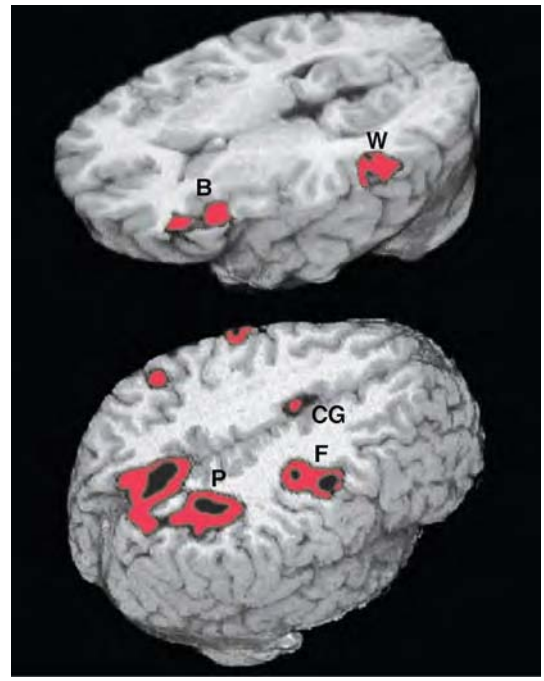

FIGURE 27-2 Functional magnetic resonance imaging of language and spatial attention in neurologically intact subjects. The dark areas show regions of task-related significant activation. (*Top*) The subjects were asked to determine if two words were synonymous. This language task led to the simultaneous activation of the two epicenters of the language network, Broca's area (B) and Wernicke's area (W). The activations are exclusively in the left hemisphere. (*Bottom*) The subjects were asked to shift spatial attention to a peripheral target. This task led to the simultaneous activation of the three epicenters of the attentional network, the posterior parietal cortex (P), the frontal eye fields (F), and the cingulate gyrus (CG). The activations are predominantly in the right hemisphere. (*Courtesy of Darren Gitelman, MD; with permission.*)

draws a large circle [12–15 cm (5–6 in.) in diameter] and asks the patient to place the numbers 1–12 as if the circle represented the face of a clock, there is a tendency to crowd the numbers on the right side and leave the left side empty. When asked to copy a simple line drawing, the patient fails to copy detail on the left; and when asked to write, there is a tendency to leave an unusually wide margin on the left.

Two bedside tests that are useful in assessing neglect are *simultaneous bilateral stimulation* and *visual target cancellation*. In the former, the examiner provides either unilateral or simultaneous bilateral stimulation in the visual, auditory, and tactile modalities. Following right hemisphere injury, patients who have no difficulty detecting unilateral stimuli on either side experience the bilaterally presented stimulus as coming only from the right. This phenomenon is known as *extinction* and is a manifestation of the sensory-representational aspect of hemispatial neglect. In the target detection task, targets (e.g., As) are interspersed with foils (e.g., other letters of the alphabet) on a 21.5 × 28.0 cm (8.5 × 11 in.) sheet of paper and the patient is asked to circle all the targets. A failure to detect targets on the left is a manifestation of the exploratory deficit in hemispatial neglect (Fig. 27-3*A*). Hemianopia, by itself, does not interfere with performance in this task since the patient is free to turn the head and eyes to the left. The normal tendency in target detection tasks is to start from the left upper quadrant and move systematically in horizontal or vertical sweeps. Some patients show a tendency to start the process from the right and proceed in a haphazard fashion. This represents a subtle manifestation of left neglect, even if the patient eventually manages to detect all the appropriate targets. Some patients with neglect may also deny the existence of hemiparesis and may even deny ownership of the paralyzed limb, a condition known as *anosognosia*.

Cerebrovascular lesions and neoplasms in the right hemisphere are the most common causes of hemispatial neglect. Depending on the

B

FIGURE 27-3 Evidence of left hemispatial neglect and simultanagnosia. ***A.*** A 47-year-old man with a large frontoparietal lesion in the right hemisphere was asked to circle all the As. Only targets on the right are circled. This is a manifestation of left hemispatial neglect. ***B.*** A 70-year-old woman with a 2-year history of degenerative dementia was able to circle most of the small targets but ignored the larger ones. This is a manifestation of simultanagnosia.

site of the lesion, the patient with neglect may also have hemiparesis, hemihypesthesia, and hemianopia on the left, but these are not invariant findings. The majority of patients display considerable improvement of hemispatial neglect, usually within the first several weeks.

BÁLINT'S SYNDROME, SIMULTANAGNOSIA, DRESSING APRAXIA, AND CONSTRUCTION APRAXIA

Bilateral involvement of the network for spatial attention, especially its parietal components, leads to a state of severe spatial disorientation known as *Bálint's syndrome*. Bálint's syndrome involves deficits in the orderly visuomotor scanning of the environment (*oculomotor apraxia*) and in accurate manual reaching toward visual targets (*optic ataxia*). The third and most dramatic component of Bálint's syndrome is known as *simultanagnosia* and reflects an inability to integrate visual information in the center of gaze with more peripheral information. The patient gets stuck on the detail that falls in the center of gaze without attempting to scan the visual environment for additional information. The patient with simultanagnosia "misses the forest for the trees." Complex visual scenes cannot be grasped in their entirety, leading to severe limitations in the visual identification of objects and scenes. For example, a patient who is shown a table lamp and asked to name the object may look at its circular base and call it an ash tray. Some patients with simultanagnosia report that objects they look at may suddenly vanish, probably indicating an inability to look back at the original point of gaze after brief saccadic displacements. Movement and distracting stimuli greatly exacerbate the difficulties of visual perception. Simultanagnosia can sometimes occur without the other two components of Bálint's syndrome.

A modification of the letter cancellation task described above can be used for the bedside diagnosis of simultanagnosia. In this modification, some of the targets (e.g., As) are made to be much larger than the others [7.5–10 cm vs 2.5 cm (3–4 in. vs 1 in.) in height], and all targets are embedded among foils. Patients with simultanagnosia display a counterintuitive but characteristic tendency to miss the larger targets (Fig. 27-3*B*). This occurs because the information needed for the identification of the larger targets cannot be confined to the immediate line of gaze and requires the integration of visual information across a more extensive field of view. The greater difficulty in the detection of the larger targets also indicates that poor acuity is not responsible for the impairment of visual function and that the problem is central rather than peripheral. Bálint's syndrome results from bilateral dorsal parietal lesions; common settings include watershed infarction between the middle and posterior cerebral artery territories, hypoglycemia, sagittal sinus thrombosis, or atypical forms of Alzheimer's disease. In patients with Bálint's syndrome due to stroke, bilateral visual field defects (usually inferior quadrantanopias) are common.

Another manifestation of bilateral (or right-sided) dorsal parietal lobe lesions is *dressing apraxia*. The patient with this condition is unable to align the body axis with the axis of the garment and can be seen struggling as he or she holds a coat from its bottom or extends his or her arm into a fold of the garment rather than into its sleeve. Lesions that involve the posterior parietal cortex also lead to severe difficulties in copying simple line drawings. This is known as a *construction apraxia* and is much more severe if the lesion is in the right hemisphere. In some patients with right hemisphere lesions, the drawing difficulties are confined to the left side of the figure and represent a manifestation of hemispatial neglect; in others, there is a more universal deficit in reproducing contours and three-dimensional perspective. Dressing apraxia and construction apraxia represent special instances of a more general disturbance in spatial orientation.

THE OCCIPITOTEMPORAL NETWORK FOR FACE AND OBJECT RECOGNITION: PROSOPAGNOSIA AND OBJECT AGNOSIA

Perceptual information about faces and objects is initially encoded in primary (striate) visual cortex and adjacent (upstream) peristriate visual association areas. This information is subsequently relayed first to the downstream visual association areas of occipitotemporal cortex

and then to other heteromodal and paralimbic areas of the cerebral cortex. Bilateral lesions in the fusiform and lingual gyri of the occipitotemporal cortex disrupt this process and interfere with the ability of otherwise intact perceptual information to activate the distributed multimodal associations that lead to the recognition of faces and objects. The resultant face and object recognition deficits are known as *prosopagnosia* and *visual object agnosia*.

The patient with prosopagnosia cannot recognize familiar faces, including, sometimes, the reflection of his or her own face in the mirror. This is not a perceptual deficit since prosopagnosic patients can easily tell if two faces are identical or not. Furthermore, a prosopagnosic patient who cannot recognize a familiar face by visual inspection alone can use auditory cues to reach appropriate recognition if allowed to listen to the person's voice. The deficit in prosopagnosia is therefore modality-specific and reflects the existence of a lesion that prevents the activation of otherwise intact multimodal templates by relevant visual input. Damasio has pointed out that the deficit in prosopagnosia is not limited to the recognition of faces but that it can also extend to the recognition of individual members of larger generic object groups. For example, prosopagnosic patients characteristically have no difficulty with the generic identification of a face as a face or of a car as a car, but they cannot recognize the identity of an individual face or the make of an individual car. This reflects a visual recognition deficit for proprietary features that characterize individual members of an object class. When recognition problems become more generalized and extend to the generic identification of common objects, the condition is known as visual object agnosia. In contrast to prosopagnosic patients, those with object agnosia cannot recognize a face as a face or a car as a car.

It is important to distinguish visual object agnosia from anomia. The patient with anomia cannot name the object but can describe its use. In contrast, the patient with visual agnosia is unable either to name a visually presented object or to describe its use. The characteristic lesions in prosopagnosia and visual object agnosia consist of bilateral infarctions in the territory of the posterior cerebral arteries. Associated deficits can include visual field defects (especially superior quadrantanopias) or a centrally based color blindness known as *achromatopsia*. Rarely, the responsible lesion is unilateral. In such cases, prosopagnosia is associated with lesions in the right hemisphere and object agnosia with lesions in the left.

THE LIMBIC NETWORK FOR MEMORY: AMNESIAS

Limbic and paralimbic areas (such as the hippocampus, amygdala, and entorhinal cortex), the anterior and medial nuclei of the thalamus, the medial and basal parts of the striatum, and the hypothalamus collectively constitute a distributed network known as the *limbic system*. The behavioral affiliations of this network include the coordination of emotion, motivation, autonomic tone, and endocrine function. An additional area of specialization for the limbic network, and the one which is of most relevance to clinical practice, is that of declarative (conscious) memory for recent episodes and experiences. A disturbance in this function is known as an *amnestic state*. In the absence of deficits in motivation, attention, language, or visuospatial function, the clinical diagnosis of a persistent global amnestic state is always associated with bilateral damage to the limbic network, usually within the hippocampo-entorhinal complex or the thalamus.

Although the limbic network is the site of damage for amnestic states, it is almost certainly not the storage site for memories. Memories are stored in widely distributed form throughout the cerebral cortex. The role attributed to the limbic network is to bind these distributed fragments into coherent events and experiences that can sustain conscious recall. Damage to the limbic network does not necessarily destroy memories but interferes with their conscious (declarative) recall in coherent form. The individual fragments of information remain preserved despite the limbic lesions and can sustain what is known as *implicit memory*. For example, patients with amnestic states can acquire new motor or perceptual skills, even though they may have no conscious knowledge of the experiences that led to the acquisition of these skills.

The memory disturbance in the amnestic state is multimodal and includes retrograde and anterograde components. The *retrograde amnesia* involves an inability to recall experiences that occurred before the onset of the amnestic state. Relatively recent events are more vulnerable to retrograde amnesia than more remote and more extensively consolidated events. A patient who comes to the emergency room complaining that he cannot remember his identity but who can remember the events of the previous day is almost certainly not suffering from a neurologic cause of memory disturbance. The second and most important component of the amnestic state is the *anterograde amnesia*, which indicates an inability to store, retain, and recall new knowledge. Patients with amnestic states cannot remember what they ate a few minutes ago or the details of an important event they may have experienced a few hours ago. In the acute stages, there may also be a tendency to fill in memory gaps with inaccurate, fabricated, and often implausible information. This is known as *confabulation*. Patients with the amnestic syndrome forget that they forget and tend to deny the existence of a memory problem when questioned.

The patient with an amnestic state is almost always disoriented, especially to time. Accurate temporal orientation and accurate knowledge of current news rule out a major amnestic state. The anterograde component of an amnestic state can be tested with a list of four to five words read aloud by the examiner up to five times or until the patient can immediately repeat the entire list without intervening delay. In the next phase of testing, the patient is allowed to concentrate on the words and to rehearse them internally for 1 min before being asked to recall them. Accurate performance in this phase indicates that the patient is motivated and sufficiently attentive to hold the words online for at least 1 min. The final phase of the testing involves a retention period of 5–10 min, during which the patient is engaged in other tasks. Adequate recall at the end of this interval requires offline storage, retention, and retrieval. Amnestic patients fail this phase of the task and may even forget that they were given a list of words to remember. Accurate recognition of the words by multiple choice in a patient who cannot recall them indicates a less severe memory disturbance that affects mostly the retrieval stage of memory. The retrograde component of an amnesia can be assessed with questions related to autobiographical or historic events. The anterograde component of amnestic states is usually much more prominent than the retrograde component. In rare instances, usually associated with temporal lobe epilepsy or benzodiazepine intake, the retrograde component may dominate.

The assessment of memory can be quite challenging. Bedside evaluations may only detect the most severe impairments. Less severe memory impairments, as in the case of patients with temporal lobe epilepsy, mild head injury, or early dementia, require quantitative evaluations by neuropsychologists. Confusional states caused by toxic-metabolic encephalopathies and some types of frontal lobe damage interfere with attentional capacity and lead to secondary memory impairments, even in the absence of any limbic lesions. This sort of memory impairment can be differentiated from the amnestic state by the presence of additional impairments in the attention-related tasks described below in the section on the frontal lobes.

Many neurologic diseases can give rise to an amnestic state. These include tumors (of the sphenoid wing, posterior corpus callosum, thalamus, or medial temporal lobe), infarctions (in the territories of the anterior or posterior cerebral arteries), head trauma, herpes simplex encephalitis, Wernicke-Korsakoff encephalopathy, paraneoplastic limbic encephalitis, and degenerative dementias such as Alzheimer's or Pick's disease. The one common denominator of all these diseases is that they lead to the bilateral lesions within one or more components in the limbic network, most commonly the hippocampus, entorhinal cortex, the mammillary bodies of the hypothalamus, and the limbic thalamus. Occasionally, unilateral left-sided lesions can give rise to an amnestic state, but the memory disorder tends to be transient. Depending on the nature and distribution of the underlying neurologic disease, the patient may also have visual field deficits, eye movement limitations, or cerebellar findings.

Transient global amnesia is a distinctive syndrome usually seen in late middle age. Patients become acutely disoriented and repeatedly ask who they are, where they are, what they are doing. The spell is characterized by anterograde amnesia (inability to retain new information)

and a retrograde amnesia for relatively recent events that occurred before the onset. The syndrome usually resolves within 24–48 h and is followed by the filling-in of the period affected by the retrograde amnesia, although there is persistent loss of memory for the events that occurred during the ictus. Recurrences are noted in ~20% of patients. Migraine, temporal lobe seizures, and transient ischemic events in the posterior cerebral territory have been postulated as causes of transient global amnesia. The absence of associated neurologic findings may occasionally lead to the incorrect diagnosis of a psychiatric disorder.

THE PREFRONTAL NETWORK FOR ATTENTION AND BEHAVIOR

Approximately one-third of all the cerebral cortex in the human brain is located in the frontal lobes. The frontal lobes can be subdivided into motor-premotor, dorsolateral prefrontal, medial prefrontal, and orbitofrontal components. The terms *frontal lobe syndrome* and *prefrontal cortex* refer only to the last three of these four components. These are the parts of the cerebral cortex that show the greatest phylogenetic expansion in primates and especially in humans. The dorsolateral prefrontal, medial prefrontal, and orbitofrontal areas, and the subcortical structures with which they are interconnected (i.e., the head of the caudate and the dorsomedial nucleus of the thalamus), collectively make up a large-scale network that coordinates exceedingly complex aspects of human cognition and behavior.

The prefrontal network plays an important role in behaviors that require an integration of thought with emotion and motivation. There is no simple formula for summarizing the diverse functional affiliations of the prefrontal network. Its integrity appears important for the simultaneous awareness of context, options, consequences, relevance, and emotional impact so as to allow the formulation of adaptive inferences, decisions, and actions. Damage to this part of the brain impairs mental flexibility, reasoning, hypothesis formation, abstract thinking, foresight, judgment, the online (attentive) holding of information, and the ability to inhibit inappropriate responses. Behaviors impaired by prefrontal cortex lesions, especially those related to the manipulation of mental content, are often referred to as "executive functions."

Even very large bilateral prefrontal lesions may leave all sensory, motor, and basic cognitive functions intact while leading to isolated but dramatic alterations of personality and behavior. The most common clinical manifestations of damage to the prefrontal network take the form of two relatively distinct syndromes. In the *frontal abulic syndrome*, the patient shows a loss of initiative, creativity, and curiosity and displays a pervasive emotional blandness and apathy. In the *frontal disinhibition syndrome*, the patient becomes socially disinhibited and shows severe impairments of judgment, insight, and foresight. The dissociation between intact cognitive function and a total lack of even rudimentary common sense is striking. Despite the preservation of all essential memory functions, the patient cannot learn from experience and continues to display inappropriate behaviors without appearing to feel emotional pain, guilt, or regret when such behaviors repeatedly lead to disastrous consequences. The impairments may emerge only in real-life situations when behavior is under minimal external control and may not be apparent within the structured environment of the medical office. Testing judgment by asking patients what they would do if they detected a fire in a theater or found a stamped and addressed envelope on the road is not very informative since patients who answer these questions wisely in the office may still act very foolishly in the more complex real-life setting. The physician must therefore be prepared to make a diagnosis of frontal lobe disease on the basis of historic information alone even when the office examination of mental state may be quite intact.

The abulic syndrome tends to be associated with damage to the dorsolateral prefrontal cortex, and the disinhibition syndrome with the medial prefrontal or orbitofrontal cortex. These syndromes tend to arise almost exclusively after bilateral lesions, most frequently in the setting of head trauma, stroke, ruptured aneurysms, hydrocephalus, tumors (including metastases, glioblastoma, and falx or olfactory groove meningiomas), or focal degenerative diseases. Unilateral lesions confined to the prefrontal cortex may remain silent until the pathology spreads to the other side. The emergence of developmentally primitive reflexes, also known as frontal release signs, such as grasping (elicited by stroking the palm) and sucking (elicited by stroking the lips) are seen primarily in patients with large structural lesions that extend into the premotor components of the frontal lobes or in the context of metabolic encephalopathies. The vast majority of patients with prefrontal lesions and frontal lobe behavioral syndromes do not display these reflexes.

Damage to the frontal lobe disrupts a variety of attention-related functions including working memory (the transient online holding of information), concentration span, the scanning and retrieval of stored information, the inhibition of immediate but inappropriate responses, and mental flexibility. The capacity for focusing on a trend of thought and the ability to voluntarily shift the focus of attention from one thought or stimulus to another can become impaired. Digit span (which should be seven forward and five reverse) is decreased; the recitation of the months of the year in reverse order (which should take less than 15 s) is slowed; and the fluency in producing words starting with a, f, or s that can be generated in 1 min (normally ≥12 per letter) is diminished even in nonaphasic patients. Characteristically, there is a progressive slowing of performance as the task proceeds; e.g., the patient asked to count backwards by 3s may say "100, 97, 94, . . . 91, . . . 88," etc., and may not complete the task. In "go–no-go" tasks (where the instruction is to raise the finger upon hearing one tap but to keep it still upon hearing two taps), the patient shows a characteristic inability to keep still in response to the "no-go" stimulus; mental flexibility (tested by the ability to shift from one criterion to another in sorting or matching tasks) is impoverished; distractibility by irrelevant stimuli is increased; and there is a pronounced tendency for impersistence and perseveration.

These attentional deficits disrupt the orderly registration and retrieval of new information and lead to *secondary* memory deficits. Such memory deficits can be differentiated from the *primary* memory impairments of the amnestic state by showing that they improve when the attentional load of the task is decreased. Working memory (also known as immediate memory) is an attentional function based on the temporary online holding of information. It is closely associated with the integrity of the prefrontal network and the ascending reticular activating system. Retentive memory, on the other hand, depends on the stable (offline) storage of information and is associated with the integrity of the limbic network. The distinction of the underlying neural mechanisms is illustrated by the observation that severely amnestic patients who cannot remember events that occurred a few minutes ago may have intact if not superior working memory capacity as shown in tests of digit span.

Lesions in the caudate nucleus or in the dorsomedial nucleus of the thalamus (subcortical components of the prefrontal network) can also produce a frontal lobe syndrome. This is one reason why the mental state changes associated with degenerative basal ganglia diseases, such as Parkinson's or Huntington's disease, may take the form of a frontal lobe syndrome. Because of its widespread connections with other regions of association cortex, one essential computational role of the prefrontal network is to function as an integrator, or "orchestrator," for other networks. Bilateral multifocal lesions of the cerebral hemispheres, none of which are individually large enough to cause specific cognitive deficits such as aphasia or neglect, can collectively interfere with the connectivity and integrating function of the prefrontal cortex. A frontal lobe syndrome is the single most common behavioral profile associated with a variety of bilateral multifocal brain diseases including metabolic encephalopathy, multiple sclerosis, vitamin B_{12} deficiency, and others. In fact, the vast majority of patients with the clinical diagnosis of a frontal lobe syndrome tend to have lesions that do not involve prefrontal cortex but involve either the subcortical components of the prefrontal network or its connections with other parts of the brain. In order to avoid making a diagnosis of "frontal lobe syndrome" in a patient with no evidence of frontal cortex disease, it is advisable to use the diagnostic term *frontal network syndrome*, with the understanding that the responsible lesions can lie anywhere within this distributed network.

The patient with frontal lobe disease raises potential dilemmas in differential diagnosis: the abulia and blandness may be misinterpreted as depression, and the disinhibition as idiopathic mania or acting-out. Appropriate intervention may be delayed while a treatable tumor keeps expanding. An informed approach to frontal lobe disease and its behavioral manifestations may help to avoid such errors.

CARING FOR THE PATIENT WITH DEFICITS OF HIGHER CEREBRAL FUNCTION

Some of the deficits described in this chapter are so complex that they may bewilder not only the patient and family but also the physician. It is imperative to carry out a systematic clinical evaluation in order to characterize the nature of the deficits and explain them in lay terms to the patient and family. Such an explanation can allay at least some of the anxieties, address the mistaken impression that the deficit (e.g., social disinhibition or inability to recognize family members) is psychologically motivated, and lead to practical suggestions for daily living activities. The consultation of a skilled neuropsychologist may aid in the formulation of diagnosis and management. Patients with simultanagnosia, for example, may benefit from the counterintuitive instruction to stand back when they cannot find an item so that a greater search area falls within the immediate field of gaze. Some patients with frontal lobe disease can be extremely irritable and abusive to spouses and yet display all the appropriate social graces during the visit to the medical office. In such cases, the history may be more important than the bedside examination in charting a course of treatment.

Reactive depression is common in patients with higher cerebral dysfunction and should be treated. These patients may be sensitive to the usual doses of antidepressants or anxiolytics and deserve a careful titration of dosage. Brain damage may cause a dissociation between feeling states and their expression, so that a patient who may superficially appear jocular could still be suffering from an underlying depression that deserves to be treated. In many cases, agitation may be controlled with reassurance. In other cases, treatment with sedating antidepressants may become necessary. The use of neuroleptics for the control of agitation should be reserved for refractory cases since extrapyramidal side effects are frequent in patients with coexisting brain damage.

Spontaneous improvement of cognitive deficits due to acute neurologic lesions is common. It is most rapid in the first few weeks but may continue for up to 2 years, especially in young individuals with single brain lesions. The mechanisms for this recovery are incompletely understood. Some of the initial deficits appear to arise from remote dysfunction (diaschisis) in parts of the brain that are interconnected with the site of initial injury. Improvement in these patients may reflect, at least in part, a normalization of the remote dysfunction. Other mechanisms may involve functional reorganization in surviving neurons adjacent to the injury or the compensatory use of homologous structures, e.g., the right superior temporal gyrus with recovery from Wernicke's aphasia. In some patients with large lesions involving Broca's and Wernicke's areas, only Wernicke's area may show contralateral compensatory reorganization (or bilateral functionality), giving rise to a situation where a lesion that should have caused a global aphasia becomes associated with a residual Broca's aphasia. Prognosis for recovery from aphasia is best when Wernicke's area is spared. Cognitive rehabilitation procedures have been used in the treatment of higher cortical deficits. There are few controlled studies, but some do show a benefit of rehabilitation in the recovery from hemispatial neglect and aphasia. Some types of deficits may be more prone to recovery than others. For example, patients with nonfluent aphasias are more likely to benefit from speech therapy than patients with fluent aphasias and comprehension deficits. In general, lesions that lead to a denial of illness (e.g., anosognosia) are associated with cognitive deficits that are more resistant to rehabilitation. The recovery from higher cortical dysfunction is rarely complete. Periodic neuropsychological assessment is necessary for quantifying the pace of the improvement and for generating specific recommendations for cognitive rehabilitation, modifications in the home environment, and the timetable for returning to school or work.

In general medical practice, most patients with deficits in higher cognitive functions will be suffering from dementia. There is a mistaken belief that dementias are anatomically diffuse and that they cause global cognitive impairments. This is only true at the terminal stages. During most of the clinical course, dementias are exquisitely selective with respect to anatomy and cognitive pattern. Alzheimer's disease, for example, causes the greatest destruction in medial temporal areas belonging to the memory network and is clinically characterized by a correspondingly severe amnesia. There are other dementias where memory is intact. Frontal lobe dementia results from a selective degeneration of the frontal lobe and leads to a gradual dissolution of behavior and complex attention. Primary progressive aphasia is characterized by a gradual atrophy of the left perisylvian language network and leads to a progressive dissolution of language that can remain isolated for up to 10 years. An enlightened approach to the differential diagnosis and treatment of these patients requires an understanding of the principles that link neural networks to higher cerebral functions.

28 Sleep Disorders

Charles A. Czeisler, John W. Winkelman, Gary S. Richardson

Disturbed sleep is among the most frequent health complaints physicians encounter. More than one-half of adults in the United States experience at least intermittent sleep disturbances. For most, it is an occasional night of poor sleep or daytime sleepiness. However, the Institute of Medicine estimates that 50–70 million Americans suffer from a chronic disorder of sleep and wakefulness, which can lead to serious impairment of daytime functioning. In addition, such problems may contribute to or exacerbate medical or psychiatric conditions. Thirty years ago, many such complaints were treated with hypnotic medications without further diagnostic evaluation. Since then, a distinct class of sleep and arousal disorders has been identified.

PHYSIOLOGY OF SLEEP AND WAKEFULNESS

Most adults sleep 7–8 h per night, although the timing, duration, and internal structure of sleep vary among healthy individuals and as a

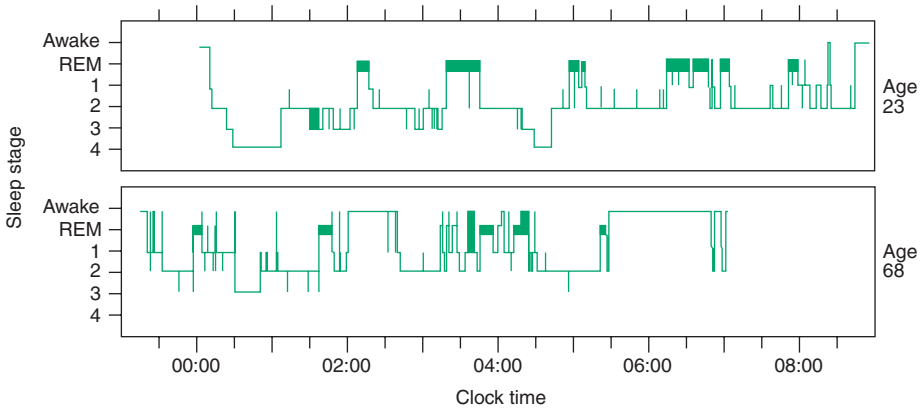

FIGURE 28-1 Stages of REM sleep (solid bars), the four stages of NREM sleep, and wakefulness over the course of the entire night for representative young and older adult men. Characteristic features of sleep in older people include reduction of slow-wave sleep, frequent spontaneous awakenings, early sleep onset, and early morning awakening. *(From the Division of Sleep Medicine, Brigham and Women's Hospital.)*

function of age. At the extremes, infants and the elderly have frequent interruptions of sleep. In the United States, adults of intermediate age tend to have one consolidated sleep episode per day, although in some cultures sleep may be divided into a mid-afternoon nap and a shortened night sleep. Two principal systems govern the sleep-wake cycle: one actively generates sleep and sleep-related processes and another times sleep within the 24-h day. Either intrinsic abnormalities in these systems or extrinsic disturbances (environmental, drug- or illness-related) can lead to sleep or circadian rhythm disorders.

STATES AND STAGES OF SLEEP

States and stages of human sleep are defined on the basis of characteristic patterns in the electroencephalogram (EEG), the electrooculogram (EOG—a measure of eye-movement activity), and the surface electromyogram (EMG) measured on the chin and neck. The continuous recording of this array of electrophysiologic parameters to define sleep and wakefulness is termed *polysomnography*.

Polysomnographic profiles define two states of sleep: (1) rapid-eye-movement (REM) sleep, and (2) non-rapid-eye-movement (NREM) sleep. NREM sleep is further subdivided into four stages, characterized by increasing arousal threshold and slowing of the cortical EEG. REM sleep is characterized by a low-amplitude, mixed-frequency EEG similar to that of NREM stage 1 sleep. The EOG shows bursts of REM similar to those seen during eyes-open wakefulness. Chin EMG activity is absent, reflecting the brainstem-mediated muscle atonia that is characteristic of that state.

ORGANIZATION OF HUMAN SLEEP

Normal nocturnal sleep in adults displays a consistent organization from night to night (Fig. 28-1). After sleep onset, sleep usually progresses through NREM stages 1–4 within 45–60 min. Slow-wave sleep (NREM stages 3 and 4) predominates in the first third of the night and comprises 15–25% of total nocturnal sleep time in young adults. The percentage of slow-wave sleep is influenced by several factors, most notably age (see below). Prior sleep deprivation increases the rapidity of sleep onset and both the intensity and amount of slow-wave sleep.

The first REM sleep episode usually occurs in the second hour of sleep. More rapid onset of REM sleep in a young adult (particularly if <30 min) may suggest pathology such as endogenous depression, narcolepsy, circadian rhythm disorders, or drug withdrawal. NREM and REM alternate through the night with an average period of 90–110 min (the "ultradian" sleep cycle). Overall, REM sleep constitutes 20–25% of total sleep, and NREM stages 1 and 2 are 50–60%.

Age has a profound impact on sleep state organization (Fig. 28-1). Slow-wave sleep is most intense and prominent during childhood, decreasing sharply at puberty and across the second and third decades of life. After age 30, there is a progressive decline in the amount of slow-wave sleep, and the amplitude of delta EEG activity comprising slow-wave sleep is profoundly reduced. The depth of slow-wave sleep, as measured by the arousal threshold to auditory stimulation, also decreases with age. In the otherwise healthy older person, slow-wave sleep may be completely absent, particularly in males.

A different age profile exists for REM sleep than for slow-wave sleep. In infancy, REM sleep may comprise 50% of total sleep time, and the percentage is inversely proportional to developmental age. The amount of REM sleep falls off sharply over the first postnatal year as a mature REM-NREM cycle develops; thereafter, REM sleep occupies a relatively constant percentage of total sleep time.

NEUROANATOMY OF SLEEP

Experimental studies in animals have variously implicated the medullary reticular formation, the thalamus, and the basal forebrain in the generation of sleep, while the brainstem reticular formation, the midbrain, the subthalamus, the thalamus, and the basal forebrain have all been suggested to play a role in the generation of wakefulness or EEG arousal.

Current models suggest that the capacity for sleep and wakefulness generation is distributed along an axial "core" of neurons extending from the brainstem rostrally to the basal forebrain. A cluster of γ-aminobutyric acid (GABA) and galaninergic neurons in the ventrolateral preoptic (VLPO) hypothalamus is selectively activated coincident with sleep onset. These neurons project to and inhibit multiple distinct wakefulness centers including the tuberomammilary (histaminergic) nucleus that are important to the ascending arousal system, indicating that the hypothalamic VLPO neurons play a key executive role in sleep regulation.

Specific regions in the pons are associated with the neurophysiologic correlates of REM sleep. Small lesions in the dorsal pons result in the loss of the descending muscle inhibition normally associated with REM sleep; microinjections of the cholinergic agonist carbachol into the pontine reticular formation appear to produce a state with all of the features of REM sleep. These experimental manipulations are mimicked by pathologic conditions in humans and animals. In narcolepsy, for example, abrupt, complete, or partial paralysis (cataplexy) occurs in response to a variety of stimuli. In dogs with this condition, physostigmine, a central cholinesterase inhibitor, increases the frequency of cataplectic attacks, while atropine decreases their frequency. Conversely, in REM sleep behavior disorder (see below), patients suffer from incomplete motor inhibition during REM sleep, resulting in involuntary, occasionally violent movement during REM sleep.

NEUROCHEMISTRY OF SLEEP

Early experimental studies that focused on the raphe nuclei of the brainstem appeared to implicate serotonin as the primary sleep-promoting neurotransmitter, while catecholamines were considered to be responsible for wakefulness. Simple neurochemical models have given way to more complex formulations involving multiple parallel waking systems. Pharmacologic studies suggest that histamine, acetylcholine, dopamine, serotonin, and noradrenaline are all involved in wake promotion. In addition, pontine cholinergic neurotransmission is known to play a role in REM sleep generation. The alerting influence of caffeine implicates adenosine, whereas the hypnotic effect of benzodiazepines and barbiturates suggests a role for endogenous ligands of the $GABA_A$ receptor complex. A newly characterized neuropeptide, hypocretin (orexin), has recently been implicated in the pathophysiology of narcolepsy (see below), but its role in normal sleep regulation remains to be defined.

A variety of sleep-promoting substances have been identified, although it is not known whether they are involved in the endogenous sleep-wake regulatory process. These include prostaglandin D_2, delta

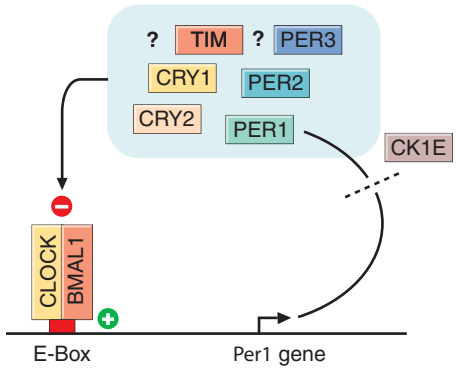

FIGURE 28-2 Model of the molecular feedback loop at the core of the mammalian circadian clock. The positive element of the feedback loop (+) is the transcriptional activation of the *Per1* gene (and probably other clock genes) by a heterodimer of the transcription factors CLOCK and BMAL1 (also called MOP3) bound to an E-box DNA regulatory element. The *Per1* transcript and its product, the clock component PER1 protein, accumulate in the cell cytoplasm. As it accumulates, the PER1 protein is recruited into a multiprotein complex thought to contain other circadian clock component proteins such as cryptochromes (CRYs), Period proteins (PERs), and others. This complex is then transported into the cell nucleus (across the dotted line), where it functions as the negative element in the feedback loop (–) by inhibiting the activity of the CLOCK-BMAL1 transcription factor heterodimer. As a consequence of this action, the concentration of PER1 and other clock proteins in the inhibitory complex falls, allowing CLOCK-BMAL1 to activate transcription of *Per1* and other genes and begin another cycle. The dynamics of the 24-h molecular cycle are controlled at several levels, including regulation of the rate of PER protein degradation by casein kinase-1 epsilon (CK1E). Additional limbs of this genetic regulatory network, omitted for the sake of clarity, are thought to contribute stability. Question marks denote putative clock proteins, such as Timeless (TIM), as yet lacking genetic proof of a role in the mammalian clock mechanism. *(Copyright Charles J. Weitz, Ph.D., Department of Neurobiology, Harvard Medical School.)*

sleep–inducing peptide, muramyl dipeptide, interleukin 1, fatty acid primary amides, and melatonin. The hypnotic effect of these substances is commonly limited to NREM or slow-wave sleep, although peptides that increase REM sleep have also been reported. Many putative "sleep factors," including interleukin 1 and prostaglandin D_2, are immunologically active as well, suggesting a link between immune function and sleep-wake states.

PHYSIOLOGY OF CIRCADIAN RHYTHMICITY

The sleep-wake cycle is the most evident of the many 24-h rhythms in humans. Prominent daily variations also occur in endocrine, thermoregulatory, cardiac, pulmonary, renal, gastrointestinal, and neurobehavioral functions. At the molecular level, endogenous circadian rhythmicity is driven by self-sustaining transcriptional/translational feedback loops (Fig. 28-2). In evaluating a daily variation in humans, it is important to distinguish between those rhythmic components passively evoked by periodic environmental or behavioral changes (e.g., the increase in blood pressure and heart rate upon assumption of the upright posture) and those actively driven by an endogenous oscillatory process (e.g., the circadian variation in plasma cortisol that persists under a variety of environmental and behavioral conditions).

While it is now recognized that many peripheral tissues in mammals have circadian clocks that regulate diverse physiologic processes, these independent tissue-specific oscillations are coordinated by a central neural pacemaker located in the suprachiasmatic nuclei (SCN) of the hypothalamus. Bilateral destruction of these nuclei results in a loss of the endogenous circadian rhythm of locomotor activity, which can be restored only by transplantation of the same structure from a donor animal. The genetically determined period of this endogenous neural oscillator, which averages ~24.2 h in humans, is normally synchronized to the 24-h period of the environmental light-dark cycle. Small differences in circadian period underlie variations in diurnal preference, with the circadian period shorter in individuals who typically rise early compared to those who typically go to bed late. Entrainment of mammalian circadian rhythms by the light-dark cycle is mediated via the retinohypothalamic tract, a monosynaptic pathway that links specialized, photoreceptive retinal ganglion cells directly to the SCN. Humans are exquisitely sensitive to the resetting effects of light, particularly at the blue end (~460–480 nm) of the visible spectrum.

The timing and internal architecture of sleep are directly coupled to the output of the endogenous circadian pacemaker. Paradoxically, the endogenous circadian rhythms of sleep tendency, sleepiness, and REM sleep propensity all peak near the habitual wake time, just after the nadir of the endogenous circadian temperature cycle, whereas the circadian wake propensity rhythm peaks 1–3 h before the habitual bedtime. These rhythms are thus timed to oppose the homeostatic decline of sleep tendency during the habitual sleep episode and the rise of sleep tendency throughout the usual waking day, respectively. Misalignment of the output of the endogenous circadian pacemaker with the desired sleep-wake cycle can, therefore, induce insomnia, decreased alertness, and impaired performance evident in night-shift workers and airline travelers.

BEHAVIORAL CORRELATES OF SLEEP STATES AND STAGES

Polysomnographic staging of sleep correlates with behavioral changes during specific states and stages. During the transitional state between wakefulness and sleep (stage 1 sleep), subjects may respond to faint auditory or visual signals without "awakening." Memory incorporation is inhibited at the onset of NREM stage 1 sleep, which may explain why individuals aroused from that transitional sleep stage frequently deny having been asleep. Such transitions may intrude upon behavioral wakefulness after sleep deprivation, notwithstanding attempts to remain continuously awake (see "Shift-Work Disorder," below).

Awakenings from REM sleep are associated with recall of vivid dream imagery >80% of the time. The reliability of dream recall increases with REM sleep episodes occurring later in the night. Imagery may also be reported after NREM sleep interruptions, though these typically lack the detail and vividness of REM sleep dreams. The incidence of NREM sleep dream recall can be increased by selective REM sleep deprivation, suggesting that REM sleep and dreaming per se are not inexorably linked.

PHYSIOLOGIC CORRELATES OF SLEEP STATES AND STAGES

All major physiologic systems are influenced by sleep. Changes in cardiovascular function include a decrease in blood pressure and heart rate during NREM and particularly during slow-wave sleep. During REM sleep, phasic activity (bursts of eye movements) is associated with variability in both blood pressure and heart rate mediated principally by the vagus. Cardiac dysrhythmias may occur selectively during REM sleep. Respiratory function also changes. In comparison to relaxed wakefulness, respiratory rate becomes more regular during NREM sleep (especially slow-wave sleep) and tonic REM sleep and becomes very irregular during phasic REM sleep. Minute ventilation decreases in NREM sleep out of proportion to the decrease in metabolic rate at sleep onset, resulting in a higher P_{CO_2}.

Endocrine function also varies with sleep. Slow-wave sleep is associated with secretion of growth hormone, while sleep in general is associated with augmented secretion of prolactin. Sleep has a complex effect on the secretion of luteinizing hormone (LH): during puberty, sleep is associated with increased LH secretion, whereas sleep in the postpubertal female inhibits LH secretion in the early follicular phase of the menstrual cycle. Sleep onset (and probably slow-wave sleep) is associated with inhibition of thyroid-stimulating hormone and of the adrenocorticotropic hormone–cortisol axis, an effect that is superimposed on the prominent circadian rhythms in the two systems.

The pineal hormone melatonin is secreted predominantly at night in both day- and night-active species, reflecting the direct modulation of pineal activity by the circadian pacemaker through a circuitous neural pathway from the SCN to the pineal gland. Melatonin secretion is not dependent upon the occurrence of sleep, persisting in individuals kept awake at night. In addition, exogenous melatonin increases sleep-

iness and increases sleep duration when administered to healthy adults attempting to sleep during daylight hours, at a time when endogenous melatonin levels are low. The efficacy of melatonin as a sleep-promoting therapy for patients with insomnia is currently not known.

Sleep is also accompanied by alterations of thermoregulatory function. NREM sleep is associated with an attenuation of thermoregulatory responses to either heat or cold stress, and animal studies of thermosensitive neurons in the hypothalamus document an NREM-sleep-dependent reduction of the thermoregulatory set-point. REM sleep is associated with complete absence of thermoregulatory responsiveness, effectively resulting in functional poikilothermy. However, the potential adverse impact of this failure of thermoregulation is blunted by inhibition of REM sleep by extreme ambient temperatures.

TABLE 28-1 EVALUATION OF THE PATIENT WITH THE COMPLAINT OF EXCESSIVE DAYTIME SOMNOLENCE

Findings on History and Physical Examination	Diagnostic Evaluation	Diagnosis	Therapy
Obesity, snoring, hypertension	Polysomnography with respiratory monitoring	Obstructive sleep apnea	Continuous positive airway pressure; ENT surgery (e.g., uvulopalatopharyngoplasty); dental appliance; pharmacologic therapy (e.g., protriptyline); weight loss
Cataplexy, hypnogogic hallucinations, sleep paralysis, family history	Polysomnography with multiple sleep latency testing	Narcolepsy-cataplexy syndrome	Stimulants (e.g., modafinil, methylphenidate); REM-suppressant antidepressants (e.g., protriptyline); genetic counseling
Restless legs, disturbed sleep, predisposing medical condition (e.g., iron deficiency or renal failure)	Assesment for predisposing medical conditions	Restless legs syndrome	Treatment of predisposing condition, if possible; dopamine agonists (e.g., pramipexole, ropinirole)
Disturbed sleep, predisposing medical conditions (e.g., asthma) and/or predisposing medical therapies (e.g., theophylline)	Sleep-wake diary recording	Insomnias (see text)	Treatment of predisposing condition and/or change in therapy, if possible; behavioral therapy; short-acting benzodiazepine receptor agonist (e.g., zolpidem)

Note: ENT, ears, nose, throat; REM, rapid eye movement; EMG, electromyogram.

DISORDERS OF SLEEP AND WAKEFULNESS

APPROACH TO THE PATIENT: Sleep Disorders

Patients may seek help from a physician because of one of several symptoms: (1) an acute or chronic inability to initiate or maintain sleep adequately at night (insomnia); (2) chronic fatigue, sleepiness, or tiredness during the day; or (3) a behavioral manifestation associated with sleep itself. Complaints of insomnia or excessive daytime sleepiness should be approached as symptoms (much like fever or pain) of underlying disorders. Knowledge of the differential diagnosis of these presenting complaints is essential to identify any underlying medical disorder. Only then can appropriate treatment, rather than nonspecific approaches (e.g., over-the-counter sleeping aids), be applied. Diagnoses of exclusion, such as primary insomnia, should be made only after other diagnoses have been ruled out. Table 28-1 outlines the diagnostic and therapeutic approach to the patient with a complaint of excessive daytime sleepiness.

A careful history is essential. In particular, the duration, severity, and consistency of the symptoms are important, along with the patient's estimate of the consequences of the sleep disorder on waking function. Information from a friend or family member can be invaluable; some patients may be unaware of, or will underreport, such potentially embarrassing symptoms as heavy snoring or falling asleep while driving. Patients with excessive sleepiness should be advised to avoid all driving until effective therapy has been achieved.

Completion by the patient of a day-by-day sleep-work-drug log for at least 2 weeks can help the physician better understand the nature of the complaint. Work times and sleep times (including daytime naps and nocturnal awakenings) as well as drug and alcohol use, including caffeine and hypnotics, should be noted each day.

Polysomnography is necessary for the diagnosis of specific disorders such as narcolepsy and sleep apnea and may be of utility in other settings as well. In addition to the three electrophysiologic variables used to define sleep states and stages, the standard clinical polysomnogram includes measures of respiration (respiratory effort, air flow, and oxygen saturation), anterior tibialis EMG, and electrocardiogram.

EVALUATION OF INSOMNIA

Insomnia is the complaint of inadequate sleep; it can be classified according to the nature of sleep disruption and the duration of the complaint. Insomnia is subdivided into difficulty falling asleep (*sleep onset insomnia*), frequent or sustained awakenings (*sleep maintenance insomnia*), early morning awakenings (*sleep offset insomnia*), or persistent sleepiness/fatigue despite sleep of adequate duration (*nonrestorative sleep*). Similarly, the duration of the symptom influences diagnostic and therapeutic considerations. An insomnia complaint lasting one to several nights (within a single episode) is termed *transient insomnia* and is typically the result of situational stress or a change in sleep schedule or environment (e.g., jet lag disorder). *Short-term insomnia* lasts from a few days to 3 weeks. Disruption of this duration is usually associated with more protracted stress, such as recovery from surgery or short-term illness. *Long-term insomnia*, or *chronic insomnia*, lasts for months or years and, in contrast with short-term insomnia, requires a thorough evaluation of underlying causes (see below). Chronic insomnia is often a waxing and waning disorder, with spontaneous or stressor-induced exacerbations.

An occasional night of poor sleep, typically in the setting of stress or excitement about external events, is both common and without lasting consequences. However, persistent insomnia can lead to impaired daytime function, injury due to accidents, and the development of major depression. In addition, there is emerging evidence that individuals with chronic insomnia have increased utilization of health care resources, even after controlling for co-morbid medical and psychiatric disorders.

All insomnias can be exacerbated and perpetuated by behaviors that are not conducive to initiating or maintaining sleep. *Inadequate sleep hygiene* is characterized by a behavior pattern prior to sleep or a bedroom environment that is not conducive to sleep. Noise or light in the bedroom can interfere with sleep, as can a bed partner with periodic limb movements during sleep or one who snores loudly. Clocks can heighten the anxiety about the time it has taken to fall asleep. Drugs that act on the central nervous system, large meals, vigorous exercise, or hot showers just before sleep may all interfere with sleep onset. Many individuals participate in stressful work-related activities in the evening, producing a state incompatible with sleep onset. In preference to hypnotic medications, patients should be counseled to avoid stressful activities before bed, develop a soporific bedtime ritual, and to prepare and reserve the bedroom environment for sleeping. Consistent, regular rising times should be maintained daily, including weekends.

PRIMARY INSOMNIA

Many patients with chronic insomnia have no clear, single identifiable underlying cause for their difficulties with sleep. Rather, such patients often have multiple etiologies for their insomnia, which may evolve over the years. In addition, the chief sleep complaint may change over time, with initial insomnia predominating at one point, and multiple awakenings or nonrestorative sleep occurring at other times. Subsyn-

dromal psychiatric disorders (e.g., anxiety and mood complaints), negative conditioning to the sleep environment (psychophysiologic insomnia, see below), amplification of the time spent awake (paradoxical insomnia), physiologic hyperarousal, and poor sleep hygiene (see above) may all be present. As these processes may be both causes and consequences of chronic insomnia, many individuals will have a progressive course to their symptoms in which the severity is proportional to the chronicity, and much of the complaint may persist even after effective treatment of the initial inciting etiology. Treatment of insomnia is often directed to each of the putative contributing factors: behavior therapies for anxiety and negative conditioning (see below), pharmacotherapy and/or psychotherapy for mood/anxiety disorders, and an emphasis on maintenance of good sleep hygiene.

If insomnia persists after treatment of these contributing factors, empirical pharmacotherapy is often used on a nightly or intermittent basis. A variety of sedative compounds are used for this purpose. Alcohol and antihistamines are the most commonly used nonprescription sleep aids. The former may help with sleep onset but is associated with sleep disruption during the night and can escalate into abuse, dependence, and withdrawal in the predisposed individual. Antihistamines may be of benefit when used intermittently but often produce rapid tolerance and may have multiple side effects (especially anticholinergic), which limit their use, particularly in the elderly. Benzodiazepine-receptor agonists are the most effective and well-tolerated class of medications for insomnia. The broad range of half-lives allows flexibility in the duration of sedative action. The most commonly prescribed agents in this family are zaleplon (5–20 mg), with a half-life of 1–2 h; zolpidem (5–10 mg) and triazolam (0.125–0.25 mg), with half-lives of 2–3 h; eszopiclone (1–3 mg), with a half-life of 5.5–8 h; and temazepam (15–30 mg) and lorazepam (0.5–2 mg), with half-lives of 6–12 h. Generally, side effects are minimal when the dose is kept low and the serum concentration is minimized during the waking hours (by using the shortest-acting, effective agent). Recent data suggest that at least one benzodiazepine receptor agonist (eszopiclone) continues to be effective for 6 months of nightly use. However, longer durations of use have not been evaluated, and it is unclear whether this is true of other agents in this class. Moreover, with even brief continuous use of benzodiazepine-receptor agonists, rebound insomnia can occur upon discontinuation. The likelihood of rebound insomnia and tolerance can be minimized by short durations of treatment, intermittent use, or gradual tapering of the dose. For acute insomnia, nightly use of a benzodiazepine receptor agonist for a maximum of 2–4 weeks is advisable. For chronic insomnia, intermittent use is recommended, unless the consequences of untreated insomnia outweigh concerns regarding chronic use. Benzodiazepine receptor agonists should be avoided, or used very judiciously, in patients with a history of substance or alcohol abuse. The heterocyclic antidepressants (trazodone, amitriptyline, and doxepin) are the most commonly prescribed alternatives to benzodiazepine receptor agonists due to their lack of abuse potential and lower cost. Trazodone (25–100 mg) is used more commonly than the tricyclic antidepressants as it has a much shorter half-life (5–9 h), has much less anticholinergic activity (sparing patients, particularly the elderly, constipation, urinary retention, and tachycardia), is associated with less weight gain, and is much safer in overdose. The risk of priapism is small (~1 in 10,000).

Psychophysiologic Insomnia Persistent *psychophysiologic insomnia* is a behavioral disorder in which patients are preoccupied with a perceived inability to sleep adequately at night. This sleep disorder begins like any other acute insomnia; however, the poor sleep habits and sleep-related anxiety ("insomnia phobia") persist long after the initial incident. Such patients become hyperaroused by their own efforts to sleep or by the sleep environment, and the insomnia becomes a conditioned or learned response. Patients may be able to fall asleep more easily at unscheduled times (when not trying) or outside the home environment. Polysomnographic recording in patients with psychophysiologic insomnia reveals an objective sleep disturbance, often with an abnormally long sleep latency; frequent nocturnal awakenings; and an increased amount of stage 1 transitional sleep. Rigorous attention should be paid to improving sleep hygiene, correction of counterproductive, arousing behaviors before bedtime, and minimizing exaggerated beliefs regarding the negative consequences of insomnia. Behavioral therapies are the treatment modality of choice, with intermittent use of medications. When patients are awake for >20 min, they should read or perform other relaxing activities to distract themselves from insomnia-related anxiety. In addition, bedtime and wake time should be scheduled to restrict time in bed to be equal to their perceived total sleep time. This will generally produce sleep deprivation, greater sleep drive, and, eventually, better sleep. Time in bed can then be gradually expanded. In addition, methods directed towards producing relaxation in the sleep setting (e.g., meditation, muscle relaxation) are encouraged.

Adjustment Insomnia (Acute Insomnia) This typically develops after a change in the sleeping environment (e.g., in an unfamiliar hotel or hospital bed) or before or after a significant life event, such as a change of occupation, loss of a loved one, illness, or anxiety over a deadline or examination. Increased sleep latency, frequent awakenings from sleep, and early morning awakening can all occur. Recovery is generally rapid, usually within a few weeks. Treatment is symptomatic, with intermittent use of hypnotics and resolution of the underlying stress. *Altitude insomnia* describes a sleep disturbance that is a common consequence of exposure to high altitude. Periodic breathing of the Cheyne-Stokes type occurs during NREM sleep about half the time at high altitude, with restoration of a regular breathing pattern during REM sleep. Both hypoxia and hypocapnia are thought to be involved in the development of periodic breathing. Frequent awakenings and poor quality sleep characterize altitude insomnia, which is generally worse on the first few nights at high altitude but may persist. Treatment with acetazolamide can decrease time spent in periodic breathing and substantially reduce hypoxia during sleep.

COMORBID INSOMNIA

Insomnia Associated with Mental Disorders Approximately 80% of patients with psychiatric disorders describe sleep complaints. There is considerable heterogeneity, however, in the nature of the sleep disturbance both between conditions and among patients with the same condition. *Depression* can be associated with sleep onset insomnia, sleep maintenance insomnia, or early morning wakefulness. However, hypersomnia occurs in some depressed patients, especially adolescents and those with either bipolar or seasonal (fall/winter) depression (Chap. 386). Indeed, sleep disturbance is an important vegetative sign of depression and may commence before any mood changes are perceived by the patient. Consistent polysomnographic findings in depression include decreased REM sleep latency, lengthened first REM sleep episode, and shortened first NREM sleep episode; however, these findings are not specific for depression, and the extent of these changes varies with age and symptomatology. Depressed patients also show decreased slow-wave sleep and reduced sleep continuity.

In *mania* and *hypomania*, sleep latency is increased and total sleep time can be reduced. Patients with *anxiety disorders* tend not to show the changes in REM sleep and slow-wave sleep seen in endogenously depressed patients. *Chronic alcoholics* lack slow-wave sleep, have decreased amounts of REM sleep (as an acute response to alcohol), and have frequent arousals throughout the night. This is associated with impaired daytime alertness. The sleep of chronic alcoholics may remain disturbed for years after discontinuance of alcohol usage. Sleep architecture and physiology are disturbed in *schizophrenia* (with a decreased amount of stage 4 sleep and a lack of augmentation of REM sleep following REM sleep deprivation); chronic schizophrenics often show day-night reversal, sleep fragmentation, and insomnia.

Insomnia Associated with Neurologic Disorders A variety of neurologic diseases result in sleep disruption through both indirect, nonspecific mechanisms (e.g., pain in cervical spondylosis or low back pain) or by impairment of central neural structures involved in the generation and control of sleep itself. For example, *dementia* from any cause has long been associated with disturbances in the timing of the sleep-wake cycle, often characterized by nocturnal wandering and an exacerbation of symptomatology at night (so-called sundowning).

Epilepsy may rarely present as a sleep complaint (Chap. 363). Often the history is of abnormal behavior, at times with convulsive move-

ments during sleep. The differential diagnosis includes REM sleep behavior disorder, sleep apnea syndrome, and periodic movements of sleep (see above). Diagnosis requires nocturnal polysomnography with a full EEG montage. Other neurologic diseases associated with abnormal movements, such as *Parkinson's disease*, *hemiballismus*, *Huntington's chorea*, and *Tourette syndrome* (Chap. 366), are also associated with disrupted sleep, presumably through secondary mechanisms. However, the abnormal movements themselves are greatly reduced during sleep. Headache syndromes (*migraine* or *cluster headache*) may show sleep-associated exacerbations (Chap. 15) by unknown mechanisms.

Fatal familial insomnia is a rare hereditary disorder caused by degeneration of anterior and dorsomedial nuclei of the thalamus. Insomnia is a prominent early symptom. Patients develop progressive autonomic dysfunction, followed by dysarthria, myoclonus, coma, and death. The pathogenesis is a mutation in the prion gene (Chap. 378).

Insomnia Associated with Other Medical Disorders A number of medical conditions are associated with disruptions of sleep. The association is frequently nonspecific, e.g., sleep disruption due to chronic pain from rheumatologic disorders. Attention to this association is important in that sleep-associated symptoms are often the presenting or most bothersome complaint. Treatment of the underlying medical problem is the most useful approach. Sleep disruption can also result from the use of medications such as glucocorticoids (see below).

One prominent association is between sleep disruption and *asthma*. In many asthmatics there is a prominent daily variation in airway resistance that results in marked increases in asthmatic symptoms at night, especially during sleep. In addition, treatment of asthma with theophylline-based compounds, adrenergic agonists, or glucocorticoids can independently disrupt sleep. When sleep disruption is a side effect of asthma treatment, inhaled glucocorticoids (e.g., beclomethasone) that do not disrupt sleep may provide a useful alternative.

Cardiac ischemia may also be associated with sleep disruption. The ischemia itself may result from increases in sympathetic tone as a result of sleep apnea. Patients may present with complaints of nightmares or vivid, disturbing dreams, with or without awareness of the more classic symptoms of angina or of the sleep disordered breathing. Treatment of the sleep apnea may substantially improve the angina and the nocturnal sleep quality. *Paroxysmal nocturnal dyspnea* can also occur as a consequence of sleep-associated cardiac ischemia that causes pulmonary congestion exacerbated by the recumbent posture.

Chronic obstructive pulmonary disease is also associated with sleep disruption, as is *cystic fibrosis*, *menopause*, *hyperthyroidism*, *gastroesophageal reflux*, *chronic renal failure*, and *liver failure*.

Medication-, Drug-, or Alcohol-Dependent Insomnia Disturbed sleep can result from ingestion of a wide variety of agents. Caffeine is perhaps the most common pharmacologic cause of insomnia. It produces increased latency to sleep onset, more frequent arousals during sleep, and a reduction in total sleep time for up to 8–14 h after ingestion. Even small amounts of coffee can significantly disturb sleep in some patients; therefore, a 1- to 2-month trial without caffeine should be attempted in patients with these symptoms. Similarly, alcohol and nicotine can interfere with sleep, despite the fact that many patients use them to relax and promote sleep. Although alcohol can increase drowsiness and shorten sleep latency, even moderate amounts of alcohol increase awakenings in the second half of the night. In addition, alcohol ingestion prior to sleep is contraindicated in patients with sleep apnea because of the inhibitory effects of alcohol on upper airway muscle tone. Acutely, amphetamines and cocaine suppress both REM sleep and total sleep time, which return to normal with chronic use. Withdrawal leads to a REM sleep rebound. A number of prescribed medications can produce insomnia. Antidepressants, sympathomimetics, and glucocorticoids are common causes. In addition, severe rebound insomnia can result from the acute withdrawal of hypnotics, especially following the use of high doses of benzodiazepines with a short half-life. For this reason, hypnotic doses should be low to moderate and prolonged drug tapering is encouraged.

RESTLESS LEGS SYNDROME (RLS)

Patients with this sensory-motor disorder report an irresistible urge to move the legs, or sometimes the upper extremities, that is often associated with a creepy-crawling or aching dysesthesias deep within the affected limbs. For most patients with RLS, the dysesthesias and restlessness are much worse in the evening or night compared to the daytime and frequently interfere with the ability to fall asleep. The symptoms appear with inactivity and are temporarily relieved by movement. In contrast, paresthesias secondary to peripheral neuropathy persist with activity. The severity of this chronic disorder may wax and wane over time and can be exacerbated by sleep deprivation, caffeine, alcohol, serotonergic antidepressants, and pregnancy. The prevalence is 1–5% of young to middle-age adults and 10–20% of those >60 years. There appear to be important differences in RLS prevalence among racial groups, with higher prevalence in those of Northern European ancestry. Roughly one-third of patients (particularly those with an early age of onset) will have multiple affected family members. At least three separate chromosomal loci have been identified in familial RLS, though no gene has been identified to date. Iron deficiency and renal failure may cause RLS, which is then considered secondary RLS. The symptoms of RLS are exquisitely sensitive to dopaminergic drugs (e.g., pramipexole 0.25–0.5 mg q8PM or ropinirole 0.5–4.0 mg q8PM), which are the treatments of choice. Opiods, benzodiazepines, and gabapentin may also be of therapeutic value. Most patients with restless legs also experience periodic limb movements of sleep, although the reverse is not the case.

PERIODIC LIMB MOVEMENT DISORDER (PLMD)

Periodic limb movements of sleep (PLMS), previously known as *nocturnal myoclonus*, consists of stereotyped, 0.5- to 5.0-s extensions of the great toe and dorsiflexion of the foot, which recur every 20–40 s during NREM sleep, in episodes lasting from minutes to hours, as documented by bilateral surface EMG recordings of the anterior tibialis on polysomnography. PLMS is the principal objective polysomnographic finding in 17% of patients with insomnia and 11% of those with excessive daytime somnolence (Fig. 28-3). It is often unclear whether it is an incidental finding or the cause of disturbed sleep. When deemed to be the latter, PLMS is called PLMD. PLMS occurs in a wide variety of sleep disorders (including narcolepsy, sleep apnea, REM sleep behavior disorder, and various forms of insomnia) and may be associated with frequent arousals and an increased number of sleep-stage transitions. The pathophysiology is not well understood, though individuals with high spinal transections can exhibit periodic leg movements during sleep, suggesting the existence of a spinal generator. Treatment options include dopaminergic medications or benzodiazepines.

EVALUATION OF DAYTIME SLEEPINESS

Daytime impairment due to sleep loss may be difficult to quantify for several reasons. First, sleepiness is not necessarily proportional to subjectively assessed sleep deprivation. In obstructive sleep apnea, for example, the repeated brief interruptions of sleep associated with resumption of respiration at the end of apneic episodes result in daytime sleepiness, despite the fact that the patient may be unaware of the sleep fragmentation. Second, subjective descriptions of waking impairment vary from patient to patient. Patients may describe themselves as "sleepy," "fatigued," or "tired" and may have a clear sense of the meaning of those terms, while others may use the same terms to describe a completely different condition. Third, sleepiness, particularly when profound, may affect judgment in a manner analogous to ethanol, such that subjective awareness of the condition and the consequent cognitive and motor impairment is reduced. Finally, patients may be reluctant to admit that sleepiness is a problem, both because they are generally unaware of what constitutes normal alertness and because sleepiness is generally viewed pejoratively, ascribed more often to a deficit in motivation than to an inadequately addressed physiologic sleep need.

Specific questioning about the occurrence of sleep episodes during normal waking hours, both intentional and unintentional, is necessary to determine the extent of the adverse effects of sleepiness on a patient's day-

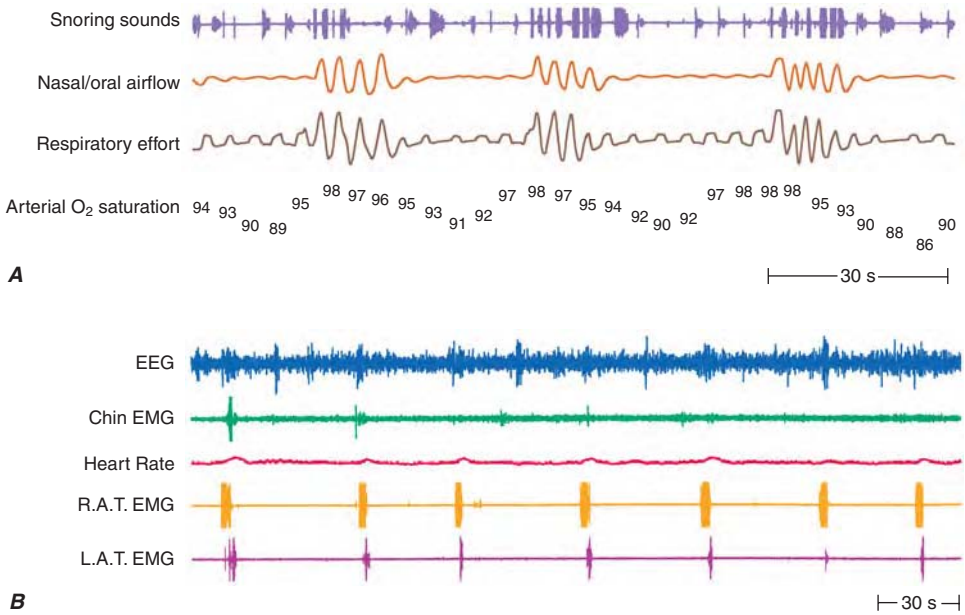

FIGURE 28-3 Polysomnographic recordings of (*A*) obstructive sleep apnea and (*B*) periodic limb movement of sleep. Note the snoring and reduction in air flow in the presence of continued respiratory effort, associated with the subsequent oxygen desaturation (upper panel). Periodic limb movements occur with a relatively constant intermovement interval and are associated with changes in the EEG and heart rate acceleration (lower panel). Abbreviations: R.A.T., right anterior tibialis; L.A.T., left anterior tibialis. *(From the Division of Sleep Medicine, Brigham and Women's Hospital.)*

time function. Specific areas to be addressed include the occurrence of inadvertent sleep episodes while driving or in other safety-related settings, sleepiness while at work or school (and the relationship of sleepiness to work and school performance), and the effect of sleepiness on social and family life. Driving is particularly hazardous for patients with increased sleepiness. Reaction time is equally impaired by 24 h of sleep loss as by a blood alcohol level of 0.10 g/dL. More than half of Americans admit to driving when drowsy. An estimated 250,000 motor vehicle crashes per year are due to drowsy drivers, thus causing 20% of all serious crash injuries. Drowsy driving legislation, aimed at improving education of all drivers about the hazards of driving drowsy and establishing sanctions comparable to those for drunk driving, is pending in several states. Screening for sleep disorders, provision of an adequate number of safe highway rest areas, maintenance of unobstructed shoulder rumble strips, and strict enforcement and compliance monitoring of hours-of-service policies are needed to reduce the risk of sleep-related transportation crashes. Evidence for significant daytime impairment [in association either with the diagnosis of a primary sleep disorder, such as narcolepsy or sleep apnea, or with imposed or self-selected sleep-wake schedules (see "Shift-Work Disorder," below)] raises the issue of the physician's responsibility to notify motor vehicle licensing authorities of the increased risk of sleepiness-related vehicle accidents. As with epilepsy, legal requirements vary from state to state, and existing legal precedents do not provide a consistent interpretation of the balance between the physician's responsibility and the patient's right to privacy. At a minimum, physicians should document discussions with the patient regarding the increased risk of operating a vehicle, as well as a recommendation that driving be suspended until successful treatment or a schedule modification can be instituted.

The distinction between fatigue and sleepiness can be useful in the differentiation of patients with complaints of fatigue or tiredness in the setting of disorders such as fibromyalgia (Chap. 329), chronic fatigue syndrome (Chap. 384), or endocrine deficiencies such as hypothyroidism (Chap. 335) or Addison's disease (Chap. 336). While patients with these disorders can typically distinguish their daytime symptoms from the sleepiness that occurs with sleep deprivation, substantial overlap can occur. This is particularly true when the primary disorder also results in chronic sleep disruption (e.g., sleep apnea in hypothyroidism) or in abnormal sleep (e.g., fibromyalgia).

While clinical evaluation of the complaint of excessive sleepiness is usually adequate, objective quantification is sometimes necessary. Assessment of daytime functioning as an index of the adequacy of sleep can be made with the multiple sleep latency test (MSLT), which involves repeated measurement of sleep latency (time to onset of sleep) under standardized conditions during a day following quantified nocturnal sleep. The average latency across four to six tests (administered every 2 h across the waking day) provides an objective measure of daytime sleep tendency. Disorders of sleep that result in pathologic daytime somnolence can be reliably distinguished with the MSLT. In addition, the multiple measurements of sleep onset may identify direct transitions from wakefulness to REM sleep that are suggestive of specific pathologic conditions (e.g., narcolepsy).

NARCOLEPSY

Narcolepsy is both a disorder of the ability to sustain wakefulness voluntarily and a disorder of REM sleep regulation (Table 28-2). The classic "narcolepsy tetrad" consists of excessive daytime somnolence plus three specific symptoms related to an intrusion of REM sleep characteristics (e.g., muscle atonia, vivid dream imagery) into the transition between wakefulness and sleep: (1) sudden weakness or loss of muscle tone without loss of consciousness, often elicited by emotion (cataplexy); (2) hallucinations at sleep onset (hypnogogic hallucinations) or upon awakening (hypnopompic hallucinations); and (3) muscle paralysis upon awakening (sleep paralysis). The severity of cataplexy varies, as patients may have two to three attacks per day or per decade. Some patients with objectively confirmed narcolepsy (see below) may show no evidence of cataplexy. In those with cataplexy, the extent and duration of an attack may also vary, from a transient sagging of the jaw lasting a few seconds to rare cases of flaccid paralysis of the entire voluntary musculature for up to 20–30 min. Symptoms of narcolepsy typically begin in the second decade, although the onset ranges from ages 5–50. Once established, the disease is chronic without remissions. Secondary forms of narcolepsy have been described (e.g., after head trauma).

Narcolepsy affects about 1 in 4000 people in the United States and appears to have a genetic basis. Recently, several convergent lines of evidence suggest that the hypothalamic neuropeptide hypocretin (orexin) is involved in the pathogenesis of narcolepsy: (1) a mutation in the hypocretin receptor 2 gene has been associated with canine narcolepsy; (2) hypocretin "knockout" mice that are genetically unable to produce this neuropeptide exhibit behavioral and electrophysiologic features resembling human narcolepsy; and (3) cerebrospinal fluid levels of hypocretin are reduced in most patients who have narcolepsy

TABLE 28-2 PREVALENCE OF SYMPTOMS IN NARCOLEPSY

Symptom	Prevalence, %
Excessive daytime somnolence	100
Disturbed sleep	87
Cataplexy	76
Hypnagogic hallucinations	68
Sleep paralysis	64
Memory problems	50

with cataplexy. The inheritance pattern of narcolepsy in humans is more complex than in the canine model. However, almost all narcoleptics with cataplexy are positive for HLA DQB1*0602 (Chap. 309), suggesting that an autoimmune process may be responsible.

Diagnosis The diagnostic criteria continue to be a matter of debate. Certainly, objective verification of excessive daytime somnolence, typically with MSLT mean sleep latencies <8 min, is an essential if nonspecific diagnostic feature. Other conditions that cause excessive sleepiness, such as sleep apnea or chronic sleep deprivation, must be rigorously excluded. The other objective diagnostic feature of narcolepsy is the presence of REM sleep in at least two of the naps during the MSLT. Abnormal regulation of REM sleep is also manifested by the appearance of REM sleep immediately or within minutes after sleep onset in 50% of narcoleptic patients, a rarity in unaffected individuals maintaining a conventional sleep-wake schedule. The REM-related symptoms of the classic narcolepsy tetrad are variably present. There is increasing evidence that narcoleptics with cataplexy (one-half to two-thirds of patients) may represent a more homogeneous group than those without this symptom. However, a history of cataplexy can be difficult to establish reliably. Hypnogogic and hypnopompic hallucinations and sleep paralysis are often found in noncataleptic individuals and may be present in only one-half of narcoleptics. Nocturnal sleep disruption is commonly observed in narcolepsy but is also a nonspecific symptom. Similarly, a history of "automatic behavior" during wakefulness (a trancelike state during which simple motor behaviors persist) is not specific for narcolepsy and serves principally to corroborate the presence of daytime somnolence.

℞ NARCOLEPSY

The treatment of narcolepsy is symptomatic. Somnolence is treated with wake-promoting therapeutics. Modafinil is now the drug of choice, principally because it is associated with fewer side effects than older stimulants and has a long half-life; 200–400 mg is given as a single daily dose. Older drugs such as methylphenidate (10 mg bid to 20 mg qid) or dextroamphetamine (10 mg bid) are still used as alternatives, particularly in refractory patients. These latter medications are now available in slow-release formulations, extending their duration of action and allowing once daily dosing.

Treatment of the REM-related phenomena cataplexy, hypnogogic hallucinations, and sleep paralysis requires the potent REM sleep suppression produced by antidepressant medications. The tricyclic antidepressants [e.g., protriptyline (10–40 mg/d) and clomipramine (25–50 mg/d)] and the selective serotonin reuptake inhibitors (SSRIs) [e.g., fluoxetine (10–20 mg/d)] are commonly used for this purpose. Efficacy of the antidepressants is limited largely by anticholinergic side effects (tricyclics) and by sleep disturbance and sexual dysfunction (SSRIs). Alternately, gamma hydroxybutyrate (GHB), given at bed time, and 4 h later, is effective in reducing daytime cataplectic episodes. Adequate nocturnal sleep time and planned daytime naps (when possible) are important preventative measures.

SLEEP APNEA SYNDROMES

Respiratory dysfunction during sleep is a common, serious cause of excessive daytime somnolence as well as of disturbed nocturnal sleep. An estimated 2–5 million individuals in the United States have a reduction or cessation of breathing for 10–150 s, from thirty to several hundred times every night during sleep. These episodes may be due to either an occlusion of the airway (*obstructive sleep apnea*), absence of respiratory effort (*central sleep apnea*), or a combination of these factors (*mixed sleep apnea*) (Fig. 28-3). Failure to recognize and treat these conditions appropriately may lead to impairment of daytime alertness, increased risk of sleep-related motor vehicle accidents, hypertension and other serious cardiovascular complications, and increased mortality. Sleep apnea is particularly prevalent in overweight men and in the elderly, yet it is estimated to remain undiagnosed in 80–90% of affected individuals. This is unfortunate since effective treatments are available. **Readers are referred to Chap. 259 for a comprehensive review of the diagnosis and treatment of patients with these conditions.**

PARASOMNIAS

The term *parasomnia* refers to abnormal behaviors or experiences that arise from or occur during sleep. A continuum of parasomnias arise from NREM sleep, from brief confusional arousals to sleepwalking and night terrors. The presenting complaint is usually related to the behavior itself, but the parasomnias can disturb sleep continuity or lead to mild impairments in daytime alertness. Two main parasomnias occur in REM sleep: REM sleep behavior disorder (RBD), which will be described below, and nightmare disorder.

Sleepwalking (Somnambulism) Patients affected by this disorder carry out automatic motor activities that range from simple to complex. Individuals may walk, urinate inappropriately, eat, or exit from the house while remaining only partially aware. Full arousal may be difficult, and individuals may rarely respond to attempted awakening with agitation or even violence. Sleepwalking arises from stage 3 or 4 NREM sleep, usually in the first 2 hours of the night, and is most common in children and adolescents, when these sleep stages are most robust. Episodes are usually isolated but may be recurrent in 1–6% of patients. The cause is unknown, though it has a familial basis in roughly one-third of cases.

Sleep Terrors This disorder, also called *pavor nocturnus*, occurs primarily in young children during the first several hours after sleep onset, in stages 3 and 4 of NREM sleep. The child suddenly screams, exhibiting autonomic arousal with sweating, tachycardia, and hyperventilation. The individual may be difficult to arouse and rarely recalls the episode on awakening in the morning. Parents are usually reassured to learn that the condition is self-limited and benign and that no specific therapy is indicated. Both sleep terrors and sleepwalking represent abnormalities of arousal. In contrast, *nightmares* occur during REM sleep and cause full arousal, with intact memory for the unpleasant episode.

Sleep Bruxism Bruxism is an involuntary, forceful grinding of teeth during sleep that affects 10–20% of the population. The patient is usually unaware of the problem. The typical age of onset is 17–20 years, and spontaneous remission usually occurs by age 40. Sex distribution appears to be equal. In many cases, the diagnosis is made during dental examination, damage is minor, and no treatment is indicated. In more severe cases, treatment with a rubber tooth guard is necessary to prevent disfiguring tooth injury. Stress management or, in some cases, biofeedback can be useful when bruxism is a manifestation of psychological stress. There are anecdotal reports of benefit using benzodiazepines.

Sleep Enuresis Bedwetting, like sleepwalking and night terrors, is another parasomnia that occurs during sleep in the young. Before age 5 or 6, nocturnal enuresis should probably be considered a normal feature of development. The condition usually improves spontaneously by puberty, has a prevalence in late adolescence of 1–3%, and is rare in adulthood. In older patients with enuresis a distinction must be made between primary and secondary enuresis, the latter being defined as bedwetting in patients who have previously been fully continent for 6–12 months. Treatment of primary enuresis is reserved for patients of appropriate age (>5 or 6 years) and consists of bladder training exercises and behavioral therapy. Urologic abnormalities are more common in primary enuresis and must be assessed by urologic examination. Important causes of secondary enuresis include emotional disturbances, urinary tract infections or malformations, cauda equina lesions, epilepsy, sleep apnea, and certain medications. Symptomatic pharmacotherapy is usually accomplished with desmopressin (0.2 mg qhs), oxybutynin chloride (5–10 mg qhs) or imipramine (10–50 mg qhs).

Miscellaneous Parasomnias Other clinical entities may be characterized as a parasomnia or a sleep-related movement disorder in that they occur selectively during sleep and are associated with some degree of sleep disruption. Examples include *jactatio capitis nocturna* (nocturnal headbanging, rhythmic movement disorder), confusional arousals, sleep-related eating disorder, and nocturnal leg cramps.

REM Sleep Behavior Disorder (RBD) RBD is a rare condition that is distinct from other parasomnias in that it occurs during REM sleep. It primarily afflicts men of middle age or older, many of whom have an existing, or developing, neurologic disease. Approximately one-half of patients with RBD will develop Parkinson's disease (Chap. 366) within 10–20 years. Presenting symptoms consist of agitated or violent behavior during sleep, as reported by a bed partner. In contrast to typical somnambulism, injury to the patient or bed partner is not uncommon, and, upon awakening, the patient reports vivid, often unpleasant, dream imagery. The principal differential diagnosis is nocturnal seizures, which can be excluded with polysomnography. In RBD, seizure activity is absent on the EEG, and disinhibition of the usual motor atonia is observed in the EMG during REM sleep, at times associated with complex motor behaviors. The pathogenesis is unclear, but damage to brainstem areas mediating descending motor inhibition during REM sleep may be responsible. In support of this hypothesis are the remarkable similarities between RBD and the sleep of animals with bilateral lesions of the pontine tegmentum in areas controlling REM sleep motor inhibition. Treatment with clonazepam (0.5–1.0 mg qhs) provides sustained improvement in almost all reported cases.

CIRCADIAN RHYTHM SLEEP DISORDERS

A subset of patients presenting with either insomnia or hypersomnia may have a disorder of sleep *timing* rather than sleep *generation*. Disorders of sleep timing can be either organic (i.e., due to an intrinsic defect in the circadian pacemaker or its input from entraining stimuli) or environmental (i.e., due to a disruption of exposure to entraining stimuli from the environment). Regardless of etiology, the symptoms reflect the influence of the underlying circadian pacemaker on sleep-wake function. Thus, effective therapeutic approaches should aim to entrain the oscillator at an appropriate phase.

Jet Lag Disorder More than 60 million persons experience transmeridian air travel annually, which is often associated with excessive daytime sleepiness, sleep onset insomnia, and frequent arousals from sleep, particularly in the latter half of the night. Gastrointestinal discomfort is common. The syndrome is transient, typically lasting 2–14 d depending on the number of time zones crossed, the direction of travel, and the traveler's age and phase-shifting capacity. Travelers who spend more time outdoors reportedly adapt more quickly than those who remain in hotel rooms, presumably due to bright (outdoor) light exposure. Avoidance of antecedent sleep loss and obtaining nap sleep on the afternoon prior to overnight travel greatly reduces the difficulty of extended wakefulness. Laboratory studies suggest that sub-milligram doses of the pineal hormone melatonin can enhance sleep efficiency, but only if taken when endogenous melatonin concentrations are low (i.e., during biologic daytime), and that melatonin may induce phase shifts in human rhythms. A large-scale clinical trial evaluating the safety and efficacy of melatonin as a treatment for jet lag disorder and other circadian sleep disorders is needed.

Shift-Work Disorder More than 7 million workers in the United States regularly work at night, either on a permanent or rotating schedule. In addition, each week millions more elect to remain awake at night to meet deadlines, drive long distances, or participate in recreational activities. This results in both sleep loss and misalignment of the circadian rhythm with respect to the sleep-wake cycle.

Studies of regular night-shift workers indicate that the circadian timing system usually fails to adapt successfully to such inverted schedules. This leads to a misalignment between the desired work-rest schedule and the output of the pacemaker and in disturbed daytime sleep in most individuals. Sleep deprivation, increased length of time awake prior to work, and misalignment of circadian phase produce decreased alertness and performance, increased reaction time, and increased risk of performance lapses, thereby resulting in greater safety hazards among night workers and other sleep-deprived individuals. Sleep disturbance nearly doubles the risk of a fatal work accident. Additional problems include higher rates of cancer and of cardiac, gastrointestinal, and reproductive disorders in chronic night-shift workers.

Sleep onset is associated with marked attenuation in perception of both auditory and visual stimuli and lapses of consciousness. The sleepy individual may thus attempt to perform routine and familiar motor tasks during the transition state between wakefulness and sleep (stage 1 sleep) in the absence of adequate processing of sensory input from the environment. Motor vehicle operators are especially vulnerable to sleep-related accidents since the sleep-deprived driver or operator often fails to heed the warning signs of fatigue. Such attempts to override the powerful biologic drive for sleep by the sheer force of will can yield a catastrophic outcome when sleep processes intrude involuntarily upon the waking brain. Such sleep-related attentional failures typically last only seconds but are known on occasion to persist for longer durations. These frequent brief intrusions of stage 1 sleep into behavioral wakefulness are a major component of the impaired psychomotor performance seen with sleepiness. There is a significant increase in the risk of sleep-related, fatal-to-the-driver highway crashes in the early morning and late afternoon hours, coincident with bimodal peaks in the daily rhythm of sleep tendency.

Medical housestaff constitute another group of workers at risk for accidents and other adverse consequences of lack of sleep and misalignment of the circadian rhythm. Recent research has demonstrated that the practice of scheduling interns and residents to work shifts of 30 consecutive hours both doubles the risk of attentional failures among intensive care unit interns working at night and significantly increases the risk of serious medical errors in intensive care units. Moreover, working for >24 h consecutively increases the risk of needlestick injuries and more than doubles the risk of motor vehicle crashes on the commute home. Some 20% of hospital interns report making a fatigue-related mistake that injured a patient, and 5% admit making a mistake that results in the death of a patient.

From 5–10% of individuals scheduled to work at night or in the early morning hours have much greater than average difficulties remaining awake during night work and sleeping during the day; these individuals are diagnosed with chronic and severe shift-work disorder (SWD). Patients with this disorder have a level of excessive sleepiness during night work and insomnia during day sleep that the physician judges to be clinically significant; the condition is associated with an increased risk of sleep-related accidents and with some of the illnesses associated with night-shift work. Patients with chronic and severe SWD are profoundly sleepy at night. In fact, their sleep latencies during night work average just 2 min, comparable to mean sleep latency durations of patients with narcolepsy or severe daytime sleep apnea.

Rx SHIFT-WORK DISORDER

Caffeine is frequently used to promote wakefulness. However, it cannot forestall sleep indefinitely, and it does not shield users from sleep-related performance lapses. Postural changes, exercise, and strategic placement of nap opportunities can sometimes temporarily reduce the risk of fatigue-related performance lapses. Properly timed exposure to bright light can facilitate rapid adaptation to night-shift work.

While many techniques (e.g., light treatment) used to facilitate adaptation to night shift work may help patients with this disorder, modafinil is the only therapeutic intervention that has ever been evaluated as a treatment for this specific patient population. Modafinil (200 mg, taken 30–60 min before the start of each night shift) is approved by the U.S. Food and Drug Administration as a treatment for the excessive sleepiness during night work in patients with SWD. Although treatment with modafinil significantly increases sleep latency and reduces the risk of lapses of attention during night work, SWD patients remain excessively sleepy at night, even while being treated with modafinil.

Safety programs should promote education about sleep and increase awareness of the hazards associated with night work. The goal should be to minimize both sleep deprivation and circadian disruption. Work schedules should be designed to minimize: (1) exposure to night work, (2) the frequency of shift rotation so that shifts do not rotate more than once every 2–3 weeks, (3) the number of consecutive night shifts, and (4) the duration of night shifts. Shift durations of >16 h should be universally recognized as increasing the risk of sleep-related errors and performance lapses to a level that is unacceptable in nonemergency circumstances.

Delayed Sleep Phase Disorder Delayed sleep phase disorder is characterized by: (1) reported sleep onset and wake times intractably later than desired, (2) actual sleep times at nearly the same clock hours daily, and (3) essentially normal all-night polysomnography except for delayed sleep onset. Patients exhibit an abnormally delayed endogenous circadian phase, with the temperature minimum during the constant routine occurring later than normal. This delayed phase could be due to: (1) an abnormally long, genetically determined intrinsic period of the endogenous circadian pacemaker; (2) an abnormally reduced phase-advancing capacity of the pacemaker; or (3) an irregular prior sleep-wake schedule, characterized by frequent nights when the patient chooses to remain awake well past midnight (for social, school, or work reasons). In most cases, it is difficult to distinguish among these factors, since patients with an abnormally long intrinsic period are more likely to "choose" such late-night activities because they are unable to sleep at that time. Patients tend to be young adults. This self-perpetuating condition can persist for years and does not usually respond to attempts to reestablish normal bedtime hours. Treatment methods involving bright-light phototherapy during the morning hours or melatonin administration in the evening hours show promise in these patients, although the relapse rate is high.

Advanced Sleep Phase Disorder Advanced sleep phase disorder (ASPD) is the converse of the delayed sleep phase syndrome. Most commonly, this syndrome occurs in older people, 15% of whom report that they cannot sleep past 5 A.M., with twice that number complaining that they wake up too early at least several times per week. Patients with ASPD experience excessive daytime sleepiness during the evening hours, when they have great difficulty remaining awake, even in social settings. Typically, patients awaken from 3–5 A.M. each day, often several hours before their desired wake times. In addition to age-related ASPD, an early-onset familial variant of this condition has also been reported. In one such family, autosomal dominant ASPD was due to a missense mutation in a circadian clock component (PER2, as shown in Fig. 28-2) that altered the circadian period. Patients with ASPD may benefit from bright-light phototherapy during the evening hours, designed to reset the circadian pacemaker to a later hour.

Non-24-Hour Sleep-Wake Disorder This condition can occur when the maximal phase-advancing capacity of the circadian pacemaker is not adequate to accommodate the difference between the 24-h geophysical day and the intrinsic period of the pacemaker in the patient. Alternatively, patients' self-selected exposure to artificial light may drive the circadian pacemaker to a >24-h schedule. Affected patients are not able to maintain a stable phase relationship between the output of the pacemaker and the 24-h day. Such patients typically present with an incremental pattern of successive delays in sleep onsets and wake times, progressing in and out of phase with local time. When the patient's endogenous rhythms are out of phase with the local environment, insomnia coexists with excessive daytime sleepiness. Conversely, when the endogenous rhythms are in phase with the local environment, symptoms remit. The intervals between symptomatic periods may last several weeks to several months. Blind individuals unable to perceive light are particularly susceptible to this disorder. Nightly low-dose (0.5 mg) melatonin administration has been reported to improve sleep and, in some cases, to induce synchronization of the circadian pacemaker.

MEDICAL IMPLICATIONS OF CIRCADIAN RHYTHMICITY

Prominent circadian variations have been reported in the incidence of acute myocardial infarction, sudden cardiac death, and stroke, the leading causes of death in the United States. Platelet aggregability is increased after arising in the early morning hours, coincident with the peak incidence of these cardiovascular events. A better understanding of the possible role of circadian rhythmicity in the acute destabilization of a chronic condition such as atherosclerotic disease could improve the understanding of the pathophysiology.

Diagnostic and therapeutic procedures may also be affected by the time of day at which data are collected. Examples include blood pressure, body temperature, the dexamethasone suppression test, and plasma cortisol levels. The timing of chemotherapy administration has been reported to have an effect on the outcome of treatment. Few physicians realize the extent to which routine measures are affected by the time (or sleep/wake state) when the measurement is made.

In addition, both the toxicity and effectiveness of drugs can vary during the day. For example, more than a fivefold difference has been observed in mortality rates following administration of toxic agents to experimental animals at different times of day. Anesthetic agents are particularly sensitive to time-of-day effects. Finally, the physician must be increasingly aware of the public health risks associated with the ever-increasing demands made by the duty-rest-recreation schedules in our round-the-clock society.

SECTION 4 DISORDERS OF EYES, EARS, NOSE, AND THROAT

29 Disorders of the Eye

Jonathan C. Horton

THE HUMAN VISUAL SYSTEM

The visual system provides a supremely efficient means for the rapid assimilation of information from the environment to aid in the guidance of behavior. The act of seeing begins with the capture of images focused by the cornea and lens upon a light-sensitive membrane in the back of the eye, called the *retina*. The retina is actually part of the brain, banished to the periphery to serve as a transducer for the conversion of patterns of light energy into neuronal signals. Light is absorbed by photopigment in two types of receptors: rods and cones. In the human retina there are 100 million rods and 5 million cones. The rods operate in dim (scotopic) illumination. The cones function under daylight (photopic) conditions. The cone system is specialized for color perception and high spatial resolution. The majority of cones are located within the macula, the portion of the retina serving the central 10° of vision. In the middle of the macula a small pit termed the *fovea*, packed exclusively with cones, provides best visual acuity.

Photoreceptors hyperpolarize in response to light, activating bipolar, amacrine, and horizontal cells in the inner nuclear layer. After processing of photoreceptor responses by this complex retinal circuit, the flow of sensory information ultimately converges upon a final common pathway: the ganglion cells. These cells translate the visual image impinging upon the retina into a continuously varying barrage of action potentials that propagates along the primary optic pathway to vi-

sual centers within the brain. There are a million ganglion cells in each retina, and hence a million fibers in each optic nerve.

Ganglion cell axons sweep along the inner surface of the retina in the nerve fiber layer, exit the eye at the optic disc, and travel through the optic nerve, optic chiasm, and optic tract to reach targets in the brain. The majority of fibers synapse upon cells in the lateral geniculate body, a thalamic relay station. Cells in the lateral geniculate body project in turn to the primary visual cortex. This massive afferent retinogeniculocortical sensory pathway provides the neural substrate for visual perception. Although the lateral geniculate body is the main target of the retina, separate classes of ganglion cells project to other subcortical visual nuclei involved in different functions. Ganglion cells that mediate pupillary constriction and circadian rhythms are light sensitive, owing to a novel visual pigment, melanopsin. Pupil responses are mediated by input to the pretectal olivary nuclei in the midbrain. The pretectal nuclei send their output to the Edinger-Westphal nuclei, which in turn provide parasympathetic innervation to the iris sphincter via an interneuron in the ciliary ganglion. Circadian rhythms are timed by a retinal projection to the suprachiasmatic nucleus. Visual orientation and eye movements are served by retinal input to the superior colliculus. Gaze stabilization and optokinetic reflexes are governed by a group of small retinal targets known collectively as the *brainstem accessory optic system*.

The eyes must be rotated constantly within their orbits to place and maintain targets of visual interest upon the fovea. This activity, called *foveation*, or looking, is governed by an elaborate efferent motor system. Each eye is moved by six extraocular muscles, supplied by cranial nerves from the oculomotor (III), trochlear (IV), and abducens (VI) nuclei. Activity in these ocular motor nuclei is coordinated by pontine and midbrain mechanisms for smooth pursuit, saccades, and gaze stabilization during head and body movements. Large regions of the frontal and parietooccipital cortex control these brainstem eye movement centers by providing descending supranuclear input.

CLINICAL ASSESSMENT OF VISUAL FUNCTION

REFRACTIVE STATE

In approaching the patient with reduced vision, the first step is to decide whether refractive error is responsible. In *emmetropia*, parallel rays from infinity are focused perfectly upon the retina. Sadly, this condition is enjoyed by only a minority of the population. In *myopia*, the globe is too long, and light rays come to a focal point in front of the retina. Near objects can be seen clearly, but distant objects require a diverging lens in front of the eye. In *hyperopia*, the globe is too short, and hence a converging lens is used to supplement the refractive power of the eye. In *astigmatism*, the corneal surface is not perfectly spherical, necessitating a cylindrical corrective lens. In recent years it has become possible to correct refractive error with the excimer laser by performing LASIK (laser in situ keratomileusis) to alter the curvature of the cornea.

With the onset of middle age, *presbyopia* develops as the lens within the eye becomes unable to increase its refractive power to accommodate upon near objects. To compensate for presbyopia, the emmetropic patient must use reading glasses. The patient already wearing glasses for distance correction usually switches to bifocals. The only exception is the myopic patient, who may achieve clear vision at near simply by removing glasses containing the distance prescription.

Refractive errors usually develop slowly and remain stable after adolescence, except in unusual circumstances. For example, the acute onset of diabetes mellitus can produce sudden myopia because of lens edema induced by hyperglycemia. Testing vision through a pinhole aperture is a useful way to screen quickly for refractive error. If the visual acuity is better through a pinhole than with the unaided eye, the patient needs a refraction to obtain best corrected visual acuity.

VISUAL ACUITY

The Snellen chart is used to test acuity at a distance of 6 m (20 ft). For convenience, a scale version of the Snellen chart, called the Rosenbaum card, is held at 36 cm (14 in) from the patient (Fig. 29-1). All subjects should be able to read the 6/6 m (20/20 ft) line with each eye using their refractive correction, if any. Patients who need reading glasses because of presbyopia must wear them for accurate testing with the Rosenbaum card. If 6/6 (20/20) acuity is not present in each eye, the deficiency in vision must be explained. If worse than 6/240 (20/800), acuity should be recorded in terms of counting fingers, hand motions, light perception, or no light perception. Legal blindness is defined by the Internal Revenue Service as a best corrected acuity of 6/60 (20/200) or less in the better eye, or a binocular visual field subtending 20° or less. For driving the laws vary by state, but most require a corrected acuity of 6/12 (20/40) in at least one eye for unrestricted privileges. Patients with a homonymous hemianopia should not drive.

FIGURE 29-1 The Rosenbaum card is a miniature, scale version of the Snellen chart for testing visual acuity at near. When the visual acuity is recorded, the Snellen distance equivalent should bear a notation indicating that vision was tested at near, not at 6 m (20 ft), or else the Jaeger number system should be used to report the acuity.

PUPILS

The pupils should be tested individually in dim light with the patient fixating on a distant target. If they respond briskly to light, there is no need to check the near response, because isolated loss of constriction (miosis) to accommodation does not occur. For this reason, the ubiquitous abbreviation PERRLA (pupils equal, round, and reactive to light and accommodation) implies a wasted effort with the last step.

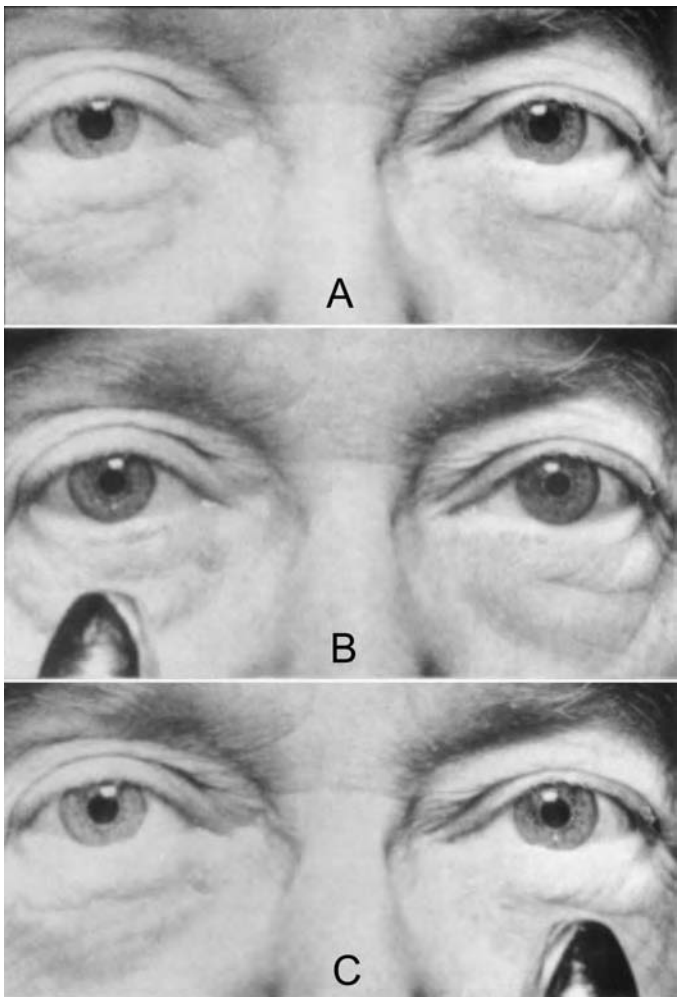

FIGURE 29-2 Demonstration of a relative afferent pupil defect (Marcus Gunn pupil) in the left eye, done with the patient fixating upon a distant target. ***A.*** With dim background lighting, the pupils are equal and relatively large. ***B.*** Shining a flashlight into the right eye evokes equal, strong constriction of both pupils. ***C.*** Swinging the flashlight over to the damaged left eye causes dilation of both pupils, although they remain smaller than in ***A.*** Swinging the flashlight back over to the healthy right eye would result in symmetric constriction back to the appearance shown in ***B.*** Note that the pupils always remain equal; the damage to the left retina/optic nerve is revealed by weaker bilateral pupil constriction to a flashlight in the left eye compared with the right eye. *(From P Levatin, Arch Ophthalmol 62:768, 1959.)*

However, it is important to test the near response if the light response is poor or absent. Light-near dissociation occurs with neurosyphilis (Argyll Robertson pupil), lesions of the dorsal midbrain (obstructive hydrocephalus, pineal region tumors), and after aberrant regeneration (oculomotor nerve palsy, Adie's tonic pupil).

An eye with no light perception has no pupillary response to direct light stimulation. If the retina or optic nerve is only partially injured, the direct pupillary response will be weaker than the consensual pupillary response evoked by shining a light into the other eye. This *relative afferent pupillary defect* (Marcus Gunn pupil) can be elicited with the swinging flashlight test (Fig. 29-2). It is an extremely useful sign in retrobulbar optic neuritis and other optic nerve diseases, where it may be the sole objective evidence for disease.

Subtle inequality in pupil size, up to 0.5 mm, is a fairly common finding in normal persons. The diagnosis of essential or physiologic anisocoria is secure as long as the relative pupil asymmetry remains constant as ambient lighting varies. Anisocoria that increases in dim light indicates a sympathetic paresis of the iris dilator muscle. The triad of miosis with ipsilateral ptosis and anhidrosis constitutes *Horner's syndrome*, although anhidrosis is an inconstant feature. Brainstem stroke, carotid dissection, or neoplasm impinging upon the sympathetic chain are occasionally identified as the cause of Horner's syndrome, but most cases are idiopathic.

Anisocoria that increases in bright light suggests a parasympathetic palsy. The first concern is an oculomotor nerve paresis. This possibility is excluded if the eye movements are full and the patient has no ptosis or diplopia. Acute pupillary dilation (mydriasis) can occur from damage to the ciliary ganglion in the orbit. Common mechanisms are infection (herpes zoster, influenza), trauma (blunt, penetrating, surgical), or ischemia (diabetes, temporal arteritis). After denervation of the iris sphincter the pupil does not respond well to light, but the response to near is often relatively intact. When the near stimulus is removed, the pupil redilates very slowly compared with the normal pupil, hence the term *tonic pupil*. In *Adie's syndrome*, a tonic pupil occurs in conjunction with weak or absent tendon reflexes in the lower extremities. This benign disorder, which occurs predominantly in healthy young women, is assumed to represent a mild dysautonomia. Tonic pupils are also associated with Shy-Drager syndrome, segmental hypohidrosis, diabetes, and amyloidosis. Occasionally, a tonic pupil is discovered incidentally in an otherwise completely normal, asymptomatic individual. The diagnosis is confirmed by placing a drop of dilute (0.125%) pilocarpine into each eye. Denervation hypersensitivity produces pupillary constriction in a tonic pupil, whereas the normal pupil shows no response. Pharmacologic dilation from accidental or deliberate instillation of anticholinergic agents (atropine, scopolamine drops) into the eye can also produce pupillary mydriasis. In this situation, normal strength (1%) pilocarpine causes no constriction.

Both pupils are affected equally by systemic medications. They are small with narcotic use (morphine, heroin) and large with anticholinergics (scopolamine). Parasympathetic agents (pilocarpine, demecarium bromide) used to treat glaucoma produce miosis. In any patient with an unexplained pupillary abnormality, a slit-lamp examination is helpful to exclude surgical trauma to the iris, an occult foreign body, perforating injury, intraocular inflammation, adhesions (synechia), angle-closure glaucoma, and iris sphincter rupture from blunt trauma.

EYE MOVEMENTS AND ALIGNMENT

Eye movements are tested by asking the patient with both eyes open to pursue a small target such as a penlight into the cardinal fields of gaze. Normal ocular versions are smooth, symmetric, full, and maintained in all directions without nystagmus. Saccades, or quick refixation eye movements, are assessed by having the patient look back and forth between two stationary targets. The eyes should move rapidly and accurately in a single jump to their target. Ocular alignment can be judged by holding a penlight directly in front of the patient at about 1 m. If the eyes are straight, the corneal light reflex will be centered in the middle of each pupil. To test eye alignment more precisely, the cover test is useful. The patient is instructed to gaze upon a small fixation target in the distance. One eye is covered suddenly while observing the second eye. If the second eye shifts to fixate upon the target, it was misaligned. If it does not move, the first eye is uncovered and the test is repeated on the second eye. If neither eye moves, the eyes are aligned orthotropically. If the eyes are orthotropic in primary gaze but the patient complains of diplopia, the cover test should be performed with the head tilted or turned in whatever direction elicits diplopia. With practice the examiner can detect an ocular deviation (heterotropia) as small as 1–2° with the cover test. Deviations can be measured by placing prisms in front of the misaligned eye to determine the power required to neutralize the fixation shift evoked by covering the other eye.

STEREOPSIS

Stereoacuity is determined by presenting targets with retinal disparity separately to each eye using polarized images. The most popular office tests measure a range of thresholds from 800–40 seconds of arc. Normal stereoacuity is 40 seconds of arc. If a patient achieves this level of stereoacuity, one is assured that the eyes are aligned orthotropically and that vision is intact in each eye. Random dot stereograms have no

monocular depth cues and provide an excellent screening test for strabismus and amblyopia in children.

COLOR VISION

The retina contains three classes of cones, with visual pigments of differing peak spectral sensitivity: red (560 nm), green (530 nm), and blue (430 nm). The red and green cone pigments are encoded on the X chromosome; the blue cone pigment on chromosome 7. Mutations of the blue cone pigment are exceedingly rare. Mutations of the red and green pigments cause congenital X-linked color blindness in 8% of males. Affected individuals are not truly color blind; rather, they differ from normal subjects in how they perceive color and how they combine primary monochromatic lights to match a given color. Anomalous trichromats have three cone types, but a mutation in one cone pigment (usually red or green) causes a shift in peak spectral sensitivity, altering the proportion of primary colors required to achieve a color match. Dichromats have only two cone types and will therefore accept a color match based upon only two primary colors. Anomalous trichromats and dichromats have 6/6 (20/20) visual acuity, but their hue discrimination is impaired. Ishihara color plates can be used to detect red-green color blindness. The test plates contain a hidden number, visible only to subjects with color confusion from red-green color blindness. Because color blindness is almost exclusively X-linked, it is worth screening only male children.

The Ishihara plates are often used to detect acquired defects in color vision, although they are intended as a screening test for congenital color blindness. Acquired defects in color vision frequently result from disease of the macula or optic nerve. For example, patients with a history of optic neuritis often complain of color desaturation long after their visual acuity has returned to normal. Color blindness can also occur from bilateral strokes involving the ventral portion of the occipital lobe (cerebral achromatopsia). Such patients can perceive only shades of gray and may also have difficulty recognizing faces (prosopagnosia). Infarcts of the dominant occipital lobe sometimes give rise to color anomia. Affected patients can discriminate colors, but they cannot name them.

VISUAL FIELDS

Vision can be impaired by damage to the visual system anywhere from the eyes to the occipital lobes. One can localize the site of the lesion with considerable accuracy by mapping the visual field deficit by finger confrontation and then correlating it with the topographic anatomy of the visual pathway **(Fig. 29-3)**. Quantitative visual field mapping is performed by computer-driven perimeters (Humphrey, Octopus) that present a target of variable intensity at fixed positions in the visual field (Fig. 29-3*A*). By generating an automated printout of light thresholds, these static perimeters provide a sensitive means of detecting scotomas in the visual field. They are exceedingly useful for serial assessment of visual function in chronic diseases such as glaucoma or pseudotumor cerebri.

The crux of visual field analysis is to decide whether a lesion is before, at, or behind the optic chiasm. If a scotoma is confined to one eye, it must be due to a lesion anterior to the chiasm, involving either the optic nerve or retina. Retinal lesions produce scotomas that correspond optically to their location in the fundus. For example, a superior-nasal retinal detachment results in an inferior-temporal field cut. Damage to the macula causes a central scotoma (Fig. 29-3*B*).

Optic nerve disease produces characteristic patterns of visual field loss. Glaucoma selectively destroys axons that enter the superotemporal or inferotemporal poles of the optic disc, resulting in arcuate scotomas shaped like a Turkish scimitar, which emanate from the blind spot and curve around fixation to end flat against the horizontal meridian (Fig. 29-3*C*). This type of field defect mirrors the arrangement of the nerve fiber layer in the temporal retina. Arcuate or nerve fiber layer scotomas also occur from optic neuritis, ischemic optic neuropathy, optic disc drusen, and branch retinal artery or vein occlusion.

Damage to the entire upper or lower pole of the optic disc causes an altitudinal field cut that follows the horizontal meridian (Fig. 29-3*D*). This pattern of visual field loss is typical of ischemic optic neuropathy but also occurs from retinal vascular occlusion, advanced glaucoma, and optic neuritis.

About half the fibers in the optic nerve originate from ganglion cells serving the macula. Damage to papillomacular fibers causes a cecocentral scotoma encompassing the blind spot and macula (Fig. 29-3*E*). If the damage is irreversible, pallor eventually appears in the temporal portion of the optic disc. Temporal pallor from a cecocentral scotoma may develop in optic neuritis, nutritional optic neuropathy, toxic optic neuropathy, Leber's hereditary optic neuropathy, and compressive optic neuropathy. It is worth mentioning that the temporal side of the optic disc is slightly more pale than the nasal side in most normal individuals. Therefore, it can sometimes be difficult to decide whether the temporal pallor visible on fundus examination represents a pathologic change. Pallor of the nasal rim of the optic disc is a less equivocal sign of optic atrophy.

At the optic chiasm, fibers from nasal ganglion cells decussate into the contralateral optic tract. Crossed fibers are damaged more by compression than uncrossed fibers. As a result, mass lesions of the sellar region cause a temporal hemianopia in each eye. Tumors anterior to the optic chiasm, such as meningiomas of the tuberculum sella, produce a junctional scotoma characterized by an optic neuropathy in one eye and a superior-temporal field cut in the other eye (Fig. 29-3*G*). More symmetric compression of the optic chiasm by a pituitary adenoma (Fig. 333-4), meningioma, craniopharyngioma, glioma, or aneurysm results in a bitemporal hemianopia (Fig. 29-3*H*). The insidious development of a bitemporal hemianopia often goes unnoticed by the patient and will escape detection by the physician unless each eye is tested separately.

It is difficult to localize a postchiasmal lesion accurately, because injury anywhere in the optic tract, lateral geniculate body, optic radiations, or visual cortex can produce a homonymous hemianopia, i.e., a temporal hemifield defect in the contralateral eye and a matching nasal hemifield defect in the ipsilateral eye (Fig. 29-3*I*). A unilateral postchiasmal lesion leaves the visual acuity in each eye unaffected, although the patient may read the letters on only the left or right half of the eye chart. Lesions of the optic radiations tend to cause poorly matched or incongruous field defects in each eye. Damage to the optic radiations in the temporal lobe (Meyer's loop) produces a superior quadrantic homonymous hemianopia (Fig. 29-3*J*), whereas injury to the optic radiations in the parietal lobe results in an inferior quadrantic homonymous hemianopia (Fig. 29-3*K*). Lesions of the primary visual cortex give rise to dense, congruous hemianopic field defects. Occlusion of the posterior cerebral artery supplying the occipital lobe is a frequent cause of total homonymous hemianopia. Some patients with hemianopia after occipital stroke have macular sparing, because the macular representation at the tip of the occipital lobe is supplied by collaterals from the middle cerebral artery (Fig. 29-3*L*). Destruction of both occipital lobes produces cortical blindness. This condition can be distinguished from bilateral prechiasmal visual loss by noting that the pupil responses and optic fundi remain normal.

DISORDERS

RED OR PAINFUL EYE

Corneal Abrasions These are seen best by placing a drop of fluorescein in the eye and looking with the slit lamp using a cobalt-blue light. A penlight with a blue filter will suffice if no slit lamp is available. Damage to the corneal epithelium is revealed by yellow fluorescence of the exposed basement membrane underlying the epithelium. It is important to check for foreign bodies. To search the conjunctival fornices, the lower lid should be pulled down and the upper lid everted. A foreign body can be removed with a moistened cotton-tipped applicator after placing a drop of topical anesthetic, such as proparacaine, in the eye. Alternatively, it may be possible to flush the foreign body from the eye by irrigating copiously with saline or artificial tears. If the corneal epithelium has been abraded, antibiotic ointment and a patch should be applied to the eye. A drop of an intermediate-acting cycloplegic, such as cyclopentolate hydrochloride 1%, helps to reduce pain

by relaxing the ciliary body. The eye should be reexamined the next day. Minor abrasions may not require patching and cycloplegia.

Subconjunctival Hemorrhage This results from rupture of small vessels bridging the potential space between the episclera and conjunctiva. Blood dissecting into this space can produce a spectacular red eye, but vision is not affected and the hemorrhage resolves without treatment. Subconjunctival hemorrhage is usually spontaneous but can occur from blunt trauma, eye rubbing, or vigorous coughing. Occasionally it is a clue to an underlying bleeding disorder.

Pinguecula This is a small, raised conjunctival nodule at the temporal or nasal limbus. In adults such lesions are extremely common and have little significance, unless they become inflamed (pinguecultis). A *pterygium* resembles a pinguecula but has crossed the limbus to encroach upon the corneal surface. Removal is justified when symptoms of irritation or blurring develop, but recurrence is a common problem.

Blepharitis This refers to inflammation of the eyelids. The most common form occurs in association with acne rosacea or seborrheic dermatitis. The eyelid margins are usually colonized heavily by staphylococci. Upon close inspection, they appear greasy, ulcerated, and crusted with scaling debris that clings to the lashes. Treatment consists of warm compresses, strict eyelid hygiene, and topical antibiotics such as *erythromycin*. An external *hordeolum* (sty) is caused by staphylococcal infection of the superficial accessory glands of Zeis or Moll located in the eyelid margins. An internal hordeolum occurs after suppurative infection of the oil-secreting meibomian glands within the tarsal plate of the eyelid. Systemic antibiotics, usually tetracyclines, are sometimes necessary for treatment of meibomian gland inflammation (meibomitis) or chronic, severe blepharitis. A *chalazion* is a painless, granulomatous inflammation of a meibomian gland that produces a pealike nodule within the eyelid. It can be incised and drained, or injected with glucocorticoids. Basal cell, squamous cell, or meibomian gland carcinoma should be suspected for any nonhealing, ulcerative lesion of the eyelids.

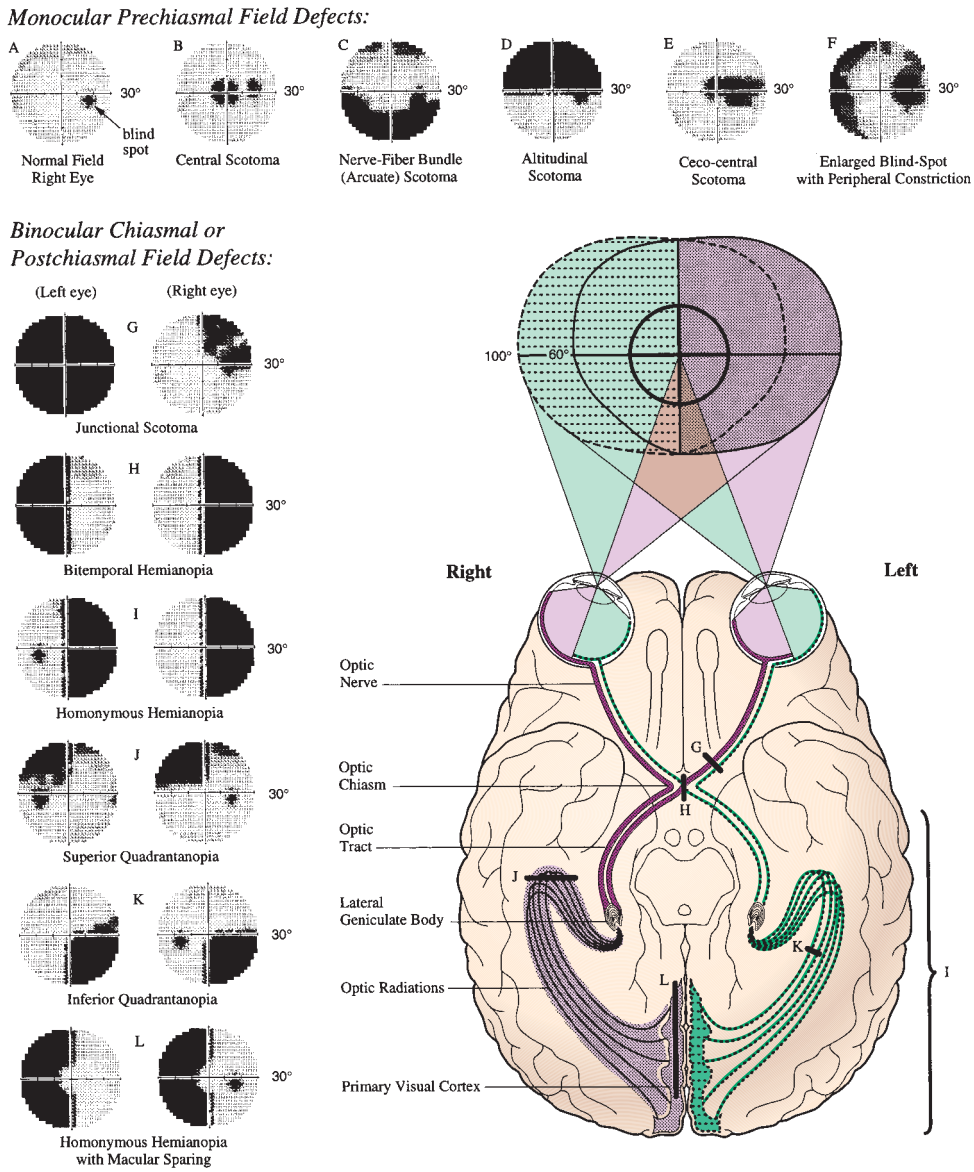

FIGURE 29-3 Ventral view of the brain, correlating patterns of visual field loss with the sites of lesions in the visual pathway. The visual fields overlap partially, creating 120° of central binocular field flanked by a 40° monocular crescent on either side. The visual field maps in this figure were done with a computer-driven perimeter (Humphrey Instruments, Carl Zeiss, Inc.). It plots the retinal sensitivity to light in the central 30° using a gray scale format. Areas of visual field loss are shown in black. The examples of common monocular, prechiasmal field defects are all shown for the right eye. By convention, the visual fields are always recorded with the left eye's field on the left, and the right eye's field on the right, just as the patient sees the world.

Dacrocystitis An inflammation of the lacrimal drainage system, this can produce epiphora (tearing) and ocular injection. Gentle pressure over the lacrimal sac evokes pain and reflux of mucus or pus from the tear puncta. Dacrocystitis usually occurs after obstruction of the lacrimal system. It is treated with topical and systemic antibiotics, followed by probing or surgery to reestablish patency. *Entropion* (inversion of the eyelid) or *ectropion* (sagging or eversion of the eyelid) can also lead to epiphora and ocular irritation.

Conjunctivitis This is the most common cause of a red, irritated eye. Pain is minimal, and the visual acuity is reduced only slightly. The most common viral etiology is adenovirus infection. It causes a watery discharge, mild foreign-body sensation, and photophobia. Bacterial infection tends to produce a more mucopurulent exudate. Mild cases of infectious conjunctivitis are usually treated empirically with broad-spectrum topical ocular antibiotics, such as sulfacetamide 10%, polymixin-bacitracin-neomycin, or trimethoprim-polymixin combination. Smears and cultures are usually reserved for severe, resistant, or recurrent cases of conjunctivitis. To prevent contagion, patients should be admonished to wash their hands frequently, not to touch their eyes, and to avoid direct contact with others.

Allergic Conjunctivitis This condition is extremely common and often mistaken for infectious conjunctivitis. Itching, redness, and epiphora are typical. The palpebral conjunctiva may become hypertropic

with giant excrescences called cobblestone papillae. Irritation from contact lenses or any chronic foreign body can also induce formation of cobblestone papillae. *Atopic conjunctivitis* occurs in subjects with atopic dermatitis or asthma. Symptoms caused by allergic conjunctivitis can be alleviated with cold compresses, topical vasoconstrictors, antihistamines, and mast cell stabilizers such as cromolyn sodium. Topical glucocorticoid solutions provide dramatic relief of immune-mediated forms of conjunctivitis, but their long-term use is ill-advised because of the complications of glaucoma, cataract, and secondary infection. Topical nonsteroidal anti-inflammatory agents (NSAIDs) such as ketorolac tromethamine are a better alternative.

Keratoconjunctivitis Sicca Also known as dry eye, it produces a burning, foreign-body sensation, injection, and photophobia. In mild cases the eye appears surprisingly normal, but tear production measured by wetting of a filter paper (Schirmer strip) is deficient. A variety of systemic drugs, including antihistaminic, anticholinergic, and psychotropic medications, result in dry eye by reducing lacrimal secretion. Disorders that involve the lacrimal gland directly, such as sarcoidosis or Sjögren's syndrome, also cause dry eye. Patients may develop dry eye after radiation therapy if the treatment field includes the orbits. Problems with ocular drying are also common after lesions affecting cranial nerves V or VII. Corneal anesthesia is particularly dangerous, because the absence of a normal blink reflex exposes the cornea to injury without pain to warn the patient. Dry eye is managed by frequent and liberal application of artificial tears and ocular lubricants. In severe cases the tear puncta can be plugged or cauterized to reduce lacrimal outflow.

Keratitis This is a threat to vision because of the risk of corneal clouding, scarring, and perforation. Worldwide, the two leading causes of blindness from keratitis are trachoma from chlamydial infection and vitamin A deficiency related to malnutrition. In the United States, contact lenses play a major role in corneal infection and ulceration. They should not be worn by anyone with an active eye infection. In evaluating the cornea, it is important to differentiate between a superficial infection (*keratoconjunctivitis*) and a deeper, more serious ulcerative process. The latter is accompanied by greater visual loss, pain, photophobia, redness, and discharge. Slit-lamp examination shows disruption of the corneal epithelium, a cloudy infiltrate or abscess in the stroma, and an inflammatory cellular reaction in the anterior chamber. In severe cases, pus settles at the bottom of the anterior chamber, giving rise to a hypopyon. Immediate empirical antibiotic therapy should be initiated after corneal scrapings are obtained for Gram's stain, Giemsa stain, and cultures. Fortified topical antibiotics are most effective, supplemented with subconjunctival antibiotics as required. A fungal etiology should always be considered in the patient with keratitis. Fungal infection is common in warm humid climates, especially after penetration of the cornea by plant or vegetable material.

Herpes Simplex The *herpes viruses* are a major cause of blindness from keratitis. Most adults in the United States have serum antibodies to herpes simplex, indicating prior viral infection (Chap. 172). Primary ocular infection is generally caused by herpes simplex type 1, rather than type 2. It manifests as a unilateral follicular blepharoconjunctivitis, easily confused with adenoviral conjunctivitis unless telltale vesicles appear on the periocular skin or conjunctiva. A dendritic pattern of corneal epithelial ulceration revealed by fluorescein staining is pathognomonic for herpes infection but is seen in only a minority of primary infections. Recurrent ocular infection arises from reactivation of the latent herpes virus. Viral eruption in the corneal epithelium may result in the characteristic herpes dendrite. Involvement of the corneal stroma produces edema, vascularization, and iridocyclitis. Herpes keratitis is treated with topical antiviral agents, cycloplegics, and oral acyclovir. Topical glucocorticoids are effective in mitigating corneal scarring but must be used with extreme caution because of the danger of corneal melting and perforation. Topical glucocorticoids also carry the risk of prolonging infection and inducing glaucoma.

Herpes Zoster Herpes zoster from reactivation of latent varicella (chickenpox) virus causes a dermatomal pattern of painful vesicular dermatitis. Ocular symptoms can occur after zoster eruption in any branch of the trigeminal nerve but are particularly common when vesicles form on the nose, reflecting nasociliary (V1) nerve involvement (Hutchinson's sign). Herpes zoster ophthalmicus produces corneal dendrites, which can be difficult to distinguish from those seen in herpes simplex. Stromal keratitis, anterior uveitis, raised intraocular pressure, ocular motor nerve palsies, acute retinal necrosis, and postherpetic scarring and neuralgia are other common sequelae. Herpes zoster ophthalmicus is treated with antiviral agents and cycloplegics. In severe cases, glucocorticoids may be added to prevent permanent visual loss from corneal scarring.

Episcleritis This is an inflammation of the episclera, a thin layer of connective tissue between the conjunctiva and sclera. Episcleritis resembles conjunctivitis but is a more localized process and discharge is absent. Most cases of episcleritis are idiopathic, but some occur in the setting of an autoimmune disease. *Scleritis* refers to a deeper, more severe inflammatory process, frequently associated with a connective tissue disease such as rheumatoid arthritis, lupus erythematosus, polyarteritis nodosa, Wegener's granulomatosis, or relapsing polychondritis. The inflammation and thickening of the sclera can be diffuse or nodular. In anterior forms of scleritis, the globe assumes a violet hue and the patient complains of severe ocular tenderness and pain. With posterior scleritis the pain and redness may be less marked, but there is often proptosis, choroidal effusion, reduced motility, and visual loss. Episcleritis and scleritis should be treated with NSAIDs. If these agents fail, topical or even systemic glucocorticoid therapy may be necessary, especially if an underlying autoimmune process is active.

Uveitis Involving the anterior structures of the eye, this is also called *iritis* or *iridocyclitis*. The diagnosis requires slit-lamp examination to identify inflammatory cells floating in the aqueous humor or deposited upon the corneal endothelium (keratic precipitates). Anterior uveitis develops in sarcoidosis, ankylosing spondylitis, juvenile rheumatoid arthritis, inflammatory bowel disease, psoriasis, Reiter's syndrome, and Behçet's disease. It is also associated with herpes infections, syphilis, Lyme disease, onchocerciasis, tuberculosis, and leprosy. Although anterior uveitis can occur in conjunction with many diseases, no cause is found to explain the majority of cases. For this reason, laboratory evaluation is usually reserved for patients with recurrent or severe anterior uveitis. Treatment is aimed at reducing inflammation and scarring by judicious use of topical glucocorticoids. Dilation of the pupil reduces pain and prevents the formation of synechiae.

Posterior Uveitis This is diagnosed by observing inflammation of the vitreous, retina, or choroid on fundus examination. It is more likely than anterior uveitis to be associated with an identifiable systemic disease. Some patients have panuveitis, or inflammation of both the anterior and posterior segments of the eye. Posterior uveitis is a manifestation of autoimmune diseases such as sarcoidosis, Behçet's disease, Vogt-Koyanagi-Harada syndrome, and inflammatory bowel disease (Fig. 29-4). It also accompanies diseases such as toxoplasmosis, onchocerciasis, cysticercosis, coccidioidomycosis, toxocariasis, and histoplasmosis; infections caused by organisms such as *Candida*, *Pneumocystis carinii*, *Cryptococcus*, *Aspergillus*, herpes, and cytomegalovirus (see Fig. 175-1); and other diseases such as syphilis, Lyme disease, tuberculosis, cat-scratch disease, Whipple's disease, and brucellosis. In multiple sclerosis, chronic inflammatory changes can develop in the extreme periphery of the retina (pars planitis or intermediate uveitis).

Acute Angle-Closure Glaucoma This is a rare and frequently misdiagnosed cause of a red, painful eye. Susceptible eyes have a shallow anterior chamber, either because the eye has a short axial length (hyperopia) or a lens enlarged by the gradual development of cataract. When the pupil becomes mid-dilated, the peripheral iris blocks aqueous outflow via the anterior chamber angle and the intraocular pressure rises

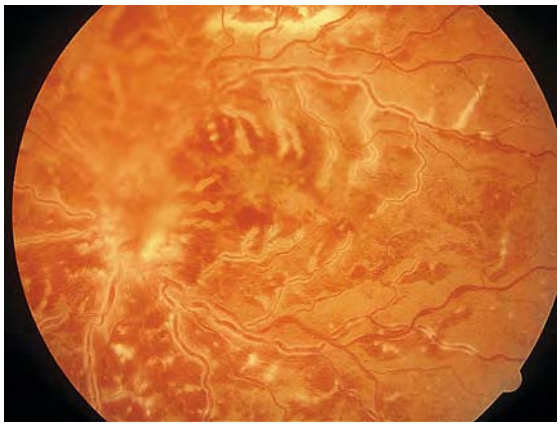

FIGURE 29-4 Retinal vasculitis, uveitis, and hemorrhage in a 32-year-old woman with Crohn's disease. Note that the veins are frosted with a white exudate. Visual acuity improved from 20/400 to 20/20 following treatment with intravenous methylprednisolone.

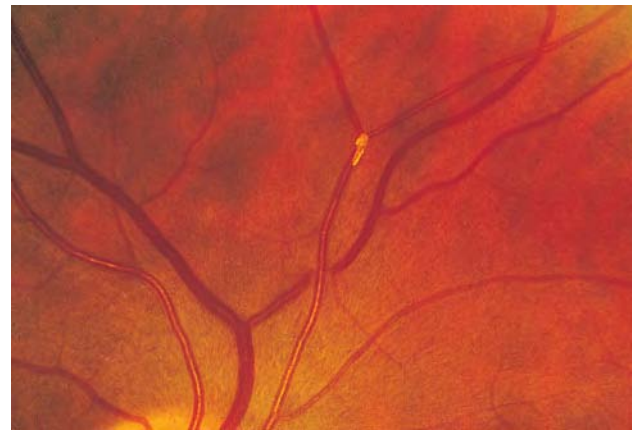

FIGURE 29-5 Hollenhorst plaque lodged at the bifurcation of a retinal arteriole proves that a patient is shedding emboli from either the carotid artery, great vessels, or heart.

abruptly, producing pain, injection, corneal edema, obscurations, and blurred vision. In some patients, ocular symptoms are overshadowed by nausea, vomiting, or headache, prompting a fruitless workup for abdominal or neurologic disease. The diagnosis is made by measuring the intraocular pressure during an acute attack or by observing a narrow chamber angle by means of a specially mirrored contact lens. Acute angle closure is treated with acetazolamide (PO or IV), topical beta blockers, prostaglandin analogues, α_2-adrenergic agonists, and pilocarpine to induce miosis. If these measures fail, a laser can be used to create a hole in the peripheral iris to relieve pupillary block. Many physicians are reluctant to dilate patients routinely for fundus examination because they fear precipitating an angle-closure glaucoma. The risk is actually remote and more than outweighed by the potential benefit to patients of discovering a hidden fundus lesion visible only through a fully dilated pupil. Moreover, a single attack of angle closure after pharmacologic dilation rarely causes any permanent damage to the eye and serves as an inadvertent provocative test to identify patients with narrow angles who would benefit from prophylactic laser iridectomy.

Endophthalmitis This occurs from bacterial, viral, fungal, or parasitic infection of the internal structures of the eye. It is usually acquired by hematogenous seeding from a remote site. Chronically ill, diabetic, or immunosuppressed patients, especially those with a history of indwelling IV catheters or positive blood cultures, are at greatest risk for endogenous endophthalmitis. Although most patients have ocular pain and injection, visual loss is sometimes the only symptom. Septic emboli, from a diseased heart valve or a dental abscess, that lodge in the retinal circulation can give rise to endophthalmitis. White-centered retinal hemorrhages (Roth's spots) are considered pathognomonic for subacute bacterial endocarditis, but they also appear in leukemia, diabetes, and many other conditions. Endophthalmitis also occurs as a complication of ocular surgery, occasionally months or even years after the operation. An occult penetrating foreign body or unrecognized trauma to the globe should be considered in any patient with unexplained intraocular infection or inflammation.

TRANSIENT OR SUDDEN VISUAL LOSS

Amaurosis Fugax This term refers to a transient ischemic attack of the retina (Chap. 364). Because neural tissue has a high rate of metabolism, interruption of blood flow to the retina for more than a few seconds results in *transient monocular blindness*, a term used interchangeably with amaurosis fugax. Patients describe a rapid fading of vision like a curtain descending, sometimes affecting only a portion of the visual field. Amaurosis fugax usually occurs from an embolus that becomes stuck within a retinal arteriole (Fig. 29-5). If the embolus breaks up or passes, flow is restored and vision returns quickly to normal without permanent damage. With prolonged interruption of blood flow, the inner retina suffers infarction. Ophthalmoscopy reveals zones of whitened, edematous retina following the distribution of branch retinal arterioles. Complete occlusion of the central retinal artery produces arrest of blood flow and a milky retina with a cherry-red fovea (Fig. 29-6). Emboli are composed of either cholesterol (Hollenhorst plaque), calcium, or platelet-fibrin debris. The most common source is an atherosclerotic plaque in the carotid artery or aorta, although emboli can also arise from the heart, especially in patients with diseased valves, atrial fibrillation, or wall motion abnormalities.

In rare instances, amaurosis fugax occurs from low central retinal artery perfusion pressure in a patient with a critical stenosis of the ipsilateral carotid artery and poor collateral flow via the circle of Willis. In this situation, amaurosis fugax develops when there is a dip in systemic blood pressure or a slight worsening of the carotid stenosis. Sometimes there is contralateral motor or sensory loss, indicating concomitant hemispheric cerebral ischemia.

Retinal arterial occlusion also occurs rarely in association with retinal migraine, lupus erythematosus, anticardiolipin antibodies (Fig. 29-6), anticoagulant deficiency states (protein S, protein C, and antithrombin III deficiency), pregnancy, IV drug abuse, blood dyscrasias, dysproteinemias, and temporal arteritis.

Marked *systemic hypertension* causes sclerosis of retinal arterioles, splinter hemorrhages, focal infarcts of the nerve fiber layer (cotton-wool spots), and leakage of lipid and fluid (hard exudate) into the macula (Fig. 29-7). In hypertensive crisis, sudden visual loss can result

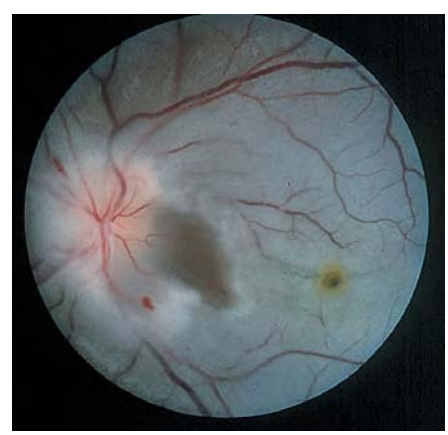

FIGURE 29-6 Central retinal artery occlusion combined with ischemic optic neuropathy in a 19-year-old woman with an elevated titer of anticardiolipin antibodies. Note the orange dot (rather than cherry red) corresponding to the fovea and the spared patch of retina just temporal to the optic disc.

FIGURE 29-7 Hypertensive retinopathy with scattered flame (splinter) hemorrhages and cotton-wool spots (nerve fiber layer infarcts) in a patient with headache and a blood pressure of 234/120.

FIGURE 29-9 Anterior ischemic optic neuropathy from temporal arteritis in a 78-year-old woman with pallid disc swelling, hemorrhage, visual loss, myalgia, and an erythrocyte sedimentation rate of 86 mm/h.

from vasospasm of retinal arterioles and retinal ischemia. In addition, acute hypertension may produce visual loss from ischemic swelling of the optic disc. Patients with acute hypertensive retinopathy should be treated by lowering the blood pressure. However, the blood pressure should not be reduced precipitously, because there is a danger of optic disc infarction from sudden hypoperfusion.

Impending *branch* or *central retinal vein occlusion* can produce prolonged visual obscurations that resemble those described by patients with amaurosis fugax. The veins appear engorged and phlebitic, with numerous retinal hemorrhages (Fig. 29-8). In some patients, venous blood flow recovers spontaneously, while others evolve a frank obstruction with extensive retinal bleeding ("blood and thunder" appearance), infarction, and visual loss. Venous occlusion of the retina is often idiopathic, but hypertension, diabetes, and glaucoma are prominent risk factors. Polycythemia, thrombocythemia, or other factors leading to an underlying hypercoagulable state should be corrected; aspirin treatment may be beneficial.

Anterior Ischemic Optic Neuropathy (AION) This is caused by insufficient blood flow through the posterior ciliary arteries supplying the optic disc. It produces painless, monocular visual loss that is usually sudden, although some patients have progressive worsening. The optic disc appears swollen and surrounded by nerve fiber layer splinter hemorrhages (Fig. 29-9). AION is divided into two forms: arteritic and nonarteritic. The nonarteritic form of AION is most common. No specific cause can be identified, although diabetes and hypertension are frequent risk factors. No treatment is available. About 5% of patients, especially those over age 60, develop the arteritic form of AION in conjunction with giant cell (temporal) arteritis (Chap. 319). It is urgent to recognize arteritic AION so that high doses of glucocorticoids can be instituted immediately to prevent blindness in the second eye. Symptoms of polymyalgia rheumatica may be present; the sedimentation rate and C-reactive protein level are usually elevated. In a patient with visual loss from suspected arteritic AION, temporal artery biopsy is mandatory to confirm the diagnosis. Glucocorticoids should be started immediately, without waiting for the biopsy to be completed. The diagnosis of arteritic AION is difficult to sustain in the face of a negative temporal artery biopsy, but such cases do occur rarely.

Posterior Ischemic Optic Neuropathy This is an infrequent cause of acute visual loss, induced by the combination of severe anemia and hypotension. Cases have been reported after major blood loss during surgery, exsanguinating trauma, gastrointestinal bleeding, and renal dialysis. The fundus usually appears normal, although optic disc swelling develops if the process extends far enough anteriorly. Vision can be salvaged in some patients by prompt blood transfusion and reversal of hypotension.

Optic Neuritis This is a common inflammatory disease of the optic nerve. In the Optic Neuritis Treatment Trial (ONTT), the mean age of patients was 32 years, 77% were female, 92% had ocular pain (especially with eye movements), and 35% had optic disc swelling. In most patients, the demyelinating event was retrobulbar and the ocular fundus appeared normal on initial examination (Fig. 29-10), although optic disc pallor slowly developed over subsequent months.

Virtually all patients experience a gradual recovery of vision after a single episode of optic neuritis, even without treatment. This rule is so reliable that failure of vision to improve after a first attack of optic

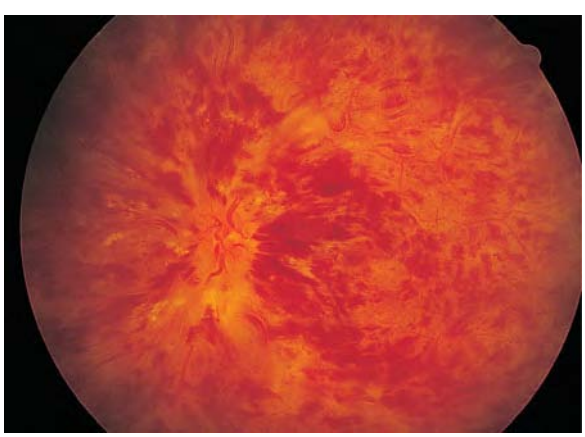

FIGURE 29-8 Central retinal vein occlusion can produce massive retinal hemorrhage ("blood and thunder"), ischemia, and vision loss.

FIGURE 29-10 Retrobulbar optic neuritis is characterized by a normal fundus examination initially, hence the rubric, "the doctor sees nothing, and the patient sees nothing." Optic atrophy develops after severe or repeated attacks.

neuritis casts doubt upon the original diagnosis. Treatment with high-dose IV methylprednisolone (250 mg every 6 h for 3 days) followed by oral prednisone (1 mg/kg per day for 11 days) makes no difference in final acuity (measured 6 months after the attack), but the recovery of visual function occurs more rapidly.

For some patients, optic neuritis remains an isolated event. However, the ONTT showed that the 10-year cumulative probability of developing clinically definite multiple sclerosis following optic neuritis is 38%. In patients with two or more demyelinating plaques on brain magnetic resonance (MR) imaging, treatment with interferon beta-1a can retard the development of more lesions. In summary, an MR scan is recommended in every patient with a first attack of optic neuritis. When visual loss is severe (worse than 20/100), treatment with intravenous followed by oral glucocorticoids hastens recovery. If multiple lesions are present on the MR scan, treatment with interferon β-1a should be considered.

Leber's Hereditary Optic Neuropathy This disease usually affects young men, causing gradual, painless, severe, central visual loss in one eye, followed weeks or months later by the same process in the other eye. Acutely, the optic disc appears mildly plethoric with surface capillary telangiectases, but no vascular leakage on fluorescein angiography. Eventually optic atrophy ensues. Leber's optic neuropathy is caused by a point mutation at codon 11778 in the mitochondrial gene encoding nicotinamide adenine dinucleotide dehydrogenase (NADH) subunit 4. Additional mutations responsible for the disease have been identified, most in mitochondrial genes encoding proteins involved in electron transport. Mitochondrial mutations causing Leber's neuropathy are inherited from the mother by all her children, but usually only sons develop symptoms. There is no treatment.

Toxic Optic Neuropathy This can result in acute visual loss with bilateral optic disc swelling and central or cecocentral scotomas. Such cases have been reported to result from exposure to ethambutol, methyl alcohol (moonshine), ethylene glycol (antifreeze), or carbon monoxide. In toxic optic neuropathy, visual loss can also develop gradually and produce optic atrophy (Fig. 29-11) without a phase of acute optic disc edema. Many agents have been implicated as a cause of toxic optic neuropathy, but the evidence supporting the association for many is weak. The following is a partial list of potential offending drugs or toxins: disulfiram, ethchlorvynol, chloramphenicol, amiodarone, monoclonal anti-CD3 antibody, ciprofloxacin, digitalis, streptomycin, lead, arsenic, thallium, D-penicillamine, isoniazid, emetine, and sulfonamides. Deficiency states, induced either by starvation, malabsorption, or alcoholism, can lead to insidious visual loss. Thiamine, vitamin B_{12}, and folate levels should be checked in any patient with unexplained, bilateral central scotomas and optic pallor.

FIGURE 29-11 Optic atrophy is not a specific diagnosis, but refers to the combination of optic disc pallor, arteriolar narrowing, and nerve fiber layer destruction produced by a host of eye diseases, especially optic neuropathies.

FIGURE 29-12 Papilledema means optic disc edema from raised intracranial pressure. This obese young woman with pseudotumor cerebri was misdiagnosed as a migraineur until fundus examination was performed, showing optic disc elevation, hemorrhages, and cotton-wool spots.

Papilledema This connotes bilateral optic disc swelling from raised intracranial pressure (Fig. 29-12). Headache is a frequent, but not invariable, accompaniment. All other forms of optic disc swelling, e.g., from optic neuritis or ischemic optic neuropathy, should be called "optic disc edema." This convention is arbitrary but serves to avoid confusion. Often it is difficult to differentiate papilledema from other forms of optic disc edema by fundus examination alone. Transient visual obscurations are a classic symptom of papilledema. They can occur in only one eye or simultaneously in both eyes. They usually last seconds but can persist longer. Obscurations follow abrupt shifts in posture or happen spontaneously. When obscurations are prolonged or spontaneous, the papilledema is more threatening. Visual acuity is not affected by papilledema unless the papilledema is severe, long-standing, or accompanied by macular edema and hemorrhage. Visual field testing shows enlarged blind spots and peripheral constriction (Fig. 29-3*F*). With unremitting papilledema, peripheral visual field loss progresses in an insidious fashion while the optic nerve develops atrophy. In this setting, reduction of optic disc swelling is an ominous sign of a dying nerve rather than an encouraging indication of resolving papilledema.

Evaluation of papilledema requires neuroimaging to exclude an intracranial lesion. MR angiography is appropriate in selected cases to search for a dural venous sinus occlusion or an arteriovenous shunt. If neuroradiologic studies are negative, the subarachnoid opening pressure should be measured by lumbar puncture. An elevated pressure, with normal cerebrospinal fluid, points by exclusion to the diagnosis of *pseudotumor cerebri* (idiopathic intracranial hypertension). The majority of patients are young, female, and obese. Treatment with a carbonic anhydrase inhibitor such as acetazolamide lowers intracranial pressure by reducing the production of cerebrospinal fluid. Weight reduction is vital but often unsuccessful. If acetazolamide and weight loss fail, and visual field loss is progressive, a shunt should be performed without delay to prevent blindness. Occasionally, emergency surgery is required for sudden blindness caused by fulminant papilledema.

Optic Disc Drusen These are refractile deposits within the substance of the optic nerve head (Fig. 29-13). They are unrelated to drusen of the retina, which occur in age-related macular degeneration. Optic disc drusen are most common in people of northern European descent. Their diagnosis is obvious when they are visible as glittering particles upon the surface of the optic disc. However, in many patients they are hidden beneath the surface, producing pseudo-papilledema. It is important to recognize optic disc drusen to avoid an unnecessary evaluation for papilledema. Ultrasound or CT scanning is sensitive for detection of buried optic disc drusen because they contain calcium. In most patients, optic disc drusen are an incidental, innocuous finding, but they can produce visual obscurations. On perimetry they give rise

FIGURE 29-13 Optic disc drusen are calcified deposits of unknown etiology within the optic disc. They are sometimes confused with papilledema.

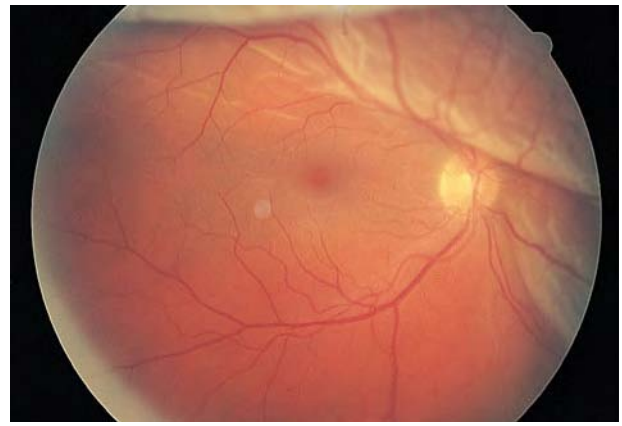

FIGURE 29-14 Retinal detachment appears as an elevated sheet of retinal tissue with folds. In this patient the fovea was spared, so acuity was normal, but a superior detachment produced an inferior scotoma.

to enlarged blind spots and arcuate scotomas from damage to the optic disc. With increasing age, drusen tend to become more exposed on the disc surface as optic atrophy develops. Hemorrhage, choroidal neovascular membrane, and AION are more likely to occur in patients with optic disc drusen. No treatment is available.

Vitreous Degeneration This occurs in all individuals with advancing age, leading to visual symptoms. Opacities develop in the vitreous, casting annoying shadows upon the retina. As the eye moves, these distracting "floaters" move synchronously, with a slight lag caused by inertia of the vitreous gel. Vitreous traction upon the retina causes mechanical stimulation, resulting in perception of flashing lights. This photopsia is brief and confined to one eye, in contrast to the bilateral, prolonged scintillations of cortical migraine. Contraction of the vitreous can result in sudden separation from the retina, heralded by an alarming shower of floaters and photopsia. This process, known as *vitreous detachment*, is a frequent involutional event in the elderly. It is not harmful unless it damages the retina. A careful examination of the dilated fundus is important in any patient complaining of floaters or photopsia to search for peripheral tears or holes. If such a lesion is found, laser application can forestall a retinal detachment. Occasionally a tear ruptures a retinal blood vessel, causing vitreous hemorrhage and sudden loss of vision. On attempted ophthalmoscopy the fundus is hidden by a dark red haze of blood. Ultrasound is required to examine the interior of the eye for a retinal tear or detachment. If the hemorrhage does not resolve spontaneously, the vitreous can be removed surgically. Vitreous hemorrhage also occurs from the fragile neovascular vessels that proliferate on the surface of the retina in diabetes, sickle cell anemia, and other ischemic ocular diseases.

Retinal Detachment This produces symptoms of floaters, flashing lights, and a scotoma in the peripheral visual field corresponding to the detachment (Fig. 29-14). If the detachment includes the fovea, there is an afferent pupil defect and the visual acuity is reduced. In most eyes, retinal detachment starts with a hole, flap, or tear in the peripheral retina (rhegmatogenous retinal detachment). Patients with peripheral retinal thinning (lattice degeneration) are particularly vulnerable to this process. Once a break has developed in the retina, liquified vitreous is free to enter the subretinal space, separating the retina from the pigment epithelium. The combination of vitreous traction upon the retinal surface and passage of fluid behind the retina leads inexorably to detachment. Patients with a history of myopia, trauma, or prior cataract extraction are at greatest risk for retinal detachment. The diagnosis is confirmed by ophthalmoscopic examination of the dilated eye.

Classic Migraine (See also Chap. 15) This usually occurs with a visual aura lasting about 20 min. In a typical attack, a small central disturbance in the field of vision marches toward the periphery, leaving a transient scotoma in its wake. The expanding border of migraine scotoma has a scintillating, dancing, or zig-zag edge, resembling the bastions of a fortified city, hence the term *fortification spectra*. Patients' descriptions of fortification spectra vary widely and can be confused with amaurosis fugax. Migraine patterns usually last longer and are perceived in both eyes, whereas amaurosis fugax is briefer and occurs in only one eye. Migraine phenomena also remain visible in the dark or with the eyes closed. Generally they are confined to either the right or left visual hemifield, but sometimes both fields are involved simultaneously. Patients often have a long history of stereotypic attacks. After the visual symptoms recede, headache develops in most patients.

Transient Ischemic Attacks Vertebrobasilar insufficiency may result in acute homonymous visual symptoms. Many patients mistakenly describe symptoms in their left or right eye, when in fact they are occurring in the left or right hemifield of both eyes. Interruption of blood supply to the visual cortex causes a sudden fogging or graying of vision, occasionally with flashing lights or other positive phenomena that mimic migraine. Cortical ischemic attacks are briefer in duration than migraine, occur in older patients, and are not followed by headache. There may be associated signs of brainstem ischemia, such as diplopia, vertigo, numbness, weakness, or dysarthria.

Stroke This occurs when interruption of blood supply from the posterior cerebral artery to the visual cortex is prolonged. The only finding on examination is a homonymous visual field defect that stops abruptly at the vertical meridian. Occipital lobe stroke is usually due to thrombotic occlusion of the vertebrobasilar system, embolus, or dissection. Lobar hemorrhage, tumor, abscess, and arteriovenous malformation are other common causes of hemianopic cortical visual loss.

Factitious (Functional, Nonorganic) Visual Loss This is claimed by hysterics or malingerers. The latter comprise the vast majority, seeking sympathy, special treatment, or financial gain by feigning loss of sight. The diagnosis is suspected when the history is atypical, physical findings are lacking or contradictory, inconsistencies emerge on testing, and a secondary motive can be identified. In our litigious society, the fraudulent pursuit of recompense has spawned an epidemic of factitious visual loss.

CHRONIC VISUAL LOSS

Cataract This is a clouding of the lens sufficient to reduce vision. Most cataracts develop slowly as a result of aging, leading to gradual impairment of vision. The formation of cataract occurs more rapidly in patients with a history of ocular trauma, uveitis, or diabetes mellitus. Cataracts are acquired in a variety of genetic diseases, such as myotonic dystrophy, neurofibromatosis type 2, and galactosemia. Radiation therapy and glucocorticoid treatment can induce cataract as a side effect. The cataracts associated with radiation or glucocorticoids have a typical posterior subcapsular location. Cataract can be detected by noting an im-

paired red reflex when viewing light reflected from the fundus with an ophthalmoscope or by examining the dilated eye using the slit lamp.

The only treatment for cataract is surgical extraction of the opacified lens. Over a million cataract operations are performed each year in the United States. The operation is generally done under local anesthesia on an outpatient basis. A plastic or silicone intraocular lens is placed within the empty lens capsule in the posterior chamber, substituting for the natural lens and leading to rapid recovery of sight. More than 95% of patients who undergo cataract extraction can expect an improvement in vision. In some patients, the lens capsule remaining in the eye after cataract extraction eventually turns cloudy, causing secondary loss of vision. A small opening is made in the lens capsule with a laser to restore clarity.

Glaucoma This is a slowly progressive, insidious optic neuropathy, usually associated with chronic elevation of intraocular pressure. In Americans of African descent it is the leading cause of blindness. The mechanism whereby raised intraocular pressure injures the optic nerve is not understood. Axons entering the inferotemporal and superotemporal aspects of the optic disc are damaged first, producing typical nerve fiber bundle or arcuate scotomas on perimetric testing. As fibers are destroyed, the neural rim of the optic disc shrinks and the physiologic cup within the optic disc enlarges (Fig. 29-15). This process is referred to as pathologic "cupping." The cup-to-disc diameter is expressed as a ratio, e.g., 0.2/1. The cup-to-disc ratio ranges widely in normal individuals, making it difficult to diagnose glaucoma reliably simply by observing an unusually large or deep optic cup. Careful documentation of serial examinations is helpful. In the patient with physiologic cupping, the large cup remains stable, whereas in the patient with glaucoma it expands relentlessly over the years. Detection of visual field loss by computerized perimetry also contributes to the diagnosis. Finally, most patients with glaucoma have raised intraocular pressure. However, many patients with typical glaucomatous cupping and visual field loss have intraocular pressures that apparently never exceed the normal limit of 20 mmHg (so-called low-tension glaucoma).

In acute angle-closure glaucoma, the eye is red and painful due to abrupt, severe elevation of intraocular pressure. Such cases account for only a minority of glaucoma cases: most patients have open, anterior chamber angles. The cause of raised intraocular pressure in open angle glaucoma is unknown, but it is associated with gene mutations in the heritable forms.

Glaucoma is usually painless (except in angle-closure glaucoma). Foveal acuity is spared until end-stage disease is reached. For these reasons, severe and irreversible damage can occur before either the patient or physician recognizes the diagnosis. Screening of patients for glaucoma by noting the cup-to-disc ratio on ophthalmoscopy and by measuring intraocular pressure is vital. Glaucoma is treated with topical adrenergic agonists, cholinergic agonists, beta blockers, and prostaglandin analogues. Occasionally, systemic absorption of beta blocker from eye drops can be sufficient to cause side effects of bradycardia, hypotension, heart block, bronchospasm, or depression. Topical or oral carbonic anhydrase inhibitors are used to lower intraocular pressure by reducing aqueous production. Laser treatment of the trabecular meshwork in the anterior chamber angle improves aqueous outflow from the eye. If medical or laser treatments fail to halt optic nerve damage from glaucoma, a filter must be constructed surgically (trabeculectomy) or a valve placed to release aqueous from the eye in a controlled fashion.

FIGURE 29-15 Glaucoma results in "cupping" as the neural rim is destroyed and the central cup becomes enlarged and excavated. The cup-to-disc ratio is about 0.7/1.0 in this patient.

FIGURE 29-16 Age-related macular degeneration begins with the accumulation of drusen within the macula. They appear as scattered yellow subretinal deposits.

Macular Degeneration This is a major cause of gradual, painless, bilateral central visual loss in the elderly. The old term, "senile macular degeneration," misinterpreted by many patients as an unflattering reference, has been replaced with "age-related macular degeneration." It occurs in a nonexudative (dry) form and an exudative (wet) form. Inflammation may be important in both forms of macular degeneration; recent genetic data indicates that susceptibility is associated with variants in the gene for complement factor H, an inhibitor of the alternative complement pathway. The nonexudative process begins with the accumulation of extracellular deposits, called drusen, underneath the retinal pigment epithelium. On ophthalmoscopy, they are pleomorphic but generally appear as small discrete yellow lesions clustered in the macula (Fig. 29-16). With time they become larger, more numerous, and confluent. The retinal pigment epithelium becomes focally detached and atrophic, causing visual loss by interfering with photoreceptor function. Treatment with vitamins C and E, beta carotene, and zinc may retard dry macular degeneration.

Exudative macular degeneration, which develops in only a minority of patients, occurs when neovascular vessels from the choroid grow through defects in Bruch's membrane into the potential space beneath the retinal pigment epithelium. Leakage from these vessels produces elevation of the retina and pigment epithelium, with distortion (metamorphopsia) and blurring of vision. Although onset of these symptoms is usually gradual, bleeding from subretinal choroidal neovascular membranes sometimes causes acute visual loss. The neovascular membranes can be difficult to see on fundus examination because they are beneath the retina. Fluorescein or indocyanine green angiography is extremely useful for their detection. Neovascular membranes are treated with either photodynamic therapy or intraocular injection of vascular endothelial growth factor antagonists. Surgical attempts to remove subretinal membranes in age-related macular degeneration have not improved vision in most patients. However, outcomes have been more encouraging for patients with choroidal neovascular membranes from ocular histoplasmosis syndrome.

Major or repeated hemorrhage under the retina from neovascular membranes results in fibrosis, development of a round (disciform) macular scar, and permanent loss of central vision.

Central Serous Chorioretinopathy This primarily affects males between the ages of 20 and 50. Leakage of serous fluid from the choroid

causes small, localized detachment of the retinal pigment epithelium and the neurosensory retina. These detachments produce acute or chronic symptoms of metamorphopsia and blurred vision when the macula is involved. They are difficult to visualize with a direct ophthalmoscope because the detached retina is transparent and only slightly elevated. Diagnosis of central serous chorioretinopathy is made easily by fluorescein angiography, which shows dye streaming into the subretinal space. The cause of central serous chorioretinopathy is unknown. Symptoms may resolve spontaneously if the retina reattaches, but recurrent detachment is common. Laser photocoagulation has benefited some patients with this condition.

Diabetic Retinopathy A rare disease until 1921, when the discovery of insulin resulted in a dramatic improvement in life expectancy for patients with diabetes mellitus, it is now a leading cause of blindness in the United States. The retinopathy of diabetes takes years to develop but eventually appears in nearly all cases. Regular surveillance of the dilated fundus is crucial for any patient with diabetes. In advanced diabetic retinopathy, the proliferation of neovascular vessels leads to blindness from vitreous hemorrhage, retinal detachment, and glaucoma (see Fig. 338-9). These complications can be avoided in most patients by administration of panretinal laser photocoagulation at the appropriate point in the evolution of the disease. **For further discussion of the manifestations and management of diabetic retinopathy, see Chap. 338.**

Retinitis Pigmentosa This is a general term for a disparate group of rod and cone dystrophies characterized by progressive night blindness, visual field constriction with a ring scotoma, loss of acuity, and an abnormal electroretinogram (ERG). It occurs sporadically or in an autosomal recessive, dominant, or X-linked pattern. Irregular black deposits of clumped pigment in the peripheral retina, called *bone spicules* because of their vague resemblance to the spicules of cancellous bone, give the disease its name (Fig. 29-17). The name is actually a misnomer because retinitis pigmentosa is not an inflammatory process. Most cases are due to a mutation in the gene for rhodopsin, the rod photopigment, or in the gene for peripherin, a glycoprotein located in photoreceptor outer segments. Vitamin A (15,000 IU/day) slightly retards the deterioration of the ERG in patients with retinitis pigmentosa but has no beneficial effect on visual acuity or fields. Some forms of retinitis pigmentosa occur in association with rare, hereditary systemic diseases (olivopontocerebellar degeneration, Bassen-Kornzweig disease, Kearns-Sayre syndrome, Refsum's disease). Chronic treatment with chloroquine, hydroxychloroquine, and phenothiazines (especially thioridazine) can produce visual loss from a toxic retinopathy that resembles retinitis pigmentosa.

Epiretinal Membrane This is a fibrocellular tissue that grows across the inner surface of the retina, causing metamorphopsia and reduced visual acuity from distortion of the macula. A crinkled, cellophane-like membrane is visible on the retinal examination. Epiretinal membrane is most common in patients over 50 years of age and is usually unilateral. Most cases are idiopathic, but some occur as a result of hypertensive retinopathy, diabetes, retinal detachment, or trauma. When visual acuity is reduced to the level of about 6/24 (20/80), vitrectomy and surgical peeling of the membrane to relieve macular puckering are recommended. Contraction of an epiretinal membrane sometimes gives rise to a *macular hole*. Most macular holes, however, are caused by local vitreous traction within the fovea. Vitrectomy can improve acuity in selected cases.

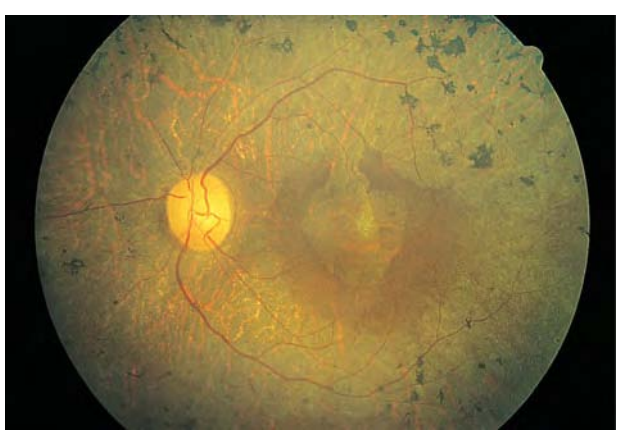

FIGURE 29-17 Retinitis pigmentosa with black clumps of pigment in the retinal periphery known as "bone spicules." There is also atrophy of the retinal pigment epithelium, making the vasculature of the choroid easily visible.

FIGURE 29-18 Melanoma of the choroid, appearing as an elevated dark mass in the inferior temporal fundus, just encroaching upon the fovea.

Melanoma and Other Tumors Melanoma is the most common primary tumor of the eye (Fig. 29-18). It causes photopsia, an enlarging scotoma, and loss of vision. A small melanoma is often difficult to differentiate from a benign choroidal nevus. Serial examinations are required to document a malignant pattern of growth. Treatment of melanoma is controversial. Options include enucleation, local resection, and irradiation. *Metastatic tumors* to the eye outnumber primary tumors. Breast and lung carcinoma have a special propensity to spread to the choroid or iris. Leukemia and lymphoma also commonly invade ocular tissues. Sometimes their only sign on eye examination is cellular debris in the vitreous, which can masquerade as a chronic posterior uveitis. *Retrobulbar tumor* of the optic nerve (meningioma, glioma) or *chiasmal tumor* (pituitary adenoma, meningioma) produces gradual visual loss with few objective findings, except for optic disc pallor. Rarely, sudden expansion of a pituitary adenoma from infarction and bleeding (*pituitary apoplexy*) causes acute retrobulbar visual loss, with headache, nausea, and ocular motor nerve palsies. In any patient with visual field loss or optic atrophy, CT or MR scanning should be considered if the cause remains unknown after careful review of the history and thorough examination of the eye.

PROPTOSIS

When the globes appear asymmetric, the clinician must first decide which eye is abnormal. Is one eye recessed within the orbit (*enophthalmos*) or is the other eye protuberant (*exophthalmos*, or *proptosis*)? A small globe or a Horner's syndrome can give the appearance of enophthalmos. True enophthalmos occurs commonly after trauma, from atrophy of retrobulbar fat, or fracture of the orbital floor. The position of the eyes within the orbits is measured using a Hertel exophthalmometer, a hand-held instrument that records the position of the anterior corneal surface relative to the lateral orbital rim. If this instrument is not available, relative eye position can be judged by bending the patient's head forward and looking down upon the orbits. A proptosis of only 2 mm in one eye is detectable from this perspective. The development of proptosis implies a space-occupying lesion in the orbit, and usually warrants CT or MR imaging.

Graves' Ophthalmopathy This is the leading cause of proptosis in adults (Chap. 335). The proptosis is often asymmetric and can even

appear to be unilateral. Orbital inflammation and engorgement of the extraocular muscles, particularly the medial rectus and the inferior rectus, account for the protrusion of the globe. Corneal exposure, lid retraction, conjunctival injection, restriction of gaze, diplopia, and visual loss from optic nerve compression are cardinal symptoms. Graves' ophthalmopathy is treated with oral prednisone (60 mg/d) for 1 month, followed by a taper over several months, topical lubricants, eyelid surgery, eye muscle surgery, or orbital decompression. Radiation therapy is not effective.

Orbital Pseudotumor This is an idiopathic, inflammatory orbital syndrome, frequently confused with Graves' ophthalmopathy. Symptoms are pain, limited eye movements, proptosis, and congestion. Evaluation for sarcoidosis, Wegener's granulomatosis, and other types of orbital vasculitis or collagen-vascular disease is negative. Imaging often shows swollen eye muscles (orbital myositis) with enlarged tendons. By contrast, in Graves' ophthalmopathy the tendons of the eye muscles are usually spared. The Tolosa-Hunt syndrome may be regarded as an extension of orbital pseudotumor through the superior orbital fissure into the cavernous sinus. The diagnosis of orbital pseudotumor is difficult. Biopsy of the orbit frequently yields nonspecific evidence of fat infiltration by lymphocytes, plasma cells, and eosinophils. A dramatic response to a therapeutic trial of systemic glucocorticoids indirectly provides the best confirmation of the diagnosis.

Orbital Cellulitis This causes pain, lid erythema, proptosis, conjunctival chemosis, restricted motility, decreased acuity, afferent pupillary defect, fever, and leukocytosis. It often arises from the paranasal sinuses, especially by contiguous spread of infection from the ethmoid sinus through the lamina papyracea of the medial orbit. A history of recent upper respiratory tract infection, chronic sinusitis, thick mucous secretions, or dental disease is significant in any patient with suspected orbital cellulitis. Blood cultures should be obtained, but they are usually negative. Most patients respond to empirical therapy with broad-spectrum IV antibiotics. Occasionally, orbital cellulitis follows an overwhelming course, with massive proptosis, blindness, septic cavernous sinus thrombosis, and meningitis. To avert this disaster, orbital cellulitis should be managed aggressively in the early stages, with immediate imaging of the orbits and antibiotic therapy that includes coverage of methicillin-resistant *Staphylococcus aureus*. Prompt surgical drainage of an orbital abscess or paranasal sinusitis is indicated if optic nerve function deteriorates despite antibiotics.

Tumors Tumors of the orbit cause painless, progressive proptosis. The most common primary tumors are hemangioma, lymphangioma, neurofibroma, dermoid cyst, adenoid cystic carcinoma, optic nerve glioma, optic nerve meningioma, and benign mixed tumor of the lacrimal gland. Metastatic tumor to the orbit occurs frequently in breast carcinoma, lung carcinoma, and lymphoma. Diagnosis by fine-needle aspiration followed by urgent radiation therapy can sometimes preserve vision.

Carotid Cavernous Fistulas With anterior drainage through the orbit these produce proptosis, diplopia, glaucoma, and corkscrew, arterialized conjunctival vessels. Direct fistulas usually result from trauma. They are easily diagnosed because of the prominent signs produced by high-flow, high-pressure shunting. Indirect fistulas, or dural arteriovenous malformations, are more likely to occur spontaneously, especially in older women. The signs are more subtle and the diagnosis is frequently missed. The combination of slight proptosis, diplopia, enlarged muscles, and an injected eye is often mistaken for thyroid ophthalmopathy. A bruit heard upon auscultation of the head, or reported by the patient, is a valuable diagnostic clue. Imaging shows an enlarged superior ophthalmic vein in the orbits. Carotid cavernous shunts can be eliminated by intravascular embolization.

PTOSIS

Blepharoptosis This is an abnormal drooping of the eyelid. Unilateral or bilateral ptosis can be congenital, from dysgenesis of the levator palpebrae superioris, or from abnormal insertion of its aponeurosis into the eyelid. Acquired ptosis can develop so gradually that the patient is unaware of the problem. Inspection of old photographs is helpful in dating the onset. A history of prior trauma, eye surgery, contact lens use, diplopia, systemic symptoms (e.g., dysphagia or peripheral muscle weakness), or a family history of ptosis should be sought. Fluctuating ptosis that worsens late in the day is typical of myasthenia gravis. Examination should focus upon evidence for proptosis, eyelid masses or deformities, inflammation, pupil inequality, or limitation of motility. The width of the palpebral fissures is measured in primary gaze to quantitate the degree of ptosis. The ptosis will be underestimated if the patient compensates by lifting the brow with the frontalis muscle.

Mechanical Ptosis This occurs in many elderly patients from stretching and redundancy of eyelid skin and subcutaneous fat (dermatochalasis). The extra weight of these sagging tissues causes the lid to droop. Enlargement or deformation of the eyelid from infection, tumor, trauma, or inflammation also results in ptosis on a purely mechanical basis.

Aponeurotic Ptosis This is an acquired dehiscence or stretching of the aponeurotic tendon, which connects the levator muscle to the tarsal plate of the eyelid. It occurs commonly in older patients, presumably from loss of connective tissue elasticity. Aponeurotic ptosis is also a frequent sequela of eyelid swelling from infection or blunt trauma to the orbit, cataract surgery, or hard contact lens usage.

Myogenic Ptosis The causes of *myogenic ptosis* include myasthenia gravis (Chap. 381) and a number of rare myopathies that manifest with ptosis. The term *chronic progressive external ophthalmoplegia* refers to a spectrum of systemic diseases caused by mutations of mitochondrial DNA. As the name implies, the most prominent findings are symmetric, slowly progressive ptosis and limitation of eye movements. In general, diplopia is a late symptom because all eye movements are reduced equally. In the *Kearns-Sayre* variant, retinal pigmentary changes and abnormalities of cardiac conduction develop. Peripheral muscle biopsy shows characteristic "ragged-red fibers." *Oculopharyngeal dystrophy* is a distinct autosomal dominant disease with onset in middle age, characterized by ptosis, limited eye movements, and trouble swallowing. *Myotonic dystrophy*, another autosomal dominant disorder, causes ptosis, ophthalmoparesis, cataract, and pigmentary retinopathy. Patients have muscle wasting, myotonia, frontal balding, and cardiac abnormalities.

Neurogenic Ptosis This results from a lesion affecting the innervation to either of the two muscles that open the eyelid: Müller's muscle or the levator palpebrae superioris. Examination of the pupil helps to distinguish between these two possibilities. In Horner's syndrome, the eye with ptosis has a smaller pupil and the eye movements are full. In an oculomotor nerve palsy, the eye with the ptosis has a larger, or a normal, pupil. If the pupil is normal but there is limitation of adduction, elevation, and depression, a pupil-sparing oculomotor nerve palsy is likely (see next section). Rarely, a lesion affecting the small, central subnucleus of the oculomotor complex will cause bilateral ptosis with normal eye movements and pupils.

DOUBLE VISION (DIPLOPIA)

The first point to clarify is whether diplopia persists in either eye after covering the opposite eye. If it does, the diagnosis is monocular diplopia. The cause is usually intrinsic to the eye and therefore has no dire implications for the patient. Corneal aberrations (e.g., keratoconus, pterygium), uncorrected refractive error, cataract, or foveal traction may give rise to monocular diplopia. Occasionally it is a symptom of malingering or psychiatric disease. Diplopia alleviated by covering one eye is binocular diplopia and is caused by disruption of ocular alignment. Inquiry should be made into the nature of the double vision (purely side-by-side versus partial vertical displacement of images), mode of onset, duration, intermittency, diurnal variation, and associ-

ated neurologic or systemic symptoms. If the patient has diplopia while being examined, motility testing should reveal a deficiency corresponding to the patient's symptoms. However, subtle limitation of ocular excursions is often difficult to detect. For example, a patient with a slight left abducens nerve paresis may appear to have full eye movements, despite a complaint of horizontal diplopia upon looking to the left. In this situation, the cover test provides a more sensitive method for demonstrating the ocular misalignment. It should be conducted in primary gaze, and then with the head turned and tilted in each direction. In the above example, a cover test with the head turned to the right will maximize the fixation shift evoked by the cover test.

Occasionally, a cover test performed in an asymptomatic patient during a routine examination will reveal an ocular deviation. If the eye movements are full and the ocular misalignment is equal in all directions of gaze (concomitant deviation), the diagnosis is strabismus. In this condition, which affects about 1% of the population, fusion is disrupted in infancy or early childhood. To avoid diplopia, vision is suppressed from the nonfixating eye. In some children, this leads to impaired vision (amblyopia, or "lazy" eye) in the deviated eye.

Binocular diplopia occurs from a wide range of processes: infectious, neoplastic, metabolic, degenerative, inflammatory, and vascular. One must decide if the diplopia is neurogenic in origin or due to restriction of globe rotation by local disease in the orbit. Orbital pseudotumor, myositis, infection, tumor, thyroid disease, and muscle entrapment (e.g., from a blowout fracture) cause restrictive diplopia. The diagnosis of restriction is usually made by recognizing other associated signs and symptoms of local orbital disease in conjunction with imaging.

Myasthenia Gravis (See also Chap. 381) This is a major cause of diplopia. The diplopia is often intermittent, variable, and not confined to any single ocular motor nerve distribution. The pupils are always normal. Fluctuating ptosis may be present. Many patients have a purely ocular form of the disease, with no evidence of systemic muscular weakness. The diagnosis can be confirmed by an IV edrophonium injection or by an assay for antiacetylcholine receptor antibodies. Negative results from these tests do not exclude the diagnosis. *Botulism* from food or wound poisoning can mimic ocular myasthenia.

After restrictive orbital disease and myasthenia gravis are excluded, a lesion of a cranial nerve supplying innervation to the extraocular muscles is the most likely cause of binocular diplopia.

Oculomotor Nerve The third cranial nerve innervates the medial, inferior, and superior recti; inferior oblique; levator palpebrae superioris; and the iris sphincter. Total palsy of the oculomotor nerve causes ptosis, a dilated pupil, and leaves the eye "down and out" because of the unopposed action of the lateral rectus and superior oblique. This combination of findings is obvious. More challenging is the diagnosis of early or partial oculomotor nerve palsy. In this setting, any combination of ptosis, pupil dilation, and weakness of the eye muscles supplied by the oculomotor nerve may be encountered. Frequent serial examinations during the evolving phase of the palsy help ensure that the diagnosis is not missed. The advent of an oculomotor nerve palsy with a pupil involvement, especially when accompanied by pain, suggests a compressive lesion, such as a tumor or circle of Willis aneurysm. Neuroimaging should be obtained, along with a CT or MR angiogram. Occasionally, a catheter arteriogram must be done to exclude an aneurysm.

A lesion of the oculomotor nucleus in the rostral midbrain produces signs that differ from those caused by a lesion of the nerve itself. There is bilateral ptosis because the levator muscle is innervated by a single central subnucleus. There is also weakness of the contralateral superior rectus, because it is supplied by the oculomotor nucleus on the other side. Occasionally both superior recti are weak. Isolated nuclear oculomotor palsy is rare. Usually neurologic examination reveals additional signs to suggest brainstem damage from infarction, hemorrhage, tumor, or infection.

Injury to structures surrounding fascicles of the oculomotor nerve descending through the midbrain has given rise to a number of classic eponymic designations. In *Nothnagel's syndrome*, injury to the superior cerebellar peduncle causes ipsilateral oculomotor palsy and contralateral cerebellar ataxia. In *Benedikt's syndrome*, injury to the red nucleus results in ipsilateral oculomotor palsy and contralateral tremor, chorea, and athetosis. *Claude's syndrome* incorporates features of both the aforementioned syndromes, by injury to both the red nucleus and the superior cerebellar peduncle. Finally, in *Weber's syndrome*, injury to the cerebral peduncle causes ipsilateral oculomotor palsy with contralateral hemiparesis.

In the subarachnoid space the oculomotor nerve is vulnerable to aneurysm, meningitis, tumor, infarction, and compression. In cerebral herniation the nerve becomes trapped between the edge of the tentorium and the uncus of the temporal lobe. Oculomotor palsy can also occur from midbrain torsion and hemorrhages during herniation. In the cavernous sinus, oculomotor palsy arises from carotid aneurysm, carotid cavernous fistula, cavernous sinus thrombosis, tumor (pituitary adenoma, meningioma, metastasis), herpes zoster infection, and the Tolosa-Hunt syndrome.

The etiology of an isolated, pupil-sparing oculomotor palsy often remains an enigma, even after neuroimaging and extensive laboratory testing. Most cases are thought to result from microvascular infarction of the nerve, somewhere along its course from the brainstem to the orbit. Usually the patient complains of pain. Diabetes, hypertension, and vascular disease are major risk factors. Spontaneous recovery over a period of months is the rule. If this fails to occur, or if new findings develop, the diagnosis of microvascular oculomotor nerve palsy should be reconsidered. Aberrant regeneration is common when the oculomotor nerve is injured by trauma or compression (tumor, aneurysm). Miswiring of sprouting fibers to the levator muscle and the rectus muscles results in elevation of the eyelid upon downgaze or adduction. The pupil also constricts upon attempted adduction, elevation, or depression of the globe. Aberrant regeneration is not seen after oculomotor palsy from microvascular infarct and hence vitiates that diagnosis.

Trochlear Nerve The fourth cranial nerve originates in the midbrain, just caudal to the oculomotor nerve complex. Fibers exit the brainstem dorsally and cross to innervate the contralateral superior oblique. The principal actions of this muscle are to depress and to intort the globe. A palsy therefore results in hypertropia and excyclotorsion. The cyclotorsion is seldom noticed by patients. Instead, they complain of vertical diplopia, especially upon reading or looking down. The vertical diplopia is also exacerbated by tilting the head toward the side with the muscle palsy, and alleviated by tilting it away. This "head tilt test" is a cardinal diagnostic feature.

Isolated trochlear nerve palsy occurs from all the causes listed above for the oculomotor nerve, except aneurysm. The trochlear nerve is particularly apt to suffer injury after closed head trauma. The free edge of the tentorium is thought to impinge upon the nerve during a concussive blow. Most isolated trochlear nerve palsies are idiopathic and hence diagnosed by exclusion as "microvascular." Spontaneous improvement occurs over a period of months in most patients. A base-down prism (conveniently applied to the patient's glasses as a stick-on Fresnel lens) may serve as a temporary measure to alleviate diplopia. If the palsy does not resolve, the eyes can be realigned by weakening the inferior oblique muscle.

Abducens Nerve The sixth cranial nerve innervates the lateral rectus muscle. A palsy produces horizontal diplopia, worse on gaze to the side of the lesion. A nuclear lesion has different consequences, because the abducens nucleus contains interneurons that project via the medial longitudinal fasciculus to the medial rectus subnucleus of the contralateral oculomotor complex. Therefore, an abducens nuclear lesion produces a complete lateral gaze palsy, from weakness of both the ipsilateral lateral rectus and the contralateral medial rectus. *Foville's syndrome* following dorsal pontine injury includes lateral gaze palsy, ipsilateral facial palsy, and contralateral hemiparesis incurred by damage to descending corticospinal fibers. *Millard-*

Gubler syndrome from ventral pontine injury is similar, except for the eye findings. There is lateral rectus weakness only, instead of gaze palsy, because the abducens fascicle is injured rather than the nucleus. Infarct, tumor, hemorrhage, vascular malformation, and multiple sclerosis are the most common etiologies of brainstem abducens palsy.

After leaving the ventral pons, the abducens nerve runs forward along the clivus to pierce the dura at the petrous apex, where it enters the cavernous sinus. Along its subarachnoid course it is susceptible to meningitis, tumor (meningioma, chordoma, carcinomatous meningitis), subarachnoid hemorrhage, trauma, and compression by aneurysm or dolichoectatic vessels. At the petrous apex, mastoiditis can produce deafness, pain, and ipsilateral abducens palsy (*Gradenigo's syndrome*). In the cavernous sinus, the nerve can be affected by carotid aneurysm, carotid cavernous fistula, tumor (pituitary adenoma, meningioma, nasopharyngeal carcinoma), herpes infection, and Tolosa-Hunt syndrome.

Unilateral or bilateral abducens palsy is a classic sign of raised intracranial pressure. The diagnosis can be confirmed if papilledema is observed on fundus examination. The mechanism is still debated but is probably related to rostral-caudal displacement of the brainstem. The same phenomenon accounts for abducens palsy from low intracranial pressure (e.g., after lumbar puncture, spinal anesthesia, or spontaneous dural cerebrospinal fluid leak).

Treatment of abducens palsy is aimed at prompt correction of the underlying cause. However, the cause remains obscure in many instances, despite diligent evaluation. As mentioned above for isolated trochlear or oculomotor palsy, most cases are assumed to represent microvascular infarcts because they often occur in the setting of diabetes or other vascular risk factors. Some cases may develop as a postinfectious mononeuritis (e.g., following a viral flu). Patching one eye or applying a temporary prism will provide relief of diplopia until the palsy resolves. If recovery is incomplete, eye muscle surgery can nearly always realign the eyes, at least in primary position. A patient with an abducens palsy that fails to improve should be reevaluated for an occult etiology (e.g., chordoma, carcinomatous meningitis, carotid cavernous fistula, myasthenia gravis).

Multiple Ocular Motor Nerve Palsies These should not be attributed to spontaneous microvascular events affecting more than one cranial nerve at a time. This remarkable coincidence does occur, especially in diabetic patients, but the diagnosis is made only in retrospect after exhausting all other diagnostic alternatives. Neuroimaging should focus on the cavernous sinus, superior orbital fissure, and orbital apex, where all three ocular motor nerves are in close proximity. In the diabetic or compromised host, fungal infection (*Aspergillus*, Mucorales, *Cryptococcus*) is a frequent cause of multiple nerve palsies. In the patient with systemic malignancy, carcinomatous meningitis is a likely diagnosis. Cytologic examination may be negative despite repeated sampling of the cerebrospinal fluid. The cancer-associated Lambert-Eaton myasthenic syndrome can also produce ophthalmoplegia. Giant cell (temporal) arteritis occasionally manifests as diplopia from ischemic palsies of extraocular muscles. Fisher syndrome, an ocular variant of Guillain-Barré, produces ophthalmoplegia with areflexia and ataxia. Often the ataxia is mild, and the reflexes are normal. Antiganglioside antibodies (GQ1b) can be detected in about 50% of cases.

Supranuclear Disorders of Gaze These are often mistaken for multiple ocular motor nerve palsies. For example, Wernicke's encephalopathy can produce nystagmus and a partial deficit of horizontal and vertical gaze that mimics a combined abducens and oculomotor nerve palsy. The disorder occurs in malnourished or alcoholic patients and can be reversed by thiamine. Infarct, hemorrhage, tumor, multiple sclerosis, encephalitis, vasculitis, and Whipple's disease are other important causes of supranuclear gaze palsy. Disorders of vertical gaze, especially downwards saccades, are an early feature of progressive supranuclear palsy. Smooth pursuit is affected later in the course of the disease. Parkinson's disease, Huntington's chorea, and olivopontocerebellar degeneration can also affect vertical gaze.

The *frontal eye field* of the cerebral cortex is involved in generation of saccades to the contralateral side. After hemispheric stroke, the eyes usually deviate towards the lesioned side because of the unopposed action of the frontal eye field in the normal hemisphere. With time, this deficit resolves. Seizures generally have the opposite effect: the eyes deviate conjugately away from the irritative focus. *Parietal lesions* disrupt smooth pursuit of targets moving toward the side of the lesion. Bilateral parietal lesions produce *Balint's syndrome*, characterized by impaired eye-hand coordination (optic ataxia), difficulty initiating voluntary eye movements (ocular apraxia), and visuospatial disorientation (simultanagnosia).

Horizontal Gaze Descending cortical inputs mediating horizontal gaze ultimately converge at the level of the pons. Neurons in the paramedian pontine reticular formation are responsible for controlling conjugate gaze toward the same side. They project directly to the ipsilateral abducens nucleus. A lesion of either the paramedian pontine reticular formation or the abducens nucleus causes an ipsilateral conjugate gaze palsy. Lesions at either locus produce nearly identical clinical syndromes, with the following exception: vestibular stimulation (oculocephalic maneuver or caloric irrigation) will succeed in driving the eyes conjugately to the side in a patient with a lesion of the paramedian pontine reticular formation, but not in a patient with a lesion of the abducens nucleus.

INTERNUCLEAR OPHTHALMOPLEGIA This results from damage to the medial longitudinal fasciculus ascending from the abducens nucleus in the pons to the oculomotor nucleus in the midbrain (hence, "internuclear"). Damage to fibers carrying the conjugate signal from abducens interneurons to the contralateral medial rectus motoneurons results in a failure of adduction on attempted lateral gaze. For example, a patient with a left internuclear ophthalmoplegia will have slowed or absent adducting movements of the left eye (Fig. 29-19). A patient with bilateral injury to the medial longitudinal fasciculus will have bilateral internuclear ophthalmoplegia. Multiple sclerosis is the most common cause, although tumor, stroke, trauma, or any brainstem process may be responsible. *One-and-a-half syndrome* is due to a combined lesion of the medial longitudinal fasciculus and the abducens nucleus on the same side. The patient's only horizontal eye movement is abduction of the eye on the other side.

Vertical Gaze This is controlled at the level of the midbrain. The neuronal circuits affected in disorders of vertical gaze are not fully elucidated, but lesions of the rostral interstitial nucleus of the medial longitudinal fasciculus and the interstitial nucleus of Cajal cause supranuclear paresis of upgaze, downgaze, or all vertical eye movements. Distal basilar artery ischemia is the most common etiology. *Skew deviation* refers to a vertical misalignment of the eyes, usually constant in all positions of gaze. The finding has poor localizing value because skew deviation has been reported after lesions in widespread regions of the brainstem and cerebellum.

PARINAUD'S SYNDROME Also known as dorsal midbrain syndrome, this is a distinct supranuclear vertical gaze disorder from damage to the posterior commissure. It is a classic sign of hydrocephalus from aqueductal stenosis. Pineal region tumors, cysticercosis, and stroke also cause Parinaud's syndrome. Features include loss of upgaze (and sometimes downgaze), convergence-retraction nystagmus on attempted upgaze, downwards ocular deviation ("setting sun" sign), lid retraction (Collier's sign), skew deviation, pseudoabducens palsy, and light-near dissociation of the pupils.

Nystagmus This is a rhythmical oscillation of the eyes, occurring physiologically from vestibular and optokinetic stimulation or pathologically in a wide variety of diseases (Chap. 22). Abnormalities of the eyes or optic nerves, present at birth or acquired in childhood, can

FIGURE 29-19 Left internuclear ophthalmoplegia (INO). *A.* In primary position of gaze the eyes appear normal. ***B.*** Horizontal gaze to the left is intact. ***C.*** On attempted horizontal gaze to the right, the left eye fails to adduct. In mildly affected patients the eye may adduct partially, or more slowly than normal. Nystagmus is usually present in the abducted eye. ***D.*** T2-weighted axial MRI image through the pons showing a demyelinating plaque in the left medial longitudinal fasciculus (*arrow*).

produce a complex, searching nystagmus with irregular pendular (sinusoidal) and jerk features. This nystagmus is commonly referred to as *congenital sensory nystagmus*. It is a poor term, because even in children with congenital lesions, the nystagmus does not appear until several months of age. *Congenital motor nystagmus*, which looks similar to congenital sensory nystagmus, develops in the absence of any abnormality of the sensory visual system. Visual acuity is also reduced in congenital motor nystagmus, probably by the nystagmus itself, but seldom below a level of 20/200.

JERK NYSTAGMUS This is characterized by a slow drift off the target, followed by a fast corrective saccade. By convention, the nystagmus is named after the quick phase. Jerk nystagmus can be downbeat, upbeat, horizontal (left or right), and torsional. The pattern of nystagmus may vary with gaze position. Some patients will be oblivious to their nystagmus. Others will complain of blurred vision, or a subjective, to-and-fro movement of the environment (oscillopsia) corresponding to their nystagmus. Fine nystagmus may be difficult to see upon gross examination of the eyes. Observation of nystagmoid movements of the optic disc on ophthalmoscopy is a sensitive way to detect subtle nystagmus.

GAZE-EVOKED NYSTAGMUS This is the most common form of jerk nystagmus. When the eyes are held eccentrically in the orbits, they have a natural tendency to drift back to primary position. The subject compensates by making a corrective saccade to maintain the deviated eye position. Many normal patients have mild gaze-evoked nystagmus. Exaggerated gaze-evoked nystagmus can be induced by drugs (sedatives, anticonvulsants, alcohol); muscle paresis; myasthenia gravis; demyelinating disease; and cerebellopontine angle, brainstem, and cerebellar lesions.

VESTIBULAR NYSTAGMUS *Vestibular nystagmus* results from dysfunction of the labyrinth (Ménière's disease), vestibular nerve, or vestibular nucleus in the brainstem. Peripheral vestibular nystagmus often occurs in discrete attacks, with symptoms of nausea and vertigo. There may be associated tinnitus and hearing loss. Sudden shifts in head position may provoke or exacerbate symptoms.

DOWNBEAT NYSTAGMUS *Downbeat nystagmus* occurs from lesions near the craniocervical junction (Chiari malformation, basilar invagination). It has also been reported in brainstem or cerebellar stroke, lithium or anticonvulsant intoxication, alcoholism, and multiple sclerosis. *Upbeat nystagmus* is associated with damage to the pontine tegmentum, from stroke, demyelination, or tumor.

Opsoclonus This rare, dramatic disorder of eye movements consists of bursts of consecutive saccades (saccadomania). When the saccades are confined to the horizontal plane, the term *ocular flutter* is preferred. It can occur from viral encephalitis, trauma, or a paraneoplastic effect of neuroblastoma, breast carcinoma, and other malignancies. It has also been reported as a benign, transient phenomenon in otherwise healthy patients.

30 Disorders of Smell, Taste, and Hearing

Anil K. Lalwani

SMELL

The sense of smell determines the flavor and palatability of food and drink and serves, along with the trigeminal system, as a monitor of inhaled chemicals, including dangerous substances such as natural gas, smoke, and air pollutants. Olfactory dysfunction affects ~1% of people under age 60 and more than half of the population beyond this age.

DEFINITIONS

Smell is the perception of odor by the nose. *Taste* is the perception of salty, sweet, sour, or bitter by the tongue. Related sensations during eating such as somatic sensations of coolness, warmth, and irritation are mediated through the trigeminal, glossopharyngeal, and vagal afferents in the nose, oral cavity, tongue, pharynx, and larynx. *Flavor* is the complex interaction of taste, smell, and somatic sensation. Terms relating to disorders of smell include *anosmia*, an absence of the ability to smell; *hyposmia*, a decreased ability to smell; *hyperosmia*, an increased sensitivity to an odorant; *dysosmia*, distortion in the perception of an odor; *phantosmia*, perception of an odorant where none is present; and *agnosia*, inability to classify, contrast, or identify odor sensations verbally, even though the ability to distinguish between odorants or to recognize them may be normal. An odor stimulus is referred to as an *odorant*. Each category of smell dysfunction can be further subclassified as total (applying to all odorants) or partial (dysfunction of only select odorants).

PHYSIOLOGY OF SMELL

The *olfactory epithelium* is located in the superior part of the nasal cavities and is highly variable in its distribution between individuals. Over time the olfactory epithelium loses its homogeneity, as small areas undergo metaplasia producing islands of respiratory-like epithelium. This process is thought to be secondary to insults from environmental toxins, bacteria, and viruses. The primary sensory neuron in the olfactory epithelium is the bipolar cell. The dendritic process of the bipolar cell has a bulb-shaped vesicle that projects into the mucous layer and bears six to eight cilia containing odorant receptors. On average, each bipolar cell elaborates 56 cm^2 (9 $in.^2$) of surface area to receive olfactory stimuli. These primary sensory neurons are unique among sensory systems in that they are short-lived, regularly replaced, and regenerate and establish new central connections after injury. Basal stem cells, located on the basal surface of the olfactory epithelium, are the progenitors that differentiate into new bipolar cells (Fig. 30-1).

Between 50 and 200 unmyelinated axons of receptor cells form the fila of the olfactory nerve; they pass through the cribriform plate to terminate within spherical masses of neuropil, termed *glomeruli*, in the olfactory bulb. Olfactory ensheathing cells, which have features resembling glia of both the central and peripheral nervous systems, surround the axons along their course. The glomeruli are the focus of a high degree of convergence of information, since many more fibers enter than leave them. The main second-order neurons are mitral cells. The primary dendrite of each mitral cell extends into a single glomerulus. Axons of the mitral cells project along with the axons of adjacent tufted cells to the limbic system, including the anterior olfactory nucleus and the amygdala. Cognitive awareness of smell requires stimulation of the prepiriform cortex or amygdaloid nuclei.

A secondary site of olfactory chemosensation is located in the epithelium of the vomeronasal organ, a tubular structure that opens on the ventral aspect of the nasal septum. In humans, this structure is rudimentary and nonfunctional, without central projections. Sensory neurons located in the vomeronasal organ detect pheromones, nonvolatile chemical signals that in lower mammals trigger innate and stereotyped reproductive and social behaviors, as well as neuroendocrine changes.

The sensation of smell begins with introduction of an odorant to the cilia of the bipolar neuron. Most odorants are hydrophobic; as they move from the air phase of the nasal cavity to the aqueous phase of the olfactory mucous, they are transported toward the cilia by small water-soluble proteins called *odorant-binding proteins* and reversibly bind to receptors on the cilia surface. Binding leads to conformational changes in the receptor protein, activation of G protein–coupled second messengers, and generation of action potentials in the primary neurons. Intensity appears to be coded by the amount of firing in the afferent neurons.

Olfactory receptor proteins belong to the large family of G protein–coupled receptors that also includes rhodopsins; α- and β-adrenergic receptors; muscarinic acetylcholine receptors; and neurotransmitter receptors for dopamine, serotonin, and substance P. In humans, there are 300–1000 olfactory receptor genes belonging to 20 different families located in clusters at >25 different chromosomal locations. Each olfactory neuron expresses only one or, at most, a few receptor genes, thus providing the molecular basis of odor discrimination. Bipolar cells that express similar receptors appear to be scattered across discrete spatial zones. These similar cells converge on a select few glomeruli in the olfactory bulb. The result is a potential spatial map of how we receive odor stimuli, much like the tonotopic organization of how we perceive sound.

DISORDERS OF THE SENSE OF SMELL

These are caused by conditions that interfere with the access of the odorant to the olfactory neuroepithelium (transport loss), injure the receptor region (sensory loss), or damage central olfactory pathways (neural loss). Currently no clinical tests exist to differentiate these different types of olfactory losses. Fortunately, the history of the disease provides important clues to the cause. The leading causes of olfactory disorders are summarized in Table 30-1; the most common etiologies are head trauma in children and young adults, and viral infections in older adults.

Head trauma is followed by unilateral or bilateral impairment of smell in up to 15% of cases; anosmia is more common than hyposmia. Olfactory dysfunction is more common when trauma is associated with loss of consciousness, moderately severe head injury (grades II–

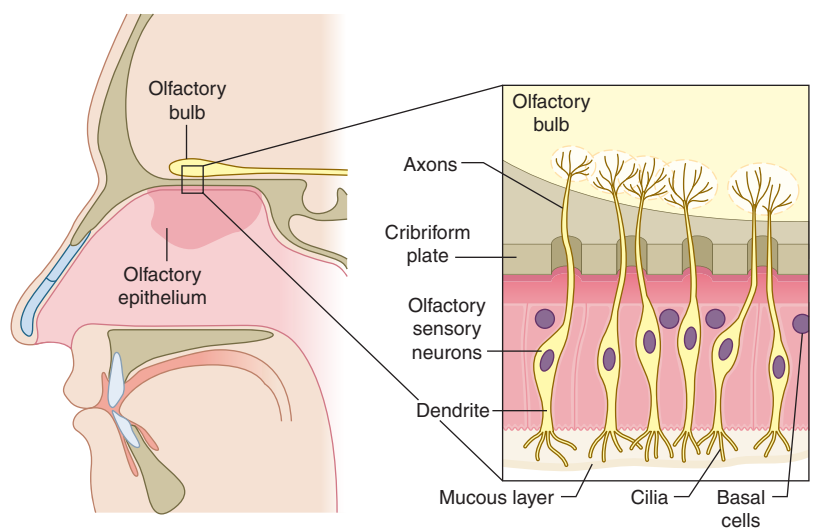

FIGURE 30-1 Olfaction. Olfactory sensory neurons (bipolar cells) are embedded in a small area of specialized epithelium in the dorsal posterior recess of the nasal cavity. These neurons project axons to the olfactory bulb of the brain, a small ovoid structure that rests on the cribriform plate of the ethmoid bone. Odorants bind to specific receptors on olfactory cilia and initiate a cascade of action potential events that lead to the production of action potentials in the sensory axons.

TABLE 30-1 CAUSES OF OLFACTORY DYSFUNCTION

Transport Losses	Neural Losses
Allergic rhinitis	AIDS
Bacterial rhinitis and sinusitis	Alcoholism
Congenital abnormalities	Alzheimer's disease
Nasal neoplasms	Cigarette smoke
Nasal polyps	Depression
Nasal septal deviation	Diabetes mellitus
Nasal surgery	Drugs/toxins
Viral infections	Huntington's chorea
Sensory Losses	Hypothyroidism
Drugs	Kallmann syndrome
Neoplasms	Malnutrition
Radiation therapy	Neoplasms
Toxin exposure	Neurosurgery
Viral infections	Parkinson's disease
	Trauma
	Vitamin B_{12} deficiency
	Zinc deficiency

V), and skull fracture. Frontal injuries and fractures disrupt the cribriform plate and olfactory axons that perforate it. Sometimes there is an associated cerebrospinal fluid (CSF) rhinorrhea resulting from a tearing of the dura overlying the cribriform plate and paranasal sinuses. Anosmia may also follow blows to the occiput. Once traumatic anosmia develops, it is usually permanent; only 10% of patients ever improve or recover. Perversion of the sense of smell may occur as a transient phase in the recovery process.

Viral infections can destroy the olfactory neuroepithelium, which is then replaced by respiratory epithelium. Parainfluenza virus type 3 appears to be especially detrimental to human olfaction. HIV infection is associated with subjective distortion of taste and smell, which may become more severe as the disease progresses. The loss of taste and smell may play an important role in the development and progression of HIV-associated wasting. Congenital anosmias are rare but important. Kallmann syndrome is an X-linked disorder characterized by congenital anosmia and hypogonadotropic hypogonadism resulting from a failure of migration from the olfactory placode of olfactory receptor neurons and neurons synthesizing gonadotropin-releasing hormone (Chap. 340). Anosmia can also occur in albinos. The receptor cells are present but are hypoplastic, lack cilia, and do not project above the surrounding supporting cells.

Meningiomas of the inferior frontal region are the most frequent neoplastic cause of anosmia; loss of smell may be the only neurologic abnormality. Rarely, anosmia can occur with gliomas of the frontal lobe. Occasionally, pituitary adenomas, craniopharyngiomas, suprasellar meningiomas, and aneurysms of the anterior part of the circle of Willis extend forward and damage olfactory structures. These tumors and hamartomas may also induce seizures with olfactory hallucinations, indicating involvement of the uncus of the temporal lobe.

Olfactory dysfunction is common in a variety of neurologic diseases, including Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, and multiple sclerosis. In Alzheimer's and Parkinson's, olfactory loss may be the first clinical sign of the disease. In Parkinson's disease, bilateral olfactory deficits occur more commonly than the cardinal signs of the disorder such as tremor. In multiple sclerosis, olfactory loss is related to lesions visible by MRI, in olfactory processing areas in the temporal and frontal lobes.

Dysosmia, subjective distortions of olfactory perception, may occur with intranasal diseases that partially impair smell or during recovery from a neurogenic anosmia. Most dysosmic disorders consist of disagreeable odors, sometimes accompanied by distortions of taste. Dysosmia also can occur with depression.

APPROACH TO THE PATIENT: Disorders of the Sense of Smell

Unilateral anosmia is rarely a complaint and is only recognized by testing of smell in each nasal cavity separately. Bilateral anosmia, on the other hand, brings patients to medical attention. Anosmic patients usually complain of a loss of the sense of taste even though their taste thresholds may be within normal limits. In actuality, they are complaining of a loss of flavor detection, which is mainly an olfactory function. The physical examination should include a thorough inspection of the ears, upper respiratory tract, and head and neck. A neurologic examination emphasizing the cranial nerves and cerebellar and sensorimotor function is essential. Any signs of depression should be noted.

Sensory olfactory function can be assessed by several methods. The Odor Stix test uses a commercially available odor-producing magic marker–like pen held approximately 8–15 cm (3–6 in.) from the patient's nose. The 30-cm alcohol test uses a freshly opened isopropyl alcohol packet held ~30 cm (12 in.) from the patient's nose. There is a commercially available scratch-and-sniff card containing three odors available for gross testing of olfaction. A superior test is the University of Pennsylvania Smell Identification Test (UPSIT). This consists of a 40-item, forced choice, scratch-and-sniff paradigm. For example, one of the items reads, "This odor smells most like (a) chocolate, (b) banana, (c) onion, or (d) fruit punch." The test is highly reliable, is sensitive to age and sex differences, and provides an accurate quantitative determination of the olfactory deficit. The UPSIT, which is a forced-choice test, can also be used to identify malingerers who typically report fewer correct responses than would be expected by chance. The average score for total anosmics is slightly higher than that expected on the basis of chance because of the inclusion of some odorants that act by trigeminal stimulation.

Olfactory threshold testing is another method of assessing olfactory function. Following assessment of sensory olfactory function, the detection threshold for an odorant such as methyl ethyl carbinol is established using graduated concentrations for each side of the nose. Nasal resistance can also be measured with anterior rhinomanometry for each side of the nose.

CT or MRI of the head is required to rule out paranasal sinusitis; neoplasms of the anterior cranial fossa, nasal cavity, or paranasal sinuses; or unsuspected fractures of the anterior cranial fossa. Bone abnormalities are best seen with CT. MRI is the most sensitive method to visualize olfactory bulbs, ventricles, and other soft tissue of the brain. Coronal CT is optimal for assessing cribriform plate, anterior cranial fossa, and sinus anatomy.

Biopsy of the olfactory epithelium is possible. However, given the widespread degeneration of the olfactory epithelium and intercalation of respiratory epithelium in the olfactory area of adults with no apparent olfactory dysfunction, biopsy results must be interpreted with caution.

℞ DISORDERS OF THE SENSE OF SMELL

Therapy for patients with transport olfactory losses due to allergic rhinitis, bacterial rhinitis and sinusitis, polyps, neoplasms, and structural abnormalities of the nasal cavities can be undertaken with a high likelihood for improvement. Allergy management; antibiotic therapy; topical and systemic glucocorticoid therapy; and surgery for nasal polyps, deviation of the nasal septum, and chronic hyperplastic sinusitis are frequently effective in restoring the sense of smell.

There is no proven treatment for sensorineural olfactory losses. Fortunately, spontaneous recovery often occurs. Zinc and vitamin therapy (especially with vitamin A) are advocated by some. Profound zinc deficiency can produce loss and distortion of the sense of smell but is not a clinically important problem except in very limited geographic areas (Chap. 71). The epithelial degeneration associated with vitamin A deficiency can cause anosmia, but in western societies the prevalence of vitamin A deficiency is low. Exposure to cigarette smoke and other airborne toxic chemicals can cause metaplasia of the olfactory epithelium, and spontaneous recovery can occur if the insult is removed. Counseling of patients is therefore helpful in such cases.

More than half of people over age 60 suffer from olfactory dysfunction. No effective treatment exists for presbyosmia, but patients are often reassured to learn that this problem is common in their age group. In addition, early recognition and counseling can help patients to compensate for the loss of smell. The incidence of natural gas–related accidents is disproportionately high in the elderly, perhaps due in part to the gradual loss of

smell. Mercaptan, the pungent odor in natural gas, is an olfactory stimulant that does not activate taste receptors. Many elderly with olfactory dysfunction experience a decrease in flavor sensation and find it necessary to hyperflavor food, usually by increasing the amount of salt in their diet.

TASTE

Compared with disorders of smell, gustatory disorders are uncommon. Loss of olfactory sensitivity is often accompanied by complaints of loss of the sense of taste, usually with normal detection thresholds for taste.

DEFINITIONS

Disturbances of the sense of taste may be categorized as *total ageusia*, total absence of gustatory function or inability to detect the qualities of sweet, salt, bitter, or sour; *partial ageusia*, ability to detect some but not all of the qualitative gustatory sensations; *specific ageusia*, inability to detect the taste quality of certain substances; *total hypogeusia*, decreased sensitivity to all tastants; *partial hypogeusia*, decreased sensitivity to some tastants; and *dysgeusia* or *phantogeusia*, distortion in the perception of a tastant, i.e., the perception of the wrong quality when a tastant is presented or the perception of a taste when there has been no tastant ingested. Confusion between sour and bitter, and less commonly between salty and bitter, may represent a semantic misunderstanding or have a true pathophysiologic basis. It may be possible to differentiate between the loss of flavor recognition in patients with olfactory losses who complain of a loss of taste as well as smell by asking if they are able to taste sweetness in sodas, saltiness in potato chips, etc.

PHYSIOLOGY OF TASTE

The taste receptor cells are located in the taste buds, spherical groups of cells arranged in a pattern resembling the segments of a citrus fruit (Fig. 30-2). At the surface, the taste bud has a pore into which microvilli of the receptor cells project. Unlike the olfactory system, the receptor cell is not the primary neuron. Instead, gustatory afferent nerve fibers contact individual taste receptor cells. The papillae lie along the lateral margin and dorsum of the tongue; at the junction of the dorsum and the base of the tongue; and in the palate, epiglottis, larynx, and esophagus.

Tastants gain access to the receptor cells through the taste pore. Four classes of taste have been traditionally recognized: sweet, salt, sour, and bitter, and more recently "umami" (monosodium glutamate, disodium gluanylate, disodium inosinate). Tastants enter the taste pore in a solution and initiate transduction by either activating receptors coupled to G-proteins or by directly activating ion channels on the microvillae within the taste bud. Individual gustatory afferent fibers almost always respond to a number of different chemicals. As with olfaction and other sensory systems, intensity appears to be encoded by the quantity of neural activity.

The sense of taste is mediated through the facial, glossopharyngeal, and vagal nerves. The chorda tympani branch of the facial nerve subserves taste from the anterior two-thirds of the tongue. The posterior third of the tongue is supplied by the lingual branch of the glossopharyngeal nerve. Afferents from the palate travel with the greater superficial petrosal nerve to the geniculate ganglion and then via the facial nerve to the brainstem. The internal branch of the superior laryngeal nerve of the vagus nerve contains the taste afferents from the larynx, including the epiglottis and esophagus.

The central connections of the nerves terminate in the brainstem in the nucleus of the tractus solitarius. The central pathway from the nucleus of the tractus solitarius projects to the ipsilateral parabrachial nuclei of the pons. Two divergent pathways project from the parabrachial nuclei. One ascends to the gustatory relay in the dorsal thalamus, synapses, and continues to the cortex of the insula. There is also evidence for a direct pathway from the parabrachial nuclei to the cortex. (Olfaction and gustation appear to be unique among sensory systems in that at least some fibers bypass the thalamus.) The other pathway from the parabrachial nuclei goes to the ventral forebrain, including the lateral hypothalamus, substantia innominata, central nucleus of the amygdala, and the stria terminalis.

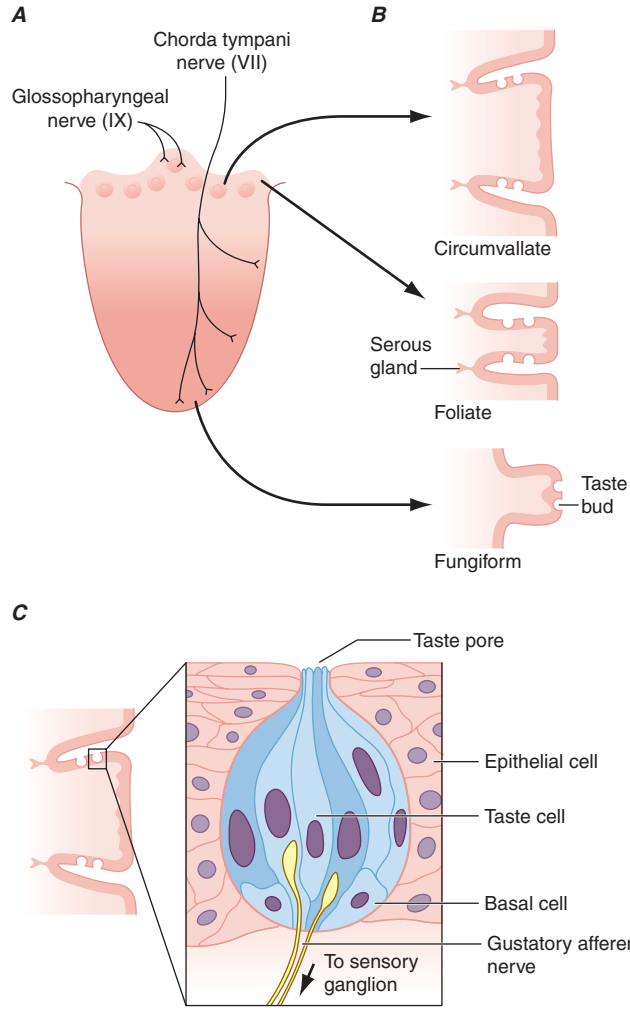

FIGURE 30-2 Taste. *A.* The taste buds of the anterior two-thirds of the tongue are innervated by the gustatory fibers that travel in a branch of the facial nerve (VII) called the chorda tympani. The taste buds of the posterior third of the tongue are innervated by gustatory fibers that travel in the lingual branch of the glossopharyngeal nerve (IX). *[Adapted from ER Kandel et al (eds): Principles of Neural Science, 4th ed, New York, McGraw-Hill, 2000; with permission.]* ***B.*** The main types of taste papillae are shown in schematic cross sections. Each type predominates in specific areas of the tongue, as indicated by the arrows from ***A. C.*** Each taste bud contains 50–150 taste cells that extend from the base of the taste bud to the taste pore, where the apical microvilli of taste cells have contact with tastants dissolved in saliva and taste pore mucus. Access of tastants to the basolateral regions of these cells is generally prevented by tight junctions between taste cells. Taste cells are short-lived cells that are replaced from stem cells at the base of the taste bud. Three types of taste cells in each taste bud (light cells, dark cells, and intermediate cells) may represent different stages of differentiation or different cell lineages. Taste stimuli, detected at the apical end of the taste cell, induce action potentials that cause the release of neurotransmitter at synapses formed at the base of the taste cell with gustatory fibers that transmit signals to the brain.

DISORDERS OF THE SENSE OF TASTE

Disorders of the sense of taste are caused by conditions that interfere with the access of the tastant to the receptor cells in the taste bud (transport loss), injure receptor cells (sensory loss), or damage gustatory afferent nerves and central gustatory pathways (neural loss) (Table 30-2). *Transport gustatory losses* result from xerostomia due to many causes, including Sjögren's syndrome, radiation therapy, heavy-metal intoxication, and bacterial colonization of the taste pore. *Sensory gustatory losses* are caused by inflammatory and degenerative diseases in the oral cavity; a vast number of drugs, particularly those that interfere with cell turnover such as antithyroid and antineoplastic agents;

TABLE 30-2 CAUSES OF GUSTATORY DYSFUNCTION

Transport Gustatory Losses	Neural Gustatory Losses
Drugs	Diabetes mellitus
Heavy-metal intoxication	Hypothyroidism
Radiation therapy	Oral neoplasms
Sjögren's syndrome	Oral surgery
Xerostomia	Radiation therapy
Sensory Gustatory Losses	Renal disease
Aging	Stroke and other CNS disorders
Candidiasis	Trauma
Drugs (antithyroid and antineoplastic)	Upper respiratory tract infections
Endocrine disorders	
Oral neoplasms	
Pemphigus	
Radiation therapy	
Viral infections (especially with herpes viruses)	

radiation therapy to the oral cavity and pharynx; viral infections; endocrine disorders; neoplasms; and aging. *Neural gustatory losses* occur with neoplasms, trauma, and surgical procedures in which the gustatory afferents are injured. Taste buds degenerate when their gustatory afferents are transected but remain when their somatosensory afferents are severed. Patients with renal disease have increased thresholds for sweet and sour tastes, which resolves with dialysis.

A side effect of medication is the single most common cause of taste dysfunction in clinical practice. Xerostomia, regardless of the etiology, can be associated with taste dysfunction. It is associated with poor oral clearance and poor dental hygiene and can adversely affect the oral mucosa, all leading to dysgeusia. However, severe salivary gland failure does not necessarily lead to taste complaints. Xerostomia, the use of antibiotics or glucocorticoids, or immunodeficiency can lead to overgrowth of *Candida*; overgrowth alone, without thrush or overt signs of infection, can be associated with bad taste or hypogeusia. When taste dysfunction occurs in a patient at risk for fungal overgrowth, a trial of nystatin or other antifungal medication is warranted.

Upper respiratory infections and head trauma can lead to both smell and taste dysfunction; taste is more likely to improve than smell. The mechanism of taste disturbance in these situations is not well understood. Trauma to the chorda tympani branch of the facial nerve during middle ear surgery or third molar extractions is relatively common and can cause dysgeusia. Bilateral chorda tympani injuries are usually associated with hypogeusia, whereas unilateral lesions produce only limited symptoms.

As noted above, aging itself may be associated with reduced taste sensitivity. The taste dysfunction may be limited to a single compound and may be mild.

APPROACH TO THE PATIENT: Disorders of the Sense of Taste

Patients who complain of loss of taste should be evaluated for both gustatory and olfactory function. Clinical assessment of taste is not as well developed or standardized as that of smell. The first step is to perform suprathreshold whole-mouth taste testing for quality, intensity, and pleasantness perception of four taste qualities: sweet, salty, sour, and bitter. Most commonly used reagents for taste testing are sucrose, citric acid or hydrochloric acid, caffeine or quinine (sulfate or hydrochloride), and sodium chloride. The taste stimuli should be freshly prepared and have similar viscosity. For quantification, detection thresholds are obtained by applying graduated dilutions to the tongue quadrants or by whole-mouth sips. Electric taste testing (*electrogustometry*) is used clinically to identify taste deficits in specific quadrants of the tongue. Regional gustatory testing may also be performed to assess for the possibility of loss localized to one or several receptor fields as a result of a peripheral or central lesion. The history of the disease and localization studies provide important clues to the causes of the taste disturbance. For example, absence of taste on the anterior two-thirds of the tongue associated with a facial paralysis indicates that the lesion is proximal to the juncture of the chorda tympani branch with the facial nerve in the mastoid.

℞ DISORDERS OF THE SENSE OF TASTE

Treatment of gustatory disorders is limited. No effective therapies exist for the sensorineural disorders of taste. Altered taste due to surgical stretch injury of the chorda tympani nerve usually improves within 3–4 months, while dysfunction is usually permanent with transection of the nerve. Taste dysfunction following trauma may resolve spontaneously without intervention and is more likely to do so than posttraumatic smell dysfunction. Idiopathic alterations of taste sensitivity usually remain stable or worsen; zinc and vitamin therapy are of unproven value. Directed therapy to address factors that affect taste perception can be of value. Xerostomia can be treated with artificial saliva, providing some benefit to patients with a disturbed salivary milieu. Oral pilocarpine may be beneficial for a variety of forms of xerostomia. Appropriate treatment of bacterial and fungal infections of the oral cavity can be of great help in improving taste function. Taste disturbance related to drugs can often be resolved by changing the prescribed medication.

HEARING

Hearing loss is one of the most common sensory disorders in humans and can present at any age. Nearly 10% of the adult population has some hearing loss, and one-third of individuals >65 years have a hearing loss of sufficient magnitude to require a hearing aid.

PHYSIOLOGY OF HEARING

(Fig. 30-3) The function of the external and middle ear is to amplify sound to facilitate mechanotransduction by hair cells in the inner ear. Sound waves enter the external auditory canal and set the tympanic membrane in motion, which in turn moves the malleus, incus, and stapes of the middle ear. Movement of the footplate of the stapes causes pressure changes in the fluid-filled inner ear eliciting a traveling wave in the basilar membrane of the cochlea. The tympanic membrane and the ossicular chain in the middle ear serve as an impedance-matching mechanism, improving the efficiency of energy transfer from air to the fluid-filled inner ear.

Stereocilia of the hair cells of the organ of Corti, which rests on the basilar membrane, are in contact with the tectorial membrane and are deformed by the traveling wave. A point of maximal displacement of the basilar membrane is determined by the frequency of the stimulating tone. High-frequency tones cause maximal displacement of the basilar membrane near the base of the cochlea. As the frequency of the stimulating tone decreases, the point of maximal displacement moves toward the apex of the cochlea.

The inner and outer hair cells of the organ of Corti have different innervation patterns, but both are mechanoreceptors. The afferent innervation relates principally to the inner hair cells, and the efferent innervation relates principally to outer hair cells. The motility of the outer hair cells alters the micromechanics of the inner hair cells, creating a cochlear amplifier, which explains the exquisite sensitivity and frequency selectivity of the cochlea.

Beginning in the cochlea, the frequency specificity is maintained at each point of the central auditory pathway: dorsal and ventral cochlear nuclei, trapezoid body, superior olivary complex, lateral lemniscus, inferior colliculus, medial geniculate body, and auditory cortex. At low frequencies, individual auditory nerve fibers can respond more or less synchronously with the stimulating tone. At higher frequencies, phase-locking occurs so that neurons alternate in response to particular phases of the cycle of the sound wave. Intensity is encoded by the amount of neural activity in individual neurons, the number of neurons that are active, and the specific neurons that are activated.

GENETIC CAUSES OF HEARING LOSS

More than half of childhood hearing impairment is thought to be hereditary; hereditary hearing impairment (HHI) can also manifest later in life. HHI may be classified as either nonsyndromic, when hearing loss is the only clinical abnormality, or syndromic, when hearing loss is associated with anomalies in other organ systems. Near-

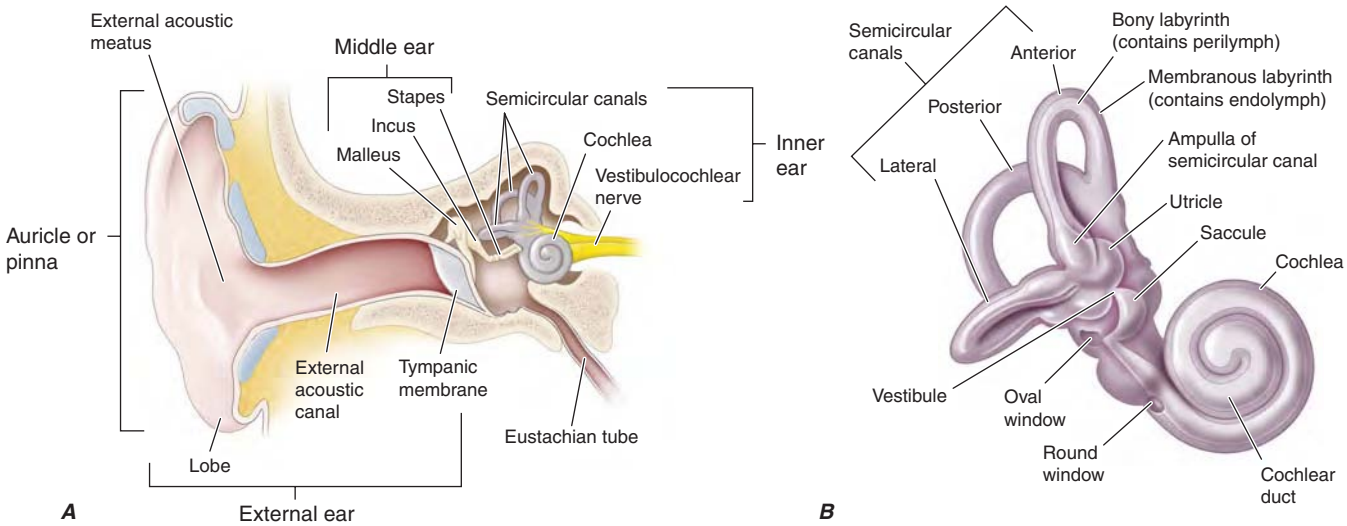

FIGURE 30-3 Ear anatomy. *A.* Drawing of modified coronal section through external ear and temporal bone, with structures of the middle and inner ear demonstrated. ***B.*** High-resolution view of inner ear.

ly two-thirds of HHIs are nonsyndromic, and the remaining one-third are syndromic. Between 70 and 80% of nonsyndromic HHI is inherited in an autosomal recessive manner and designated DFNB; another 15–20% is autosomal dominant (DFNA). Less than 5% is X-linked or maternally inherited via the mitochondria.

Nearly 100 loci harboring genes for nonsyndromic HHI have been mapped, with equal numbers of dominant and recessive modes of inheritance; numerous genes have now been cloned (Table 30-3). The hearing genes fall into the categories of structural proteins (MYH9, MYO7A, MYO15, TECTA, DIAPH1), transcription factors (POU3F4, POU4F3), ion channels (KCNQ4, SLC26A4), and gap junction proteins (GJB2, GJB3, GJB6). Several of these genes, including connexin 26 (GJB2), TECTA, and TMC1, cause both autosomal dominant and recessive forms of nonsyndromic HHI. In general, the hearing loss associated with dominant genes has its onset in adolescence or adulthood and varies in severity, whereas the hearing loss associated with recessive inheritance is congenital and profound. Connexin 26 is particularly important because it is associated with nearly 20% of cases of childhood deafness. Two frame-shift mutations, 35delG and 167delT, account for >50% of the cases; however, screening for these two mutations alone is insufficient to diagnose GJB2-related recessive deafness. The 167delT mutation is highly prevalent in Ashkenazi Jews; ~1 in 1765 individuals in this population are homozygous and affected. The hearing loss can also vary among the members of the same family, suggesting that other genes or factors influence the auditory phenotype.

The contribution of genetics to presbycusis (see below) is also becoming better understood. In addition to GJB2, several other nonsyndromic genes are associated with hearing loss that progresses with age. Sensitivity to aminoglycoside ototoxicity can be maternally transmitted through a mitochondrial mutation. Susceptibility to noise-induced hearing loss may also be genetically determined.

There are >400 syndromic forms of hearing loss. These include Usher syndrome (retinitis pigmentosa and hearing loss), Waardenburg syndrome (pigmentary abnormality and hearing loss), Pendred syndrome (thyroid organification defect and hearing loss), Alport syndrome (renal disease and hearing loss), Jervell and Lange-Nielsen syndrome (prolonged QT interval and hearing loss), neurofibromatosis type 2 (bilateral acoustic schwannoma), and mitochondrial disorders [mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS); myoclonic epilepsy and ragged red fibers (MERRF); progressive external ophthalmoplegia (PEO)] (Table 30-4).

DISORDERS OF THE SENSE OF HEARING

Hearing loss can result from disorders of the auricle, external auditory canal, middle ear, inner ear, or central auditory pathways (Fig. 30-4). *In general, lesions in the auricle, external auditory canal, or middle ear*

TABLE 30-3 HEREDITARY HEARING IMPAIRMENT GENES

Designation	Gene	Function
Autosomal Dominant		
	CRYM	Thyroid hormone binding protein
DFNA1	*DIAPH1*	Cytoskeletal protein
DFNA2	*GJB3 (Cx31)*	Gap junctions
DFNA2	*KCNQ4*	Potassium channel
DFNA3	*GJB2 (Cx26)*	Gap junctions
DFNA3	*GJB6 (Cx30)*	Gap junctions
DFNA4	*MYH14*	Class II nonmuscle myosin
DFNA5	*DFNA5*	Unknown
DFNA6/14/38	*WFS*	Transmembrane protein
DFNA8/12	*TECTA*	Tectorial membrane protein
DFNA9	*COCH*	Unknown
DFNA10	*EYA4*	Developmental gene
DFNA11	*MYO7A*	Cytoskeletal protein
DFNA13	*COL11A2*	Cytoskeletal protein
DFNA15	*POU4F3*	Transcription factor
DFNA17	*MYH9*	Cytoskeletal protein
DFNA20/26	*ACTG1*	Cytoskeletal protein
DFNA22	*MYO6*	Unconventional myosin
DFNA28	*TFCP2L3*	Transcription factor
DFNA36	*TMC1*	Transmembrane protein
DFNA48	*MYO1A*	Unconventional myosin
Autosomal Recessive		
	SLC26A5 (Prestin)	Motor protein
DFNB1	*GJB2 (CX26)*	Gap junction
	GJB6(CX30)	Gap junction
DFNB2	*MYO7A*	Cytoskeletal protein
DFNB3	*MYO15*	Cytoskeletal protein
DFNB4	*PDS(SLC26A4)*	Chloride/iodide transporter
DFNB6	*TMIE*	Transmembrane protein
DFNB7/B11	*TMC1*	Transmembrane protein
DFNB9	*OTOF*	Trafficking of membrane vesicles
DFNB8/10	*TMPRSS3*	Transmembrane serine protease
DFNB12	*CDH23*	Intercellular adherence protein
DFNB16	*STRC*	Stereocilia protein
DFNB18	*USH1C*	Unknown
DFNB21	*TECTA*	Tectorial membrane protein
DFNB22	*OTOA*	Gel attachement to nonsensory cell
DFNB23	*PCDH15*	Morphogenesis and cohesion
DFNB28	*TRIOBP*	Cytoskeletal-organizing protein
DFNB29	*CLDN14*	Tight junctions
DFNB30	*MYO3A*	Hybrid motor-signaling myosin
DFNB31	*WHRN*	PDZ domain–containing protein
DFNB36	*ESPN*	Ca-insensitive actin-bundling protein
DFNB37	*MYO6*	Unconventional myosin
DFNB67	*TMHS*	Unknown function; tetraspan protein

TABLE 30-4 SYNDROMIC HEREDITARY HEARING IMPAIRMENT GENES

Syndrome	Gene	Function
Alport syndrome	*COL4A3-5*	Cytoskeletal protein
BOR syndrome	*EYA1*	Developmental gene
	SIX1	Developmental gene
Jervell and Lange-Nielsen syndrome	*KVLQT1*	Delayed rectifier K^+ channel
	KCNE1	Delayed rectifier K^+ channel
Norrie disease	*Norrin*	Cell-cell interactions
Pendred syndrome	*SLC26A4*	Chloride/iodide transporter
Treacher Collins	*TCOF1*	Nucleolar-cytoplasmic transport
Usher syndrome	*MYO7A*	Cytoskeletal protein

WS type II	*MITF*	Transcription factor
	SLUG	Transcription factor
WS type IV	*EDNRB*	Endothelin-B receptor
	EDN3	Endothelin-B receptor ligand
	SOX10	Transcription factor

Note: BOR, branchio-oto-renal syndrome; WS, Waardenburg syndrome.

cause conductive hearing losses, whereas lesions in the inner ear or eighth nerve cause sensorineural hearing losses.

Conductive Hearing Loss This results from obstruction of the external auditory canal by cerumen, debris, and foreign bodies; swelling of the lining of the canal; atresia or neoplasms of the canal; perforations of the tympanic membrane; disruption of the ossicular chain, as occurs with necrosis of the long process of the incus in trauma or infection; otosclerosis; or fluid, scarring, or neoplasms in the middle ear. Rarely, inner-ear malformations may present as conductive hearing loss beginning in adulthood.

Cholesteatoma, stratified squamous epithelium in the middle ear or mastoid, occurs frequently in adults. This is a benign, slowly growing lesion that destroys bone and normal ear tissue. Theories of pathogenesis include traumatic implantation and invasion, immigration and invasion through a perforation, and metaplasia following chronic infection and irritation. On examination, there is often a perforation of the tympanic membrane filled with cheesy white squamous debris. A chronically draining ear that fails to respond to appropriate antibiotic therapy should raise suspicion of a cholesteatoma. Conductive hearing loss secondary to ossicular erosion is common. Surgery is required to remove this destructive process.

Conductive hearing loss with a normal ear canal and intact tympanic membrane suggests ossicular pathology. Fixation of the stapes from *otosclerosis* is a common cause of low-frequency conductive hearing loss. It occurs equally in men and women and is inherited as an autosomal dominant trait with incomplete penetrance. Hearing impairment usually presents between the late teens to the forties. In women, the otosclerotic process is accelerated during pregnancy, and the hearing loss is often first noticeable at this time. A hearing aid or a simple outpatient surgical procedure (stapedectomy) can provide adequate auditory rehabilitation. Extension of otosclerosis beyond the stapes footplate to involve the cochlea (cochlear otosclerosis) can lead to mixed or sensorineural hearing loss. Fluoride therapy to prevent hearing loss from cochlear otosclerosis is of uncertain value.

Eustachian tube dysfunction is extremely common in adults and may predispose to acute otitis media (AOM) or serous otitis media (SOM). Trauma, AOM, or chronic otitis media are the usual factors

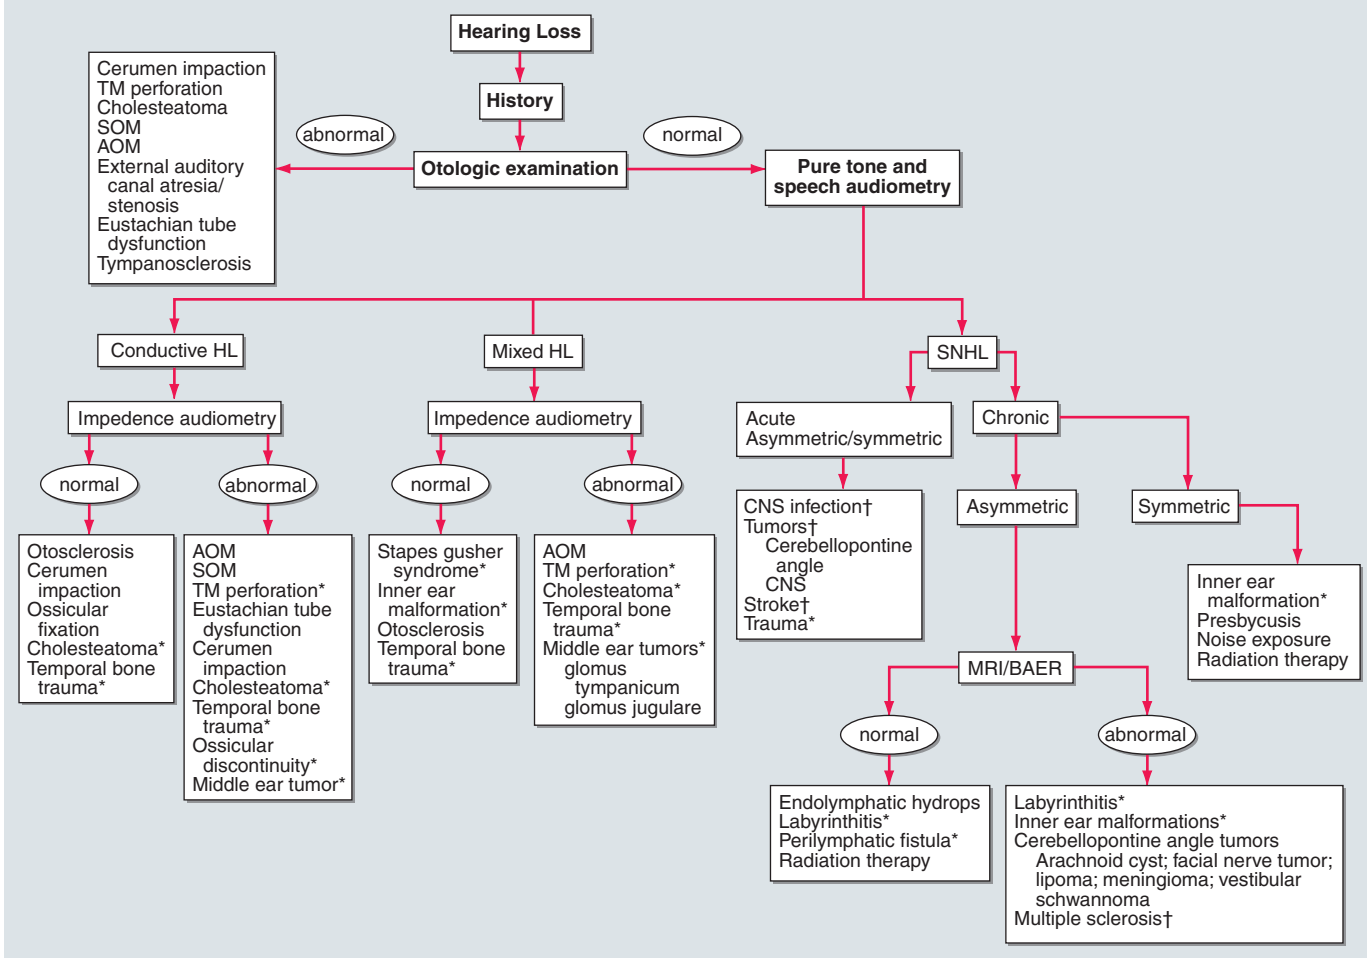

FIGURE 30-4 An algorithm for the approach to hearing loss. HL, hearing loss; SNHL, sensorineural hearing loss; TM, tympanic membrane; SOM, serous otitis media; AOM, acute otitis media; *, CT scan of temporal bone; †, MRI scan.

responsible for tympanic membrane perforation. While small perforations often heal spontaneously, larger defects usually require surgical intervention. Tympanoplasty is highly effective (>90%) in the repair of tympanic membrane perforations. Otoscopy is usually sufficient to diagnose AOM, SOM, chronic otitis media, cerumen impaction, tympanic membrane perforation, and eustachian tube dysfunction.

Sensorineural Hearing Loss Damage to the hair cells of the organ of Corti may be caused by intense noise, viral infections, ototoxic drugs (e.g., salicylates, quinine and its synthetic analogues, aminoglycoside antibiotics, loop diuretics such as furosemide and ethacrynic acid, and cancer chemotherapeutic agents such as cisplatin), fractures of the temporal bone, meningitis, cochlear otosclerosis (see above), Ménière's disease, and aging. Congenital malformations of the inner ear may be the cause of hearing loss in some adults. Genetic predisposition alone or in concert with environmental exposures may also be responsible.

Presbycusis (age-associated hearing loss) is the most common cause of sensorineural hearing loss in adults. In the early stages, it is characterized by symmetric, gentle to sharply sloping high-frequency hearing loss. With progression, the hearing loss involves all frequencies. More importantly, the hearing impairment is associated with significant loss in clarity. There is a loss of discrimination for phonemes, recruitment (abnormal growth of loudness), and particular difficulty in understanding speech in noisy environments. Hearing aids may provide limited rehabilitation once the word recognition score deteriorates below 50%. Cochlear implants are the treatment of choice when hearing aids prove inadequate, even when hearing loss is incomplete.

Ménière's disease is characterized by episodic vertigo, fluctuating sensorineural hearing loss, tinnitus, and aural fullness. Tinnitus and/or deafness may be absent during the initial attacks of vertigo, but invariably appear as the disease progresses and increase in severity during acute attacks. The annual incidence of Ménière's disease is 0.5–7.5 per 1000; onset is most frequently in the fifth decade of life but may also occur in young adults or the elderly. Histologically, there is distention of the endolymphatic system (endolymphatic hydrops) leading to degeneration of vestibular and cochlear hair cells. This may result from endolymphatic sac dysfunction secondary to infection, trauma, autoimmune disease, inflammatory causes, or tumor; an idiopathic etiology constitutes the largest category and is most accurately referred to as Ménière's disease. Although any pattern of hearing loss can be observed, typically, low-frequency, unilateral sensorineural hearing impairment is present. MRI should be obtained to exclude retrocochlear pathology such as a cerebellopontine angle tumor or demyelinating disorder. Therapy is directed towards the control of vertigo. A low-salt diet is the mainstay of treatment for control of rotatory vertigo. Diuretics, a short course of glucocorticoids, and intratympanic gentamicin may also be useful adjuncts in recalcitrant cases. Surgical therapy of vertigo is reserved for unresponsive cases and includes endolymphatic sac decompression, labyrinthectomy, and vestibular nerve section. Both labyrinthectomy and vestibular nerve section abolish rotatory vertigo in >90% of cases. Unfortunately, there is no effective therapy for hearing loss, tinnitus, or aural fullness from Ménière's disease.

Sensorineural hearing loss may also result from any neoplastic, vascular, demyelinating, infectious, or degenerative disease or trauma affecting the central auditory pathways. HIV leads to both peripheral and central auditory system pathology and is associated with sensorineural hearing impairment.

A finding of conductive and sensory hearing loss in combination is termed *mixed hearing loss*. Mixed hearing losses are due to pathology of both the middle and inner ear, as can occur in otosclerosis involving the ossicles and the cochlea, head trauma, chronic otitis media, cholesteatoma, middle ear tumors, and some inner ear malformations.

Trauma resulting in temporal bone fractures may be associated with conductive, sensorineural, or mixed hearing loss. If the fracture spares the inner ear, there may simply be conductive hearing loss due to rupture of the tympanic membrane or disruption of the ossicular chain. These abnormalities can be surgically corrected. Profound hearing loss and severe vertigo are associated with temporal bone fractures involving the inner ear. A perilymphatic fistula associated with leakage of inner-ear fluid into the middle ear can occur and may require surgical repair. An associated facial nerve injury is not uncommon. CT is best suited to assess fracture of the traumatized temporal bone, evaluate the ear canal, and determine the integrity of the ossicular chain and the involvement of the inner ear. CSF leaks that accompany temporal bone fractures are usually self-limited; the value of prophylactic antibiotics is uncertain.

Tinnitus is defined as the perception of a sound when there is no sound in the environment. It may have a buzzing, roaring, or ringing quality and may be pulsatile (synchronous with the heartbeat). Tinnitus is often associated with either a conductive or sensorineural hearing loss. The pathophysiology of tinnitus is not well understood. The cause of the tinnitus can usually be determined by finding the cause of the associated hearing loss. Tinnitus may be the first symptom of a serious condition such as a vestibular schwannoma. Pulsatile tinnitus requires evaluation of the vascular system of the head to exclude vascular tumors such as glomus jugulare tumors, aneurysms, and stenotic arterial lesions; it may also occur with SOM.

APPROACH TO THE PATIENT: Disorders of the Sense of Hearing

The goal in the evaluation of a patient with auditory complaints is to determine (1) the nature of the hearing impairment (conductive vs. sensorineural vs. mixed), (2) the severity of the impairment (mild, moderate, severe, profound), (3) the anatomy of the impairment (external ear, middle ear, inner ear, or central auditory pathway), and (4) the etiology. The history should elicit characteristics of the hearing loss, including the duration of deafness, unilateral vs. bilateral involvement, nature of onset (sudden vs. insidious), and rate of progression (rapid vs. slow). Symptoms of tinnitus, vertigo, imbalance, aural fullness, otorrhea, headache, facial nerve dysfunction, and head and neck paresthesias should be noted. Information regarding head trauma, exposure to ototoxins, occupational or recreational noise exposure, and family history of hearing impairment may also be important. A sudden onset of unilateral hearing loss, with or without tinnitus, may represent a viral infection of the inner ear or a stroke. Patients with unilateral hearing loss (sensory or conductive) usually complain of reduced hearing, poor sound localization, and difficulty hearing clearly with background noise. Gradual progression of a hearing deficit is common with otosclerosis, noise-induced hearing loss, vestibular schwannoma, or Ménière's disease. Small vestibular schwannomas typically present with asymmetric hearing impairment, tinnitus, and imbalance (rarely vertigo); cranial neuropathy, in particular of the trigeminal or facial nerve, may accompany larger tumors. In addition to hearing loss, Ménière's disease may be associated with episodic vertigo, tinnitus, and aural fullness. Hearing loss with otorrhea is most likely due to chronic otitis media or cholesteatoma.

Examination should include the auricle, external ear canal, and tympanic membrane. The external ear canal of the elderly is often dry and fragile; it is preferable to clean cerumen with wall-mounted suction and cerumen loops and to avoid irrigation. In examining the eardrum, the topography of the tympanic membrane is more important than the presence or absence of the light reflex. In addition to the pars tensa (the lower two-thirds of the eardrum), the pars flaccida above the short process of the malleus should also be examined for retraction pockets that may be evidence of chronic eustachian tube dysfunction or cholesteatoma. Insufflation of the ear canal is necessary to assess tympanic membrane mobility and compliance. Careful inspection of the nose, nasopharynx, and upper respiratory tract is indicated. Unilateral serous effusion should prompt a fiberoptic examination of the nasopharynx to exclude neoplasms. Cranial nerves should be evaluated with special attention to facial and trigeminal nerves, which are commonly affected with tumors involving the cerebellopontine angle.

The Rinne and Weber tuning fork tests, with a 512-Hz tuning fork, are used to screen for hearing loss, differentiate conductive from sensorineural hearing losses, and to confirm the findings of

audiologic evaluation. Rinne's test compares the ability to hear by air conduction with the ability to hear by bone conduction. The tines of a vibrating tuning fork are held near the opening of the external auditory canal, and then the stem is placed on the mastoid process; for direct contact, it may be placed on teeth or dentures. The patient is asked to indicate whether the tone is louder by air conduction or bone conduction. Normally, and in the presence of sensorineural hearing loss, a tone is heard louder by air conduction than by bone conduction; however, with conductive hearing loss of ≥30 dB (see "Audiologic Assessment," below), the bone-conduction stimulus is perceived as louder than the air-conduction stimulus. For the Weber test, the stem of a vibrating tuning fork is placed on the head in the midline and the patient asked whether the tone is heard in both ears or better in one ear than in the other. With a unilateral conductive hearing loss, the tone is perceived in the affected ear. With a unilateral sensorineural hearing loss, the tone is perceived in the unaffected ear. A 5-dB difference in hearing between the two ears is required for lateralization.

LABORATORY ASSESSMENT OF HEARING

Audiologic Assessment The minimum audiologic assessment for hearing loss should include the measurement of pure tone air-conduction and bone-conduction thresholds, speech reception threshold, discrimination score, tympanometry, acoustic reflexes, and acoustic-reflex decay. This test battery provides a screening evaluation of the entire auditory system and allows one to determine whether further differentiation of a sensory (cochlear) from a neural (retrocochlear) hearing loss is indicated.

Pure tone audiometry assesses hearing acuity for pure tones. The test is administered by an audiologist and is performed in a sound-attenuated chamber. The pure tone stimulus is delivered with an audiometer, an electronic device that allows the presentation of specific frequencies (generally between 250 and 8000 Hz) at specific intensities. Air and bone conduction thresholds are established for each ear. Air conduction thresholds are determined by presenting the stimulus in air with the use of headphones. Bone conduction thresholds are determined by placing the stem of a vibrating tuning fork or an oscillator of an audiometer in contact with the head. In the presence of a hearing loss, broad-spectrum noise is presented to the nontest ear for *masking* purposes so that responses are based on perception from the ear under test.

The responses are measured in decibels. An *audiogram* is a plot of intensity in decibels of hearing threshold versus frequency. A decibel (dB) is equal to 20 times the logarithm of the ratio of the sound pressure required to achieve threshold in the patient to the sound pressure required to achieve threshold in a normal hearing person. Therefore, a change of 6 dB represents doubling of sound pressure, and a change of 20 dB represents a tenfold change in sound pressure. Loudness, which depends on the frequency, intensity, and duration of a sound, doubles with approximately each 10-dB increase in sound pressure level. Pitch, on the other hand, does not directly correlate with frequency. The perception of pitch changes slowly in the low and high frequencies. In the middle tones, which are important for human speech, pitch varies more rapidly with changes in frequency.

Pure tone audiometry establishes the presence and severity of hearing impairment, unilateral vs. bilateral involvement, and the type of hearing loss. Conductive hearing losses with a large mass component, as is often seen in middle-ear effusions, produce elevation of thresholds that predominate in the higher frequencies. Conductive hearing losses with a large stiffness component, as in fixation of the footplate of the stapes in early otosclerosis, produce threshold elevations in the lower frequencies. Often, the conductive hearing loss involves all frequencies, suggesting involvement of both stiffness and mass. In general, sensorineural hearing losses such as presbycusis affect higher frequencies more than lower frequencies. An exception is Ménière's disease, which is characteristically associated with low-frequency sensorineural hearing loss. Noise-induced hearing loss has an unusual pattern of hearing impairment in which the loss at 4000 Hz is greater than at higher frequencies. Vestibular schwannomas characteristically affect the higher frequencies, but any pattern of hearing loss can be observed.

Speech recognition requires greater synchronous neural firing than is necessary for appreciation of pure tones. *Speech audiometry* tests the clarity with which one hears. The *speech reception threshold* (SRT) is defined as the intensity at which speech is recognized as a meaningful symbol and is obtained by presenting two-syllable words with an equal accent on each syllable. The intensity at which the patient can repeat 50% of the words correctly is the SRT. Once the SRT is determined, discrimination or word recognition ability is tested by presenting one-syllable words at 25–40 dB above the SRT. The words are phonetically balanced in that the phonemes (speech sounds) occur in the list of words at the same frequency that they occur in ordinary conversational English. An individual with normal hearing or conductive hearing loss can repeat 88–100% of the phonetically balanced words correctly. Patients with a sensorineural hearing loss have variable loss of discrimination. As a general rule, neural lesions produce greater deficits in discrimination than do lesions in the inner ear. For example, in a patient with mild asymmetric sensorineural hearing loss, a clue to the diagnosis of vestibular schwannoma is the presence of a substantial deterioration in discrimination ability. Deterioration in discrimination ability at higher intensities above the SRT also suggests a lesion in the eighth nerve or central auditory pathways.

Tympanometry measures the impedance of the middle ear to sound and is useful in diagnosis of middle-ear effusions. A *tympanogram* is the graphic representation of change in impedance or compliance as the pressure in the ear canal is changed. Normally, the middle ear is most compliant at atmospheric pressure, and the compliance decreases as the pressure is increased or decreased; this pattern is seen with normal hearing or in the presence of sensorineural hearing loss. Compliance that does not change with change in pressure suggests middle-ear effusion. With a negative pressure in the middle ear, as with eustachian tube obstruction, the point of maximal compliance occurs with negative pressure in the ear canal. A tympanogram in which no point of maximal compliance can be obtained is most commonly seen with discontinuity of the ossicular chain. A reduction in the maximal compliance peak can be seen in otosclerosis.

During tympanometry, an intense tone elicits contraction of the stapedius muscle. The change in compliance of the middle ear with contraction of the stapedius muscle can be detected. The presence or absence of this *acoustic reflex* is important in the anatomic localization of facial nerve paralysis as well as hearing loss. Normal or elevated acoustic reflex thresholds in an individual with sensorineural hearing impairment suggests a cochlear hearing loss. Assessment of *acoustic reflex decay* helps differentiate sensory from neural hearing losses. In neural hearing loss, the reflex adapts or decays with time.

Otoacoustic emissions (OAE) can be measured with microphones inserted into the external auditory canal. The emissions may be spontaneous or evoked with sound stimulation. The presence of OAEs indicates that the outer hair cells of the organ of Corti are intact and can be used to assess auditory thresholds and to distinguish sensory from neural hearing losses.

Evoked Responses *Electrocochleography* measures the earliest evoked potentials generated in the cochlea and the auditory nerve. Receptor potentials recorded include the cochlear microphonic, generated by the outer hair cells of the organ of Corti, and the summating potential, generated by the inner hair cells in response to sound. The whole nerve action potential representing the composite firing of the first-order neurons can also be recorded during electrocochleography. Clinically, the test is useful in the diagnosis of Ménière's disease, where an elevation of the ratio of summating potential to action potential is seen.

Brainstem auditory evoked responses (BAERs) are useful in differentiating the site of sensorineural hearing loss. In response to sound, five distinct electrical potentials arising from different stations along the peripheral and central auditory pathway can be identified using computer averaging from scalp surface electrodes. BAERs are valuable in situations in which patients cannot or will not give reliable voluntary thresholds. They are also used to assess the integrity of the auditory nerve and brainstem in various clinical situations, including intraoperative monitoring and in determination of brain death.

The *vestibular-evoked myogenic potential (VEMP) test* elicits a vestibulocollic reflex whose afferent limb arises from acoustically sensitive cells in the saccule, with signals conducted via the inferior vestibular nerve. VEMP is a biphasic, short-latency response recorded from the tonically contracted sternocleidomastoid muscle in response to loud auditory clicks or tones. VEMPs may be diminished or absent in patients with early and late Ménière's disease, vestibular neuritis, benign paroxysmal positional vertigo, and vestibular schwannoma. On the other hand, the threshold for VEMPs may be lower in cases of superior canal dehiscence and perilymphatic fistula.

Imaging Studies The choice of radiologic tests is largely determined by whether the goal is to evaluate the bony anatomy of the external, middle, and inner ear or to image the auditory nerve and brain. Axial and coronal CT of the temporal bone with fine 1-mm cuts is ideal for determining the caliber of the external auditory canal, integrity of the ossicular chain, and presence of middle-ear or mastoid disease; it can also detect inner-ear malformations. CT is also ideal for the detection of bone erosion with chronic otitis media and cholesteatoma. MRI is superior to CT for imaging of retrocochlear pathology such as vestibular schwannoma, meningioma, other lesions of the cerebellopontine angle, demyelinating lesions of the brainstem, and brain tumors. Both CT and MRI are equally capable of identifying inner-ear malformations and assessing cochlear patency for preoperative evaluation of patients for cochlear implantation.

℞ DISORDERS OF THE SENSE OF HEARING

In general, conductive hearing losses are amenable to surgical correction, while sensorineural hearing losses are more difficult to manage. Atresia of the ear canal can be surgically repaired, often with significant improvement in hearing. Tympanic membrane perforations due to chronic otitis media or trauma can be repaired with an outpatient tympanoplasty. Likewise, conductive hearing loss associated with otosclerosis can be treated by stapedectomy, which is successful in 90–95% of cases. Tympanostomy tubes allow the prompt return of normal hearing in individuals with middle-ear effusions. Hearing aids are effective and well-tolerated in patients with conductive hearing losses.

Patients with mild, moderate, and severe sensorineural hearing losses are regularly rehabilitated with hearing aids of varying configuration and strength. Hearing aids have been improved to provide greater fidelity and have been miniaturized. The current generation of hearing aids can be placed entirely within the ear canal, thus reducing any stigma associated with their use. In general, the more severe the hearing impairment, the larger the hearing aid required for auditory rehabilitation. Digital hearing aids lend themselves to individual programming, and multiple and directional microphones at the ear level may be helpful in noisy surroundings. Since all hearing aids amplify noise as well as speech, the only absolute solution to the problem of noise is to place the microphone closer to the speaker than the noise source. This arrangement is not possible with a self-contained, cosmetically acceptable device.

In many situations, including lectures and the theater, hearing-impaired persons benefit from assistive devices that are based on the principle of having the speaker closer to the microphone than any source of noise. Assistive devices include infrared and frequency-modulated (FM) transmission as well as an electromagnetic loop around the room for transmission to the individual's hearing aid. Hearing aids with telecoils can also be used with properly equipped telephones in the same way.

In the event that the hearing aid provides inadequate rehabilitation, cochlear implants may be appropriate. Criteria for implantation include severe to profound hearing loss with word recognition score ≤30% under best aided conditions. Worldwide, >20,000 deaf individuals (including 4000 children) have received cochlear implants. Cochlear implants are neural prostheses that convert sound energy to electrical energy and can be used to stimulate the auditory division of the eighth nerve directly. In most cases of profound hearing impairment, the auditory hair cells are lost but the ganglionic cells of the auditory division of the eighth nerve are preserved. Cochlear implants consist of electrodes that are inserted into the cochlea through the round window, speech processors that extract acoustical elements of speech for conversion to electrical currents, and a means of transmitting the electrical energy through the skin. Patients with implants experience sound that helps with speech reading, allows open-set word recognition, and helps in modulating the person's own voice. Usually, within 3 months after implantation, adult patients can understand speech without visual cues. With the current generation of multichannel cochlear implants, nearly 75% of patients are able to converse on the telephone. For individuals who have had both eighth nerves destroyed by trauma or bilateral vestibular schwannomas (e.g., neurofibromatosis type 2), brainstem auditory implants placed near the cochlear nucleus may provide auditory rehabilitation.

Tinnitus often accompanies hearing loss. As for background noise, tinnitus can degrade speech comprehension in individuals with hearing impairment. Therapy for tinnitus is usually directed towards minimizing the appreciation of tinnitus. Relief of the tinnitus may be obtained by masking it with background music. Hearing aids are also helpful in tinnitus suppression, as are tinnitus maskers, devices that present a sound to the affected ear that is more pleasant to listen to than the tinnitus. The use of a tinnitus masker is often followed by several hours of inhibition of the tinnitus. Antidepressants have been shown to be beneficial in helping patients cope with tinnitus.

Hard-of-hearing individuals often benefit from a reduction in unnecessary noise (e.g., radio or television) to enhance the signal-to-noise ratio. Speech comprehension is aided by lip reading; therefore the impaired listener should be seated so that the face of the speaker is well-illuminated and easily seen. Although speech should be in a loud, clear voice, one should be aware that in sensorineural hearing losses in general and in hard-of-hearing elderly in particular, recruitment (abnormal perception of loud sounds) may be troublesome. Above all, optimal communication cannot take place without both parties giving it their full and undivided attention.

PREVENTION

Conductive hearing losses may be prevented by prompt antibiotic therapy of adequate duration for AOM and by ventilation of the middle ear with tympanostomy tubes in middle-ear effusions lasting ≥12 weeks. Loss of vestibular function and deafness due to aminoglycoside antibiotics can largely be prevented by careful monitoring of serum peak and trough levels.

Some 10 million Americans have noise-induced hearing loss, and 20 million are exposed to hazardous noise in their employment. Noise-induced hearing loss can be prevented by avoidance of exposure to loud noise or by regular use of ear plugs or fluid-filled ear muffs to attenuate intense sound. High-risk activities for noise-induced hearing loss include wood and metal working with electrical equipment and target practice and hunting with small firearms. All internal-combustion and electric engines, including snow and leaf blowers, snowmobiles, outboard motors, and chain saws, require protection of the user with hearing protectors. Virtually all noise-induced hearing loss is preventable through education, which should begin before the teenage years. Programs of industrial conservation of hearing are required when the exposure over an 8-h period averages 85 dB. Workers in such noisy environments can be protected with preemployment audiologic assessment, the mandatory use of hearing protectors, and annual audiologic assessments.

31 Pharyngitis, Sinusitis, Otitis, and Other Upper Respiratory Tract Infections

Michael A. Rubin, Ralph Gonzales, Merle A. Sande

Infections of the upper respiratory tract (URIs) have a tremendous impact on public health. They are among the most common reasons for visits to primary care providers, and, although the illnesses are typically mild, their high incidence and transmission rates place them among the leading causes of time lost from work or school. Even though the minority (~25%) of cases are caused by bacteria, URIs are the leading diagnoses for which antibiotics are prescribed on an outpatient basis in the United States. The enormous consumption of antibiotics for these illnesses has contributed to the rise in antibiotic resistance among common community-acquired pathogens such as *Streptococcus pneumoniae*—a trend that in itself has had an enormous influence on public health.

Although most URIs are caused by viruses, distinguishing patients with primary viral infection from those with primary bacterial infection is difficult. Signs and symptoms of bacterial and viral URIs are, in fact, indistinguishable. Because routine, rapid testing is neither available nor practical for most syndromes, acute infections are diagnosed largely on clinical grounds. Thus the judicious use of antibiotics in this setting is challenging.

NONSPECIFIC INFECTIONS OF THE UPPER RESPIRATORY TRACT

Nonspecific URIs are a broadly defined group of disorders that collectively constitute the leading cause of ambulatory care visits in the United States. By definition, nonspecific URIs have no prominent localizing features. They are identified by a variety of descriptive names, including *acute infective rhinitis*, *acute rhinopharyngitis/nasopharyngitis*, *acute coryza*, and *acute nasal catarrh*, as well as by the inclusive label *common cold*.

Etiology The large assortment of URI classifications reflects the wide variety of causative infectious agents and the varied manifestations of common pathogens. Nearly all nonspecific URIs are caused by viruses spanning multiple virus families and many antigenic types. For instance, there are at least 100 immunotypes of rhinovirus (Chap. 179), the most common cause of URI (~30–40% of cases); other causes include influenza virus (three immunotypes; Chap. 180) as well as parainfluenza virus (four immunotypes), coronavirus (at least three immunotypes), and adenovirus (47 immunotypes) (Chap. 179). Respiratory syncytial virus (RSV) also accounts for a small percentage of cases each year, as do some viruses not typically associated with URIs (e.g., enteroviruses, rubella virus, and varicella-zoster virus). Even with sophisticated diagnostic and culture techniques, a substantial proportion (25–30%) of cases have no assigned pathogen.

Clinical Manifestations The signs and symptoms of nonspecific URI are similar to those of other URIs but lack a pronounced localization to one particular anatomic location, such as the sinuses, pharynx, or lower airway. Nonspecific URI is commonly described as an acute, mild, and self-limited catarrhal syndrome, with a median duration of ~1 week. Signs and symptoms are diverse and frequently variable across patients. The principal signs and symptoms of nonspecific URI include rhinorrhea (with or without purulence), nasal congestion, cough, and sore throat. Other manifestations, such as fever, malaise, sneezing, and hoarseness, are more variable, with fever more common among infants and young children. Occasionally, clinical features reflect the underlying viral pathogen; myalgias and fatigue, for example, are sometimes seen with influenza and parainfluenza infections, while conjunctivitis may suggest infection with adenovirus or enterovirus. Findings on physical examination are frequently nonspecific and unimpressive. Between 0.5 and 2% of colds are complicated by secondary bacterial infections (e.g., rhinosinusitis, otitis media, and pneumonia), particularly in high-risk populations such as infants, elderly persons, and chronically ill patients. Secondary bacterial infections are usually associated with a prolonged course of illness, increased severity of illness, and localization of signs and symptoms. Purulent secretions from the nares or throat have often been used as an indication of sinusitis or pharyngitis. However, these secretions are also seen in nonspecific URI and, in the absence of other clinical features, are poor predictors of bacterial infection.

℞ UPPER RESPIRATORY INFECTIONS

Antibiotics have no role in the treatment of uncomplicated nonspecific URI. In the absence of clinical evidence of bacterial infection, treatment remains entirely symptom-based, with use of decongestants and nonsteroidal anti-inflammatory drugs. Other therapies directed at specific symptoms are often useful, including dextromethorphan for cough and lozenges with topical anesthetic for sore throat. Clinical trials of zinc, vitamin C, echinacea, and other alternative remedies have revealed no consistent benefit for the treatment of nonspecific URI.

INFECTIONS OF THE SINUS

Sinusitis refers to an inflammatory condition involving the four paired structures surrounding the nasal cavities. Although most cases of sinusitis involve more than one sinus, the maxillary sinus is most commonly involved; next in frequency are the ethmoid, frontal, and sphenoid sinuses. Each sinus is lined with a respiratory epithelium that produces mucus, which is transported out by ciliary action through the sinus ostium and into the nasal cavity. Normally, mucus does not accumulate in the sinuses, which remain sterile despite their adjacency to the bacterium-filled nasal passages. When the sinus ostia are obstructed, however, or when ciliary clearance is impaired or absent, the secretions can be retained, producing the typical signs and symptoms of sinusitis. The retained secretions may become infected with a variety of pathogens, including viruses, bacteria, and fungi. Sinusitis affects a tremendous proportion of the population, accounts for millions of visits to primary care physicians each year, and is the fifth leading diagnosis for which antibiotics are prescribed. It is typically classified by duration of illness (acute vs. chronic); by etiology (infectious vs. noninfectious); and, when infectious, by the offending pathogen type (viral, bacterial, or fungal).

ACUTE SINUSITIS

Acute sinusitis—defined as sinusitis of <4 weeks' duration—constitutes the vast majority of sinusitis cases. Most cases are diagnosed in the ambulatory care setting and occur primarily as a consequence of a preceding viral URI. Differentiating acute bacterial and viral sinusitis on clinical grounds is difficult. Therefore, it is perhaps unsurprising that antibiotics are prescribed frequently (in 85–98% of all cases) for this condition.

Etiology A number of infectious and noninfectious factors can contribute to acute obstruction of the sinus ostia or impairment of ciliary clearance, with consequent sinusitis. Noninfectious causes include allergic rhinitis (with either mucosal edema or polyp obstruction), barotrauma (e.g., from deep-sea diving or air travel), or chemical irritants. Illnesses such as nasal and sinus tumors (e.g., squamous cell carcinoma) or granulomatous diseases (e.g., Wegener's granulomatosis or rhinoscleroma) can also produce obstruction of the sinus ostia, while conditions leading to altered mucus content (e.g., cystic fibrosis) can cause sinusitis through impaired mucus clearance. In the hospital setting, nasotracheal intubation is a major risk factor for nosocomial sinusitis in intensive care units.

Acute infectious sinusitis can be caused by a variety of organisms, including viruses, bacteria, and fungi. Viral rhinosinusitis is far more common than bacterial sinusitis, although relatively few studies have sampled sinus aspirates for the presence of different viruses. In those studies that have done so, the viruses most commonly isolated—both alone and with bacteria—have been rhinovirus, parainfluenza virus, and influenza virus. Bacterial causes of sinusitis have been better described. Among community-acquired cases, *S. pneumoniae* and nontypable *Haemophilus influenzae* are the most common pathogens, accounting for 50–60% of cases.

Moraxella catarrhalis causes disease in a significant percentage (20%) of children but less often in adults. Other streptococcal species and *Staphylococcus aureus* cause only a small percentage of cases, although there is increasing concern about community strains of methicillin-resistant *S. aureus* (MRSA) as an emerging cause. Anaerobes are occasionally found in association with infections of the roots of premolar teeth that spread into the adjacent maxillary sinuses. The role of *Chlamydophila pneumoniae* and *Mycoplasma pneumoniae* in the pathogenesis of acute sinusitis is still unclear. Nosocomial cases are commonly associated with bacteria found in the hospital environment, including *S. aureus*, *Pseudomonas aeruginosa*, *Serratia marcescens*, *Klebsiella pneumoniae*, and *Enterobacter* species. Often, these infections are polymicrobial and involve organisms that are highly resistant to numerous antibiotics. Fungi are also established causes of sinusitis, although most acute cases are in immunocompromised patients and represent invasive, life-threatening infections. The best-known example is rhinocerebral mucormycosis caused by fungi of the order Mucorales, which includes *Rhizopus*, *Rhizomucor*, *Mucor*, *Absidia*, and *Cunninghamella*. These infections usually occur in diabetic patients with ketoacidosis but also develop in transplant recipients, patients with hematologic malignancies, and patients receiving chronic glucocorticoid or deferoxamine therapy. Other hyaline molds, such as *Aspergillus* and *Fusarium* species, are also occasional causes of this disease.

Clinical Manifestations Most cases of acute sinusitis present after or in conjunction with a viral URI, and it can be difficult to discriminate the clinical features of one from the other. A large proportion of patients with colds have sinus inflammation, although bacterial sinusitis complicates only 0.2–2% of these viral infections. Common presenting symptoms of sinusitis include nasal drainage and congestion, facial pain or pressure, and headache. Thick, purulent or discolored nasal discharge is often thought to indicate bacterial sinusitis but also occurs early in viral infections such as the common cold and is not specific to bacterial infection. Other nonspecific manifestations include cough, sneezing, and fever. Tooth pain, most often involving the upper molars, is associated with bacterial sinusitis, as is halitosis.

In acute sinusitis, sinus pain or pressure often localizes to the involved sinus (particularly the maxillary sinus) and can be worse when the patient bends over or is supine. Although rare, manifestations of advanced sphenoid or ethmoid sinus infection can be profound, including severe frontal or retroorbital pain radiating to the occiput, thrombosis of the cavernous sinus, and signs of orbital cellulitis. Acute focal sinusitis is uncommon but should be considered in the patient with severe symptoms over the maxillary sinus and fever, regardless of illness duration. Similarly, advanced frontal sinusitis can present with a condition known as *Pott's puffy tumor*, with soft tissue swelling and pitting edema over the frontal bone from a communicating subperiosteal abscess. Life-threatening complications include meningitis, epidural abscess, and cerebral abscess.

Patients with acute fungal sinusitis (such as mucormycosis) often present with symptoms related to pressure effects, particularly when the infection has spread to the orbits and cavernous sinus. Signs such as orbital swelling and cellulitis, proptosis, ptosis, and decreased extraocular movement are common, as is retroorbital or periorbital pain. Nasopharyngeal ulcerations, epistaxis, and headaches are also frequent, and involvement of cranial nerves V and VII has been described in more advanced cases. Bony erosion may be evident on examination. Oftentimes, the patient does not appear seriously ill despite the rapidly progressive nature of these infections.

Patients with acute nosocomial sinusitis are often critically ill and thus do not manifest the typical clinical features of sinus disease. This diagnosis should be suspected, however, when hospitalized patients who have appropriate risk factors (e.g., nasotracheal intubation) develop fever of unknown origin.

Diagnosis Distinguishing viral from bacterial sinusitis in the ambulatory setting is usually difficult, given the relatively low sensitivity and specificity of the common clinical features. One clinical feature that has been used to help guide diagnostic and therapeutic decision-making is illness duration. Because acute bacterial sinusitis is uncommon in patients whose symptoms have lasted <7 days, several authorities now recommend reserving this diagnosis for patients with "persistent" symptoms (i.e., symptoms lasting >7 days in adults or >10–14 days in children) accompanied by purulent nasal discharge (Table 31-1). Even among the patients who meet these criteria, only 40–50% have true bacterial sinusitis. The use of CT or sinus radiography is not recommended for routine cases, particularly early in the course of illness (i.e., at <7 days), given the high prevalence of similar abnormalities among cases of acute viral rhinosinusitis. In the evaluation of persistent, recurrent, or chronic sinusitis, CT of the sinuses is the radiographic study of choice.

The clinical history and/or setting can often identify cases of acute anaerobic bacterial sinusitis, acute fungal sinusitis, or sinusitis from noninfectious causes (e.g., allergic rhinosinusitis). In the case of an immunocompromised patient with acute fungal sinus infection, immediate examination by an otolaryngologist is required. Biopsy specimens from involved areas should be examined by a pathologist for evidence of fungal hyphal elements and tissue invasion. Cases of suspected acute nosocomial sinusitis should be confirmed by sinus CT. Because therapy should target the offending organism, a sinus aspirate should be obtained, if possible, for culture and susceptibility testing.

℞ ACUTE SINUSITIS

Most patients with a diagnosis of acute rhinosinusitis based on clinical grounds improve without antibiotic therapy. The preferred initial approach in patients with mild to moderate symptoms of short duration is therapy aimed at facilitating sinus drainage, such as oral and topical decongestants, nasal saline lavage, and—in patients with a history of chronic sinusitis or allergies—nasal glucocorticoids. Adult patients who do not improve after 7 days, children who do not improve after 10–14 days, and patients with more severe symptoms (regardless of duration) should be treated with antibiotics (Table 31-1). Empirical therapy should consist of the narrowest-spectrum agent active against the most common bacterial pathogens, including *S. pneumoniae* and *H. influenzae*—e.g., amoxicillin. No clinical trials support the use of broad-spectrum agents for routine cases of bacterial sinusitis, even in the current era of drug-resistant *S. pneumoniae*. Up to 10% of patients do not respond to initial antimicrobial therapy; sinus aspiration and/or lavage by an otolaryngologist should be considered in these cases. Antibiotic prophylaxis to prevent episodes of recurrent acute bacterial sinusitis is not recommended.

Surgical intervention and IV antibiotic administration are usually reserved for patients with severe disease or those with intracranial complications, such as abscess or orbital involvement. Immunocompromised patients with acute invasive fungal sinusitis usually require extensive surgical debridement and treatment with IV antifungal agents active against fungal hyphal forms, such as amphotericin B. Specific therapy should be individualized according to the fungal species and the individual patient's characteristics.

Treatment of nosocomial sinusitis should begin with broad-spectrum antibiotics to cover common pathogens such as *S. aureus* and gram-negative bacilli. Therapy should then be tailored to the results of culture and susceptibility testing of sinus aspirates.

CHRONIC SINUSITIS

Chronic sinusitis is characterized by symptoms of sinus inflammation lasting >12 weeks. This illness is most commonly associated with either bacteria or fungi, and clinical cure in most cases is very difficult. Many patients have undergone treatment with repeated courses of antibacterial agents and multiple sinus surgeries, increasing their risk of colonization with antibiotic-resistant pathogens and of surgical complications. Patients often suffer significant morbidity, sometimes over many years.

In *chronic bacterial sinusitis*, infection is thought to be due to the impairment of mucociliary clearance from repeated infections rather than to persistent bacterial infection. However, the pathogenesis of this condition is poorly understood. Although certain conditions (e.g., cystic fibrosis) can predispose patients to chronic bacterial sinusitis, most patients with this infection do not have obvious underlying conditions that result in the obstruction of sinus drainage, the impairment of ciliary action, or immune dysfunction. Patients experience constant nasal congestion and sinus pressure, with intermittent periods of greater severity,

TABLE 31-1 GUIDELINES FOR THE DIAGNOSIS AND TREATMENT OF ACUTE SINUSITIS

Age Group	Diagnostic Criteria	Treatment Recommendations[a]
Adults	Moderate symptoms (e.g., nasal purulence/ congestion or cough) for >7 d *or* Severe symptoms of any duration, including unilateral/focal facial swelling or tooth pain	*Initial therapy* Amoxicillin, 500 mg PO tid or 875 mg PO bid, *or* TMP-SMX, 1 DS tablet PO bid for 10–14 d *Exposure to antibiotics within 30 d or >30% prevalence of penicillin-resistant S. pneumoniae* Amoxicillin, 1000 mg PO tid, *or* Amoxicillin/clavulanate (extended release), 2000 mg PO bid, *or* Antipneumococcal fluoroquinolone (e.g., levofloxacin, 500 mg PO qd) *Recent treatment failure* Amoxicillin/clavulanate (extended release), 2000 mg PO bid, *or* Amoxicillin, 1500 mg bid, plus clindamycin, 300 mg PO qid, *or* Antipneumococcal fluoroquinolone (e.g., levofloxacin, 500 mg PO qd)
Children	Moderate symptoms (e.g., nasal purulence/congestion or cough) for >10–14 d *or* Severe symptoms of any duration, including fever (>102°F), unilateral/ focal facial swelling or pain	*Initial therapy* Amoxicillin, 45–90 mg/kg qd (up to 2 g) PO in divided doses (bid or tid), *or* Cefuroxime axetil, 30 mg/kg qd PO in divided doses (bid), *or* Cefdinir, 14 mg/kg PO qd *Exposure to antibiotics within 30 d, recent treatment failure, or >30% prevalence of penicillin-resistant S. pneumoniae* Amoxicillin, 90 mg/kg qd (up to 2 g) PO in divided doses (bid), plus clavulanate, 6.4 mg/kg qd PO in divided doses (bid) (extra-strength suspension), *or* Cefuroxime axetil, 30 mg/kg qd PO in divided doses (bid), *or* Cefdinir, 14 mg/kg PO qd

[a]Unless otherwise specified, the duration of therapy is generally 10 d, with appropriate follow-up.
Note: DS, double-strength; TMP-SMX, trimethoprim-sulfamethoxazole.

which may persist for years. CT can be helpful in determining the extent of disease and the response to therapy. The management team should include an otolaryngologist to conduct endoscopic examinations and obtain tissue samples for histologic examination and culture.

Chronic fungal sinusitis is a disease of immunocompetent hosts and is usually noninvasive, although slowly progressive invasive disease is sometimes seen. Noninvasive disease, which is typically associated with hyaline molds such as *Aspergillus* species and dematiaceous molds such as *Curvularia* or *Bipolaris* species, can present as a number of different scenarios. In mild, indolent disease, which usually occurs in the setting of repeated failures of antibacterial therapy, only nonspecific mucosal changes may be seen on sinus CT. Endoscopic surgery is usually curative in these patients, with no need for antifungal therapy. Another form of disease presents with long-standing, often unilateral symptoms and opacification of a single sinus on imaging studies as a result of a mycetoma (fungus ball) within the sinus. Treatment for this condition is also surgical, although systemic antifungal therapy may be warranted in the rare case where bony erosion occurs. A third form of disease, known as *allergic fungal sinusitis*, is seen in patients with a history of nasal polyposis and asthma, who often have had multiple sinus surgeries. Patients with this condition produce a thick, eosinophilic mucus with the consistency of peanut butter that contains sparse fungal hyphae on histologic examination. Patients often present with pansinusitis.

Rx CHRONIC SINUSITIS

Treatment of chronic bacterial sinusitis can be challenging and consists primarily of repeated culture-guided courses of antibiotics, sometimes for 3–4 weeks at a time; administration of intranasal glucocorticoids; and mechanical irrigation of the sinus with sterile saline solution. When this management approach fails, sinus surgery may be indicated and sometimes provides significant, albeit short-term, alleviation. Treatment of chronic fungal sinusitis consists of surgical removal of impacted mucus. Recurrence, unfortunately, is common.

INFECTIONS OF THE EAR AND MASTOID

Infections of the ear and associated structures can involve both the middle and external ear, including the skin, cartilage, periosteum, ear canal, and tympanic and mastoid cavities. Both viruses and bacteria are known causes of these infections, some of which result in significant morbidity if not treated appropriately.

INFECTIONS OF THE EXTERNAL EAR STRUCTURES

Infections involving the structures of the external ear are often difficult to differentiate from noninfectious inflammatory conditions with similar clinical manifestations. Clinicians should consider inflammatory disorders as a possible cause of external ear irritation, particularly in the absence of local or regional adenopathy. Aside from the more salient causes of inflammation such as trauma, insect bite, and overexposure to sunlight or extreme cold, the differential diagnosis should include less common conditions such as autoimmune disorders (e.g., lupus or relapsing polychondritis) and vasculitides (e.g., Wegener's granulomatosis).

Auricular Cellulitis Auricular cellulitis is an infection of the skin overlying the external ear and typically follows minor local trauma. It presents with the typical signs and symptoms of a skin/soft tissue infection, with tenderness, erythema, swelling, and warmth of the external ear (particularly the lobule) but without apparent involvement of the ear canal or inner structures. Treatment consists of warm compresses and oral antibiotics such as dicloxacillin that are active against typical skin and soft tissue pathogens (specifically, *S. aureus* and streptococci). IV antibiotics, such as a first-generation cephalosporin (e.g., cefazolin) or a penicillinase-resistant penicillin (e.g., nafcillin), are occasionally needed for more severe cases.

Perichondritis Perichondritis, an infection of the perichondrium of the auricular cartilage, typically follows local trauma (e.g., ear piercing, burns, or lacerations). Occasionally, when the infection spreads down to the cartilage of the pinna itself, patients may also have chondritis. The infection may closely resemble auricular cellulitis, with erythema, swelling, and extreme tenderness of the pinna, although the lobule is less often involved in perichondritis. The most common pathogens are *P. aeruginosa* and *S. aureus*, although other gram-negative and gram-positive organisms are occasionally involved. Treatment consists of systemic antibiotics active against both *P. aeruginosa* and *S. aureus*. An antipseudomonal penicillin (e.g., piperacillin) or a combination of a penicillinase-resistant penicillin plus an antipseudomonal quinolone (e.g., nafcillin plus ciprofloxacin) is typically used. Incision and drainage may be helpful for culture and for resolution of infection, which often takes weeks. When perichondritis fails to respond to adequate antimicrobial therapy, clinicians should consider a noninfectious inflammatory etiology; for example, relapsing polychondritis is often mistaken for infectious perichondritis.

Otitis Externa The term *otitis externa* refers to a collection of diseases involving primarily the auditory meatus. Otitis externa usually results from a combination of heat, retained moisture, and desquamation and

maceration of the epithelium of the outer ear canal. The disease exists in several forms: localized, diffuse, chronic, and invasive. All forms are predominantly bacterial in origin, with *P. aeruginosa* and *S. aureus* the most common pathogens.

Acute localized otitis externa (*furunculosis*) can develop in the outer third of the ear canal, where skin overlies cartilage and hair follicles are numerous. As in furunculosis elsewhere on the body, *S. aureus* is the usual pathogen, and treatment typically consists of an oral antistaphylococcal penicillin (e.g., dicloxacillin), with incision and drainage in cases of abscess formation.

Acute diffuse otitis externa is also known as *swimmer's ear*, although it can develop in patients who have not recently been swimming. Heat, humidity, and the loss of protective cerumen lead to excessive moisture and elevation of the pH in the ear canal, which in turn lead to skin maceration and irritation. Infection may then occur; the predominant pathogen is *P. aeruginosa*, although other gram-negative and gram-positive organisms have been recovered from patients with this condition. The illness often starts with itching and progresses to severe pain, which is usually triggered by manipulation of the pinna or tragus. The onset of pain is generally accompanied by the development of an erythematous, swollen ear canal, often with scant white, clumpy discharge. Treatment consists of cleansing the canal to remove debris and to enhance the activity of topical therapeutic agents—usually hypertonic saline or mixtures of alcohol and acetic acid. Inflammation can also be decreased by adding glucocorticoids to the treatment regimen or by using Burow's solution (aluminum acetate in water). Antibiotics are most effective when given topically. Otic mixtures provide adequate pathogen coverage; these preparations usually combine neomycin with polymyxin, with or without glucocorticoids.

Chronic otitis externa is caused primarily by repeated local irritation, most commonly arising from persistent drainage from a chronic middle-ear infection. Other causes of repeated irritation, such as insertion of cotton swabs or other foreign objects into the ear canal, can lead to this condition, as can rare chronic infections such as syphilis, tuberculosis, or leprosy. Chronic otitis externa typically presents as erythematous, scaling dermatitis in which the predominant symptom is pruritus rather than pain; this condition must be differentiated from several others that produce a similar clinical picture, such as atopic dermatitis, seborrheic dermatitis, psoriasis, and dermatomycosis. Therapy consists of identifying and treating or removing the offending process, although successful resolution is frequently difficult.

Invasive otitis externa, also known as *malignant* or *necrotizing* otitis externa, is an aggressive and potentially life-threatening disease that occurs predominantly in elderly diabetic patients and other immunocompromised patients. The disease begins in the external canal, progresses slowly over weeks to months, and often is difficult to distinguish from a severe case of chronic otitis externa because of the presence of purulent otorrhea and an erythematous swollen ear and external canal. Severe, deep-seated otalgia is often noted and can help differentiate invasive from chronic otitis externa. The characteristic finding on examination is granulation tissue in the posteroinferior wall of the external canal, near the junction of bone and cartilage. If left unchecked, the infection can migrate to the base of the skull (resulting in skull-base osteomyelitis) and on to the meninges and brain, with a high associated mortality rate. Cranial nerve involvement is occasionally seen, with the facial nerve usually affected first and most often. Thrombosis of the sigmoid sinus can occur if the infection extends to that area. CT, which can reveal osseous erosion of the temporal bone and skull base, can be used to help determine the extent of disease, as can gallium and technetium-99 scintigraphy studies. *P. aeruginosa* is by far the most common pathogen, although *S. aureus*, *Staphylococcus epidermidis*, *Aspergillus*, *Actinomyces*, and some gram-negative bacteria have also been associated with this disease. In all cases, the external ear canal should be cleansed and a biopsy specimen of the granulation tissue within the canal (or of deeper tissues) should be obtained for culture of the offending organism. IV antibiotic therapy is directed specifically toward the recovered pathogen. For *P. aeruginosa*, the regimen typically includes an antipseudomonal penicillin or cephalosporin (e.g., piperacillin or ceftazidime) with an aminoglycoside. A fluoroquinolone antibiotic is frequently used in place of the aminoglycoside and can even be administered orally, given the excellent bioavailability of this drug class. In addition, antibiotic drops containing an agent active against *Pseudomonas* (e.g., ciprofloxacin) are usually prescribed and are combined with glucocorticoids to reduce inflammation. Cases of invasive *Pseudomonas* otitis externa recognized in the early stages can sometimes be treated with oral and otic fluoroquinolones alone, albeit with close follow-up. Extensive surgical debridement, once an important component of the treatment approach, is now rarely indicated.

INFECTIONS OF MIDDLE-EAR STRUCTURES

Otitis media is an inflammatory condition of the middle ear that results from dysfunction of the eustachian tube in association with a number of illnesses, including URIs and chronic rhinosinusitis. The inflammatory response to these conditions leads to the development of a sterile transudate within the middle-ear and mastoid cavities. Infection may occur if bacteria or viruses from the nasopharynx contaminate this fluid, producing an acute (or sometimes chronic) illness.

Acute Otitis Media Acute otitis media results when pathogens from the nasopharynx are introduced into the inflammatory fluid collected in the middle ear (e.g., by nose blowing during a URI). The proliferation of these pathogens in this space leads to the development of the typical signs and symptoms of acute middle-ear infection. The diagnosis of acute otitis media requires the demonstration of fluid in the middle ear (with tympanic membrane immobility) and the accompanying signs or symptoms of local or systemic illness (Table 31-2).

ETIOLOGY Acute otitis media typically follows a viral URI. The causative viruses (most commonly RSV, influenza virus, rhinovirus, and enterovirus) can themselves cause subsequent acute otitis media; more often, they predispose the patient to bacterial otitis media. Studies using tympanocentesis have consistently found *S. pneumoniae* to be the most important bacterial cause, isolated in up to 35% of cases. *H. influenzae* (nontypable strains) and *M. catarrhalis* are also common bacterial causes of acute otitis media, and concern is increasing about community strains of MRSA as an emerging etiologic agent. Viruses, such as those mentioned above, have been recovered either alone or with bacteria in 17–40% of cases.

CLINICAL MANIFESTATIONS Fluid in the middle ear is typically demonstrated or confirmed with pneumatic otoscopy. In the absence of fluid, the tympanic membrane moves visibly with the application of positive and negative pressure, but this movement is dampened when fluid is present. With bacterial infection, the tympanic membrane can also be erythematous, bulging, or retracted and occasionally can spontaneously perforate. The signs and symptoms accompanying infection can be local or systemic, including otalgia, otorrhea, diminished hearing, fever, or irritability. Erythema of the tympanic membrane is often evident but is nonspecific as it is frequently seen in association with inflammation of the upper respiratory mucosa (e.g., during examination of young children). Other signs and symptoms that are occasionally reported include vertigo, nystagmus, and tinnitus.

℞ ACUTE OTITIS MEDIA

There has been considerable debate on the usefulness of antibiotics for the treatment of acute otitis media. Although most cases resolve clinically 1 week after the onset of illness, antibiotics appear to be of some benefit. A higher proportion of treated than of untreated patients are free of illness 3–5 days after diagnosis. The difficulty of predicting which patients will benefit from antibiotic therapy has led to different approaches. In the Netherlands, for instance, physicians typically manage acute otitis media with initial observation, administering anti-inflammatory agents for aggressive pain management and reserving antibiotics for high-risk patients, patients with complicated disease, or patients who do not improve after 48–72 h. In contrast, many experts in the United States continue to recommend antibiotic therapy for children <6 months old in light of the higher

TABLE 31-2 GUIDELINES FOR THE DIAGNOSIS AND TREATMENT OF ACUTE OTITIS MEDIA

Illness Severity	Diagnostic Criteria	Treatment Recommendations
Mild to moderate	Fluid in the middle ear, evidenced by decreased tympanic membrane mobility, air/fluid level behind tympanic membrane, bulging tympanic membrane, purulent otorrhea *and* Acute onset of signs and symptoms of middle-ear inflammation, including fever, otalgia, decreased hearing, tinnitus, vertigo, erythematous tympanic membrane	*Initial therapy* [a] Observation alone (symptom relief only)[b] *or* Amoxicillin, 80–90 mg/kg qd (up to 2 g) PO in divided doses (bid or tid), *or* Cefdinir, 14 mg/kg qd PO in 1 dose or divided doses (bid), *or* Cefuroxime, 30 mg/kg qd PO in divided doses (bid), *or* Azithromycin, 10 mg/kg qd PO on day 1 followed by 5 mg/kg qd PO for 4 d *Exposure to antibiotics within 30 d or recent treatment failure*[a,c] Amoxicillin, 90 mg/kg qd (up to 2 g) PO in divided doses (bid), plus clavulanate, 6.4 mg/kg qd PO in divided doses (bid), *or* Ceftriaxone, 50 mg/kg IV/IM qd for 3 d, *or* Clindamycin, 30–40 mg/kg qd PO in divided doses (tid)
Severe	As above, with temperature ≥39.0°C *or* Moderate to severe otalgia	*Initial therapy*[a] Amoxicillin, 90 mg/kg qd (up to 2 g) PO in divided doses (bid), plus clavulanate, 6.4 mg/kg qd PO in divided doses (bid), *or* Ceftriaxone, 50 mg/kg IV/IM qd for 3 d *Exposure to antibiotics within 30 d or recent treatment failure*[a,c] Ceftriaxone, 50 mg/kg IV/IM qd for 3 d, *or* Clindamycin, 30–40 mg/kg qd PO in divided doses (tid), *or* Consider tympanocentesis with culture

[a]Duration (unless otherwise specified): 10 d for patients <6 years old and patients with severe disease; 5–7 d (with consideration of observation only in previously healthy individuals with mild disease) for patients ≥6 years old.
[b]Observation (deferring antibacterial treatment for 48–72 h and limiting management to symptom relief) is an option for mild to moderate disease in children 6 months to 2 years of age with an uncertain diagnosis and for children ≥2 years of age.
[c]Failure to improve and/or clinical worsening after 48–72 h of observation or treatment.
Sources: American Academy of Pediatrics Subcommittee on Management of Acute Otitis Media, 2004; Dowell et al, 1998.

frequency of secondary complications in this young and functionally immunocompromised population. However, observation without antimicrobial therapy is now generally considered a reasonable option in the United States for mild to moderate disease in children 6 months to 2 years of age with an uncertain diagnosis and for children ≥2 years of age (Table 31-2).

Given that most studies of the etiologic agents of acute otitis media consistently document similar pathogen profiles, therapy is generally empirical except in those few cases where tympanocentesis is warranted—e.g., cases in newborns, cases refractory to therapy, and cases in patients who are severely ill or immunodeficient. Despite resistance to penicillin and amoxicillin in roughly one-quarter of *S. pneumoniae* isolates, one-third of *H. influenzae* isolates, and nearly all *M. catarrhalis* isolates, outcome studies continue to find that amoxicillin is as successful as any other agent, and it remains the drug of first choice in recommendations from multiple sources (Table 31-2). Therapy for uncomplicated acute otitis media is typically administered for 5–7 days to patients ≥6 years old; longer courses (e.g., 10 days) should be reserved for children <6 years old and patients with severe disease, in whom short-course therapy may be inadequate.

A switch in regimen is recommended if there is no clinical improvement by the third day of therapy, given the possibility of infection with a β-lactamase-producing strain of *H. influenzae* or *M. catarrhalis* or with a strain of penicillin-resistant *S. pneumoniae*. Decongestants and antihistamines are frequently used as adjunctive agents to reduce congestion and relieve obstruction of the eustachian tube, but clinical trials have yielded no significant evidence of benefit with either class of agents.

Recurrent Acute Otitis Media Recurrent acute otitis media (more than three episodes within 6 months or four episodes within 12 months) is generally due to relapse or reinfection, although data indicate that the majority of early recurrences are new infections. In general, the same pathogens responsible for acute otitis media cause recurrent disease; even so, the recommended treatment consists of antibiotics active against β-lactamase-producing organisms. Antibiotic prophylaxis [e.g., with trimethoprim-sulfamethoxazole (TMP-SMX) or amoxicillin] can reduce recurrences in patients with recurrent acute otitis media by an average of one episode per year, but this benefit is small compared with the cost of the drug and the high likelihood of colonization with antibiotic-resistant pathogens. Other approaches, including placement of tympanostomy tubes, adenoidectomy, and tonsillectomy plus adenoidectomy, are of questionable overall value, given the relatively small benefit compared with the potential for complications.

Serous Otitis Media In serous otitis media (otitis media with effusion), fluid is present in the middle ear for an extended period and in the absence of signs and symptoms of infection. In general, acute effusions are self-limited; most resolve in 2–4 weeks. In some cases, however (in particular after an episode of acute otitis media), effusions can persist for months. These chronic effusions are often associated with a significant hearing loss in the affected ear. In younger children, persistent effusions and decreased hearing can be associated with impairment of language acquisition skills. The great majority of cases of otitis media with effusion resolve spontaneously within 3 months without antibiotic therapy. Antibiotic therapy or myringotomy with insertion of tympanostomy tubes is typically reserved for patients in whom bilateral effusion (1) has persisted for at least 3 months and (2) is associated with significant bilateral hearing loss. With this conservative approach and the application of strict diagnostic criteria for acute otitis media and otitis media with effusion, it is estimated that 6–8 million courses of antibiotics could be avoided each year in the United States.

Chronic Otitis Media Chronic suppurative otitis media is characterized by persistent or recurrent purulent otorrhea in the setting of tympanic membrane perforation. Usually, there is also some degree of conductive hearing loss. This condition can be categorized as active or inactive. Inactive disease is characterized by a central perforation of the tympanic membrane, which allows drainage of purulent fluid from the middle ear. When the perforation is more peripheral, squamous epithelium from the auditory canal may invade the middle ear through the perforation, forming a mass of keratinaceous debris (*cholesteatoma*) at the site of invasion. This mass can enlarge and has the potential to erode bone and promote further infection, which can lead to meningitis, brain abscess, or paralysis of cranial nerve VII. Treatment of chronic active otitis media is surgical; mastoidectomy, myringoplasty, and tympanoplasty can be performed as outpatient surgical procedures, with an overall success rate of ~80%. Chronic inactive otitis media is more difficult to cure, usually requiring repeated courses of topical antibiotic drops during periods of drainage. Systemic antibiotics may offer better cure rates, but their role in the treatment of this condition remains unclear.

Mastoiditis Acute mastoiditis was relatively common among children before the introduction of antibiotics. Because the mastoid air cells connect with the middle ear, the process of fluid collection and infection is usually the same in the mastoid as in the middle ear. Early and frequent treatment of acute otitis media is most likely the reason that

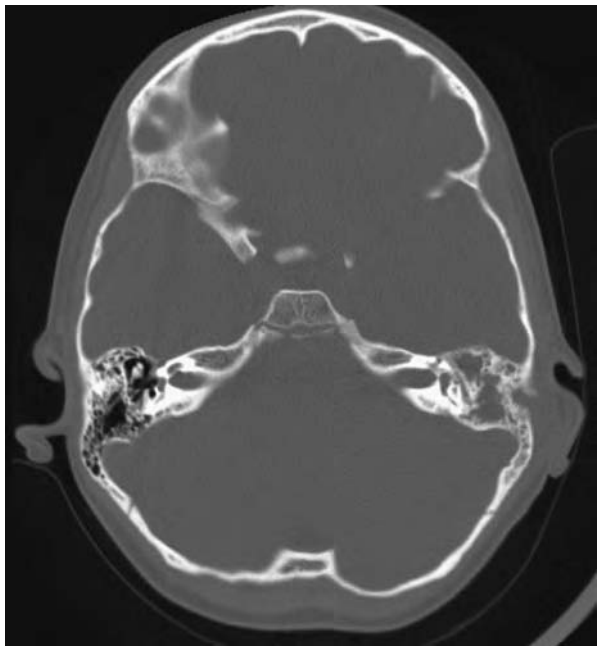

FIGURE 31-1 Acute mastoiditis. Axial CT image shows an acute fluid collection within the mastoid air cells on the left.

the incidence of acute mastoiditis has declined to only 1.2–2.0 cases per 100,000 person-years in countries with high prescribing rates for acute otitis media. In countries like the Netherlands, where antibiotics are used sparingly for acute otitis media, the incidence rate of acute mastoiditis is roughly twice that in countries like the United States. However, neighboring Denmark has a rate of acute mastoiditis similar to that in the Netherlands but an antibiotic-prescribing rate for acute otitis media more similar to that in the United States.

In typical acute mastoiditis, purulent exudate collects in the mastoid air cells (Fig. 31-1), producing pressure that may result in erosion of the surrounding bone and the formation of abscess-like cavities that are usually evident on CT. Patients typically present with pain, erythema, and swelling of the mastoid process along with displacement of the pinna, usually in conjunction with the typical signs and symptoms of acute middle-ear infection. Rarely, patients can develop severe complications if the infection tracks under the periosteum of the temporal bone to cause a subperiosteal abscess, erodes through the mastoid tip to cause a deep neck abscess, or extends posteriorly to cause septic thrombosis of the lateral sinus.

Purulent fluid should be cultured whenever possible to help guide antimicrobial therapy. Initial empirical therapy is usually directed against the typical organisms associated with acute otitis media, such as *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Some patients with more severe or prolonged courses of illness should be treated for infection with *S. aureus* and gram-negative bacilli (including *Pseudomonas*). Broad empirical therapy is usually narrowed once culture results become available. Most patients can be treated conservatively with IV antibiotics; surgery (cortical mastoidectomy) can be reserved for complicated cases and those in which conservative treatment has failed.

INFECTIONS OF THE PHARYNX AND ORAL CAVITY

Oropharyngeal infections range from mild, self-limited viral illnesses to serious, life-threatening bacterial infections. The most common presenting symptom is sore throat—one of the most frequent reasons for ambulatory care visits by both adults and children. Although sore throat is a symptom in many noninfectious illnesses as well, the overwhelming majority of patients with a new sore throat have acute pharyngitis of viral or bacterial etiology.

ACUTE PHARYNGITIS

Millions of visits to primary care providers each year are for sore throat; the majority of cases of acute pharyngitis are caused by typical respiratory viruses. The most important source of concern is infection with group A β-hemolytic *Streptococcus* (*S. pyogenes*), which is associated with acute glomerulonephritis and acute rheumatic fever. The risk of rheumatic fever can be reduced by timely penicillin therapy.

Etiology A wide variety of organisms cause acute pharyngitis. The relative importance of the different pathogens can only be estimated, since a significant proportion of cases (~30%) have no identified cause. Together, respiratory viruses are the most common identifiable cause of acute pharyngitis, with rhinoviruses and coronaviruses accounting for large proportions of cases (~20% and at least 5%, respectively). Influenza virus, parainfluenza virus, and adenovirus also account for a measurable share of cases, the latter as part of the more clinically severe syndrome of pharyngoconjunctival fever. Other important but less common viral causes include herpes simplex virus (HSV) types 1 and 2, coxsackievirus A, cytomegalovirus (CMV), and Epstein-Barr virus (EBV). Acute HIV infection can present as acute pharyngitis and should be considered in high-risk populations.

Acute bacterial pharyngitis is typically caused by *S. pyogenes*, which accounts for ~5–15% of all cases of acute pharyngitis in adults; rates vary with the season and with utilization of the health care system. Group A streptococcal pharyngitis is primarily a disease of children 5–15 years of age; it is uncommon among children <3 years old, as is rheumatic fever. Streptococci of groups C and G account for a minority of cases, although these serogroups are nonrheumatogenic. The remaining bacterial causes of acute pharyngitis are seen infrequently (<1% each) but should be considered in appropriate exposure groups because of the severity of illness if left untreated; these etiologic agents include *Neisseria gonorrhoeae*, *Corynebacterium diphtheriae*, *Corynebacterium ulcerans*, *Yersinia enterocolitica*, and *Treponema pallidum* (in secondary syphilis). Anaerobic bacteria can also cause acute pharyngitis (*Vincent's angina*) and can contribute to more serious polymicrobial infections, such as peritonsillar or retropharyngeal abscess (see below). Atypical organisms such as *M. pneumoniae* and *C. pneumoniae* have been recovered from patients with acute pharyngitis; whether these agents are commensals or causes of acute infection is debatable.

Clinical Manifestations Although the signs and symptoms accompanying acute pharyngitis are not reliable predictors of the etiologic agent, the clinical presentation occasionally suggests that one etiology is more likely than another. Acute pharyngitis due to respiratory viruses such as rhinovirus or coronavirus is usually not severe and is typically associated with a constellation of coryzal symptoms better characterized as nonspecific URI. Findings on physical examination are uncommon; fever is rare, and tender cervical adenopathy and pharyngeal exudates are not seen. In contrast, acute pharyngitis from influenza virus can be severe and is much more likely to be associated with fever as well as with myalgias, headache, and cough. The presentation of pharyngoconjunctival fever due to adenovirus infection is similar. Since pharyngeal exudate may be present on examination, this condition can be difficult to differentiate from streptococcal pharyngitis. However, adenoviral pharyngitis is distinguished by the presence of conjunctivitis in one-third to one-half of patients. Acute pharyngitis from primary HSV infection can also mimic streptococcal pharyngitis in some cases, with pharyngeal inflammation and exudate, but the presence of vesicles and shallow ulcers on the palate can help differentiate the two diseases. This HSV syndrome is distinct from pharyngitis caused by coxsackievirus (*herpangina*), which is associated with small vesicles that develop on the soft palate and uvula and then rupture to form shallow white ulcers. Acute exudative pharyngitis coupled with fever, fatigue, generalized lymphadenopathy, and (on occasion) splenomegaly is characteristic of infectious mononucleosis due to EBV or CMV. Acute primary infection with HIV is frequently associated with fever and acute pharyngitis as well as with myalgias, arthralgias, malaise, and occasionally a nonpruritic maculopapular rash, which later may be followed by lymphadenopathy and mucosal ulcerations without exudate.

The clinical features of acute pharyngitis caused by streptococci of groups A, C, and G are all similar, ranging from a relatively mild illness without many accompanying symptoms to clinically severe cases with

profound pharyngeal pain, fever, chills, and abdominal pain. A hyperemic pharyngeal membrane with tonsillar hypertrophy and exudate is usually seen, along with tender anterior cervical adenopathy. Coryzal manifestations, including cough, are typically absent; when present, they suggest a viral etiology. Strains of *S. pyogenes* that generate erythrogenic toxin can also produce scarlet fever characterized by an erythematous rash and strawberry tongue. The other types of acute bacterial pharyngitis (e.g., gonococcal, diphtherial, and yersinial) often present as exudative pharyngitis with or without other clinical features. Their etiologies are often suggested only by the clinical history.

TABLE 31-3 GUIDELINES FOR THE DIAGNOSIS AND TREATMENT OF ACUTE PHARYNGITIS

Age Group	Diagnostic Criteria	Treatment Recommendations[a]
Adults	*Clinical suspicion of streptococcal pharyngitis* (e.g., fever, tonsillar swelling, exudate, enlarged/tender anterior cervical lymph nodes, absence of cough or coryza)[b] *with:* History of rheumatic fever *or* Documented household exposure *or* Positive rapid strep screen	Penicillin V, 500 mg PO tid, *or* Amoxicillin, 500 mg PO bid, *or* Erythromycin, 250 mg PO qid, *or* Benzathine penicillin G, single dose of 1.2 million units IM
Children	*Clinical suspicion of streptococcal pharyngitis* (e.g., tonsillar swelling, exudate, enlarged/tender anterior cervical lymph nodes, absence of coryza) *with:* History of rheumatic fever *or* Documented household exposure *or* Positive rapid strep screen *or* Positive throat culture (for patients with negative rapid strep screen)	Amoxicillin, 45 mg/kg qd PO in divided doses (bid or tid), *or* Penicillin VK, 50 mg/kg qd PO in divided doses (bid), *or* Cephalexin, 50 mg/kg qd PO in divided doses (qid), *or* Benzathine penicillin G, single dose of 25,000 units/kg IM

[a]Unless otherwise specified, the duration of therapy is generally 10 d, with appropriate follow-up.
[b]Some organizations support treating adults who have these symptoms and signs without administering a rapid streptococcal antigen test.
Sources: Cooper et al, 2001; Schwartz et al, 1998.

Diagnosis The primary goal of diagnostic testing is to separate acute streptococcal pharyngitis from pharyngitis of other etiologies (particularly viral) so that antibiotics can be prescribed more efficiently for patients to whom they may be beneficial. The most appropriate standard for the diagnosis of streptococcal pharyngitis, however, has not been definitively established. Throat swab culture is generally regarded as such. However, this method cannot distinguish between infection and colonization, and it takes 24–48 h to yield results that vary according to technique and culture conditions. Rapid antigen-detection tests offer good specificity (>90%) but lower sensitivity when implemented in routine practice. The sensitivity has also been shown to vary across the clinical spectrum of disease (65–90%). Several clinical prediction systems (Table 31-3) can increase the sensitivity of rapid antigen-detection tests to >90% in controlled settings. Since the sensitivities achieved in routine clinical practice are often lower, several medical and professional societies continue to recommend that all negative rapid antigen-detection tests in children be confirmed by a throat culture to limit transmission and complications of illness caused by group A streptococci. The Centers for Disease Control and Prevention, the Infectious Diseases Society of America, the American College of Physicians, and the American Academy of Family Physicians do not recommend backup culture when adults have negative results in a high-sensitivity, rapid antigen-detection test, however, given the lower prevalence and smaller benefit in this age group.

Cultures and rapid diagnostic tests for other causes of acute pharyngitis, such as influenza virus, adenovirus, HSV, EBV, CMV, and *M. pneumoniae*, are available in some locations and can be used when these infections are suspected. The diagnosis of acute EBV infection depends primarily on the detection of antibodies to the virus with a heterophile agglutination assay (monospot slide test) or enzyme-linked immunosorbent assay. Testing for HIV RNA or antigen (p24) should be performed when acute primary HIV infection is suspected. If other bacterial causes are suspected (particularly *N. gonorrhoeae*, *C. diphtheriae*, or *Y. enterocolitica*), specific cultures should be requested since these organisms may be missed on routine throat swab culture.

Rx PHARYNGITIS

Antibiotic treatment of pharyngitis due to *S. pyogenes* confers numerous benefits, including a decrease in the risk of rheumatic fever. The magnitude of this benefit is fairly small, however, since rheumatic fever is now a rare disease, even among untreated patients. When therapy is started within 48 h of illness onset, however, symptom duration is also decreased. An additional benefit of therapy is the potential to reduce the spread of streptococcal pharyngitis, particularly in areas of overcrowding or close contact. Antibiotic therapy for acute pharyngitis is therefore recommended in cases where *S. pyogenes* is confirmed as the etiologic agent by rapid antigen-detection test or throat swab culture. Otherwise, antibiotics should be given in routine cases only when another bacterial cause has been identified. Effective therapy for streptococcal pharyngitis consists of either a single dose of IM benzathine penicillin or a full 10-day course of oral penicillin (Table 31-3). Erythromycin can be used in place of penicillin, although resistance to erythromycin among *S. pyogenes* strains in some parts of the world (particularly Europe) can prohibit the use of this drug. Newer (and more expensive) antibiotics are also active against streptococci but offer no greater efficacy than the above agents. Testing for cure is unnecessary and may reveal only chronic colonization. There is no evidence to support antibiotic treatment of group C or G streptococcal pharyngitis or of pharyngitis in which *Mycoplasma* or *Chlamydophila* has been recovered. Penicillin prophylaxis (benzathine penicillin G, 1.2 million units IM every 3–4 weeks) is indicated for patients at risk of recurrent rheumatic fever.

Treatment of viral pharyngitis is entirely symptom-based except in infection with influenza virus or HSV. For influenza, a number of therapeutic agents exist, including amantadine, rimantadine, and the two newer agents oseltamivir and zanamivir. All of these agents need to be started within 36–48 h of symptom onset to reduce illness duration meaningfully. Of these agents, only oseltamivir and zanamivir are active against both influenza A and influenza B and therefore can be used when local infection patterns are unknown. Oropharyngeal HSV infection sometimes responds to treatment with antiviral agents such as acyclovir, although these drugs are often reserved for immunosuppressed patients.

Complications Although rheumatic fever is the best-known complication of acute streptococcal pharyngitis, the risk of its following acute infection remains quite low. Other complications include acute glomerulonephritis and numerous suppurative conditions, such as peritonsillar abscess (*quinsy*), otitis media, mastoiditis, sinusitis, bacteremia, and pneumonia—all of which occur at low rates. Although antibiotic treatment of acute streptococcal pharyngitis can prevent the development of rheumatic fever, there is no evidence that it can prevent acute glomerulonephritis. Some evidence supports antibiotic use to prevent the suppurative complications of streptococcal pharyngitis, particularly peritonsillar abscess, which can also involve oral anaerobes such as *Fusobacterium*. Abscesses are usually accompanied by severe pharyngeal pain, dysphagia, fever, and dehydration; in addition, medial displacement of the tonsil and lateral displacement of the uvula are often evident on examination. Although early use of IV antibiotics (e.g., clindamycin; penicillin G with metronidazole) may obviate the need for surgical drainage in some cases, treatment typically involves needle aspiration or incision and drainage.

ORAL INFECTIONS

Aside from periodontal disease such as gingivitis, infections of the oral cavity most commonly involve HSV or *Candida* species. In addition to causing painful cold sores on the lips, HSV can infect the tongue and buccal mucosa, causing the formation of irritating vesicles. Although topical

antiviral agents (e.g., acyclovir and penciclovir) can be used externally for cold sores, oral or IV acyclovir is often needed for primary infections, extensive oral infections, and infections in immunocompromised patients. Oropharyngeal candidiasis (*thrush*) is caused by a variety of *Candida* species, most often *C. albicans*. Thrush occurs predominantly in neonates, immunocompromised patients (especially those with AIDS), and recipients of prolonged antibiotic or glucocorticoid therapy. In addition to sore throat, patients often report a burning tongue, and physical examination reveals friable white or gray plaques on the gingiva, tongue, and oral mucosa. Treatment, which usually consists of an oral antifungal suspension (nystatin or clotrimazole) or oral fluconazole, is frequently successful. In the uncommon cases of fluconazole-refractory thrush that are seen in some patients with AIDS, other therapeutic options include oral formulations of itraconazole, amphotericin B, or voriconazole as well as the IV echinocandins (caspofungin, micafungin, and anidulafungin).

Vincent's angina, also known as *acute necrotizing ulcerative gingivitis* or *trench mouth*, is a unique and dramatic form of gingivitis characterized by painful, inflamed gingiva with ulcerations of the interdental papillae that bleed easily. Since oral anaerobes are the cause, patients typically have halitosis and frequently present with fever, malaise, and lymphadenopathy. Treatment consists of debridement and oral administration of penicillin plus metronidazole, with clindamycin alone as an alternative.

Ludwig's angina is a rapidly progressive, potentially fulminant cellulitis that involves the sublingual and submandibular spaces and that typically originates from an infected or recently extracted tooth, most commonly the lower second and third molars. Improved dental care has substantially reduced the incidence of this disorder. Infection in these areas leads to dysphagia, odynophagia, and "woody" edema in the sublingual region, forcing the tongue up and back with the potential for airway obstruction. Fever, dysarthria, and drooling may also be noted, and patients may speak in a "hot potato" voice. Intubation or tracheostomy may be necessary to secure the airway, as asphyxiation is the most common cause of death. Patients should be monitored closely and treated promptly with IV antibiotics directed against streptococci and oral anaerobes. Recommended agents include ampicillin/sulbactam and high-dose penicillin plus metronidazole.

Postanginal septicemia (*Lemierre's disease*) is a rare anaerobic oropharyngeal infection caused predominantly by *Fusobacterium necrophorum*. The illness typically starts as a sore throat (most commonly in adolescents and young adults), which may present as exudative tonsillitis or peritonsillar abscess. Infection of the deep pharyngeal tissue allows organisms to drain into the lateral pharyngeal space, which contains the carotid artery and internal jugular vein. Septic thrombophlebitis of the internal jugular vein can result, with associated pain, dysphagia, and neck swelling and stiffness. Sepsis usually occurs 3–10 days after the onset of sore throat and is often coupled with metastatic infection to the lung and other distant sites. Occasionally, the infection can extend along the carotid sheath and into the posterior mediastinum, resulting in mediastinitis, or it can erode into the carotid artery, with the early sign of repeated small bleeds into the mouth. The mortality rate from these invasive infections can be as high as 50%. Treatment consists of IV antibiotics (penicillin G or clindamycin) and surgical drainage of any purulent collections. The concomitant use of anticoagulants to prevent embolization remains controversial but is often advised.

INFECTIONS OF THE LARYNX AND EPIGLOTTIS

LARYNGITIS

Laryngitis is defined as any inflammatory process involving the larynx and can be caused by a variety of infectious and noninfectious processes. The vast majority of laryngitis cases seen in clinical practice in developed countries are acute. Acute laryngitis is a common syndrome caused predominantly by the same viruses responsible for many other URIs. In fact, most cases of acute laryngitis occur in the setting of a viral URI.

Etiology Nearly all major respiratory viruses have been implicated in acute viral laryngitis, including rhinovirus, influenza virus, parainfluenza virus, adenovirus, coxsackievirus, coronavirus, and RSV. Acute laryngitis can also be associated with acute bacterial respiratory infections, such as those caused by group A *Streptococcus* or *C. diphtheriae* (although diphtheria has been all but eliminated in the United States). Another bacterial pathogen thought to play a role (albeit unclear) in the pathogenesis of acute laryngitis is *M. catarrhalis*, which has been recovered on nasopharyngeal culture from a significant percentage of people with acute laryngitis. Chronic laryngitis of infectious etiology is much less common in developed than in developing countries. Laryngitis due to *Mycobacterium tuberculosis* is often difficult to distinguish from laryngeal cancer, in part because of the frequent absence of signs, symptoms, and radiographic findings typical of pulmonary disease. *Histoplasma* and *Blastomyces* may cause laryngitis, often as a complication of systemic infection. *Candida* species can cause laryngitis as well, often in association with thrush or esophagitis and particularly in immunosuppressed patients. Rare cases of chronic laryngitis are due to *Coccidioides* and *Cryptococcus*.

Clinical Manifestations Laryngitis is characterized by hoarseness and can also be associated with reduced vocal pitch or aphonia. As acute laryngitis is caused predominantly by respiratory viruses, these symptoms usually occur in association with other symptoms and signs of URI, including rhinorrhea, nasal congestion, cough, and sore throat. Direct laryngoscopy often reveals diffuse laryngeal erythema and edema, along with vascular engorgement of the vocal folds. In addition, chronic disease (e.g., tuberculous laryngitis) often includes mucosal nodules and ulcerations visible on laryngoscopy; these lesions are sometimes mistaken for laryngeal cancer.

℞ LARYNGITIS

Acute laryngitis is usually treated with humidification and voice rest alone. Antibiotics are not recommended except when group A *Streptococcus* is cultured, in which case penicillin is the drug of choice. The choice of therapy for chronic laryngitis depends on the pathogen, whose identification usually requires biopsy with culture. Patients with laryngeal tuberculosis are highly contagious because of the large number of organisms that are easily aerosolized. These patients should be managed in the same way as patients with active pulmonary disease.

CROUP

The term *croup* actually denotes a group of diseases collectively referred to as "croup syndrome," all of which are acute and predominantly viral respiratory illnesses characterized by marked swelling of the subglottic region of the larynx. Croup primarily affects children <6 years old. For a detailed discussion of this entity, the reader is referred to a text of pediatric medicine.

EPIGLOTTITIS

Acute epiglottitis (supraglottitis) is an acute, rapidly progressive cellulitis of the epiglottis and adjacent structures that can result in complete—and potentially fatal—airway obstruction in both children and adults. Before the widespread use of *H. influenzae* type b (Hib) vaccine, this entity was much more common among children, with a peak incidence at ~3.5 years of age. In some countries, mass vaccination against Hib has reduced the annual incidence of acute epiglottitis in children by >90%; in contrast, the annual incidence in adults has changed little since the introduction of Hib vaccine. Because of the danger of airway obstruction, acute epiglottitis constitutes a medical emergency, particularly in children, and prompt diagnosis and airway protection are of utmost importance.

Etiology After the introduction of the Hib vaccine in the mid-1980s, disease incidence among children in the United States declined dramatically. Nevertheless, lack of vaccination or vaccine failure has meant that many pediatric cases seen today are still due to Hib. In adults and (more recently) in children, a variety of other bacterial pathogens have been associated with epiglottitis, the most common

FIGURE 31-2 Acute epiglottitis. In this lateral soft tissue radiograph of the neck, the arrow indicates the enlarged edematous epiglottis (the "thumbprint sign").

being group A *Streptococcus*. Other pathogens seen less frequently include *S. pneumoniae*, *Haemophilus parainfluenzae*, and *S. aureus*. Viruses have not yet been established as causes of acute epiglottitis.

Clinical Manifestations and Diagnosis Epiglottitis typically presents more acutely in young children than in adolescents or adults. On presentation, most children have had symptoms for <24 h, including high fever, severe sore throat, tachycardia, systemic toxicity, and (in many cases) drooling while sitting forward. Symptoms and signs of respiratory obstruction may also be present and may progress rapidly. The somewhat milder illness in adolescents and adults often follows 1–2 days of severe sore throat and is commonly accompanied by dyspnea, drooling, and stridor. Physical examination of patients with acute epiglottitis may reveal moderate or severe respiratory distress, with inspiratory stridor and retractions of the chest wall. These findings *diminish* as the disease progresses and the patient tires. Conversely, oropharyngeal examination reveals injection that is much less severe than would be predicted from the symptoms—a finding that should alert the clinician to a cause of symptoms and obstruction that lies beyond the tonsils. The diagnosis is often made on clinical grounds, although direct fiberoptic laryngoscopy is frequently performed in a controlled environment (e.g., an operating room) in order to visualize and culture the typical edematous "cherry-red" epiglottis and to facilitate placement of an endotracheal tube. Direct visualization in an examination room (e.g., with a tongue blade and indirect laryngoscopy) is not recommended because of the risk of immediate laryngospasm and complete airway obstruction. Lateral neck radiographs and laboratory tests can assist in the diagnosis but may delay the critical securing of the airway and cause the patient to be moved or repositioned more than is necessary, thereby increasing the risk of further airway compromise. Neck radiographs typically reveal an enlarged edematous epiglottis (the "thumbprint sign," Fig. 31-2), usually with a dilated hypopharynx and normal subglottic structures. Laboratory tests characteristically document mild to moderate leukocytosis with a predominance of neutrophils. Blood cultures are positive in a significant proportion of cases.

℞ EPIGLOTTITIS

Security of the airway is always of primary concern in acute epiglottitis, even if the diagnosis is only suspected. Mere observation for signs of impending airway obstruction is not routinely recommended, particularly in children. Many adults have been managed with observation only since the illness is perceived to be milder in this age group, but some data suggest that this approach may be risky and probably should be reserved only for adult patients who have yet to develop dyspnea or stridor. Once the airway has been secured and specimens of blood and epiglottis tissue have been obtained for culture, treatment with IV antibiotics should be given to cover the most likely organisms, particularly *H. influenzae*. Because rates of ampicillin resistance in this organism have risen significantly in recent years, therapy with a β-lactam/β-lactamase inhibitor combination or a second- or third-generation cephalosporin is recommended. Typically, ampicillin/sulbactam, cefuroxime, cefotaxime, or ceftriaxone is given, with clindamycin and TMP-SMX reserved for patients allergic to β-lactams. Antibiotic therapy should be continued for 7–10 days and should be tailored, if necessary, to the organism recovered in culture. If the household contacts of a patient with *H. influenzae* epiglottitis include an unvaccinated child under the age of 4, all members of the household (including the patient) should receive prophylactic rifampin for 4 days to eradicate carriage of *H. influenzae*.

INFECTIONS OF THE DEEP NECK STRUCTURES

Deep neck infections are usually extensions of infection from other primary sites, most often within the pharynx or oral cavity. Many of these infections are life-threatening but are difficult to detect at early stages when they may be more easily managed. Three of the most clinically relevant spaces in the neck are the submandibular (and sublingual) space, the lateral pharyngeal (or parapharyngeal) space, and the retropharyngeal space. These spaces communicate with one another and with other important structures in the head, neck, and thorax, providing pathogens with easy access to areas including the mediastinum, carotid sheath, skull base, and meninges. Once infection reaches these sensitive areas, mortality rates can be as high as 20–50%.

Infection of the submandibular and/or sublingual space typically originates from an infected or recently extracted lower tooth. The result is the severe, life-threatening infection referred to as Ludwig's angina (see "Oral Infections," above). Infection of the lateral pharyngeal (or parapharyngeal) space is most often a complication of common infections of the oral cavity and upper respiratory tract, including tonsillitis, peritonsillar abscess, pharyngitis, mastoiditis, or periodontal infection. This space, located deep to the lateral wall of the pharynx, contains a number of sensitive structures, including the carotid artery, internal jugular vein, cervical sympathetic chain, and portions of cranial nerves IX through XII; at its distal end, it opens into the posterior mediastinum. Involvement of this space with infection can therefore be rapidly fatal. Examination may reveal some tonsillar displacement, trismus, and neck rigidity, but swelling of the lateral pharyngeal wall can easily be missed. The diagnosis can be confirmed by CT. Treatment consists of airway management, operative drainage of fluid collections, and at least 10 days of IV therapy with an antibiotic active against streptococci and oral anaerobes (e.g., ampicillin/sulbactam). A particularly severe form of this infection involving the components of the carotid sheath (postanginal septicemia, Lemierre's disease) is described above (see "Oral Infections"). Infection of the retropharyngeal space can also be extremely dangerous, as this space runs posterior to the pharynx from the skull base to the superior mediastinum. Infections in this space are more common among children <5 years old because of the presence of several small retropharyngeal lymph nodes that typically atrophy by the age of 4 years. Infection is usually a consequence of extension from another site of infection, most commonly acute pharyngitis. Other sources include otitis media, tonsillitis, dental infections, Ludwig's angina, and anterior extension of vertebral osteomyelitis. Retropharyngeal space infection can also follow penetrating trauma to the posterior pharynx (e.g., from an endoscopic procedure). Infections are commonly polymicrobial, involving a mixture of aerobes and anaerobes; group A β-hemolytic streptococci and *S. aureus* are the most common pathogens. *M. tuberculosis* was a frequent cause in the past but now is rarely involved in the United States.

Patients with retropharyngeal abscess typically present with sore throat, fever, dysphagia, and neck pain and are often drooling because of difficulty and pain with swallowing. Examination may reveal tender cervical adenopathy, neck swelling, and diffuse erythema and edema of the posterior pharynx as well as a bulge in the posterior pharyngeal wall that

may not be obvious on routine inspection. A soft tissue mass is usually demonstrable by lateral neck radiography or CT. Because of the risk of airway obstruction, treatment begins with securing of the airway, which is followed by a combination of surgical drainage and IV antibiotic administration. Initial empirical therapy should cover streptococci, oral anaerobes, and *S. aureus*; ampicillin/sulbactam, clindamycin alone, or clindamycin plus ceftriaxone is usually effective. Complications result primarily from extension to other areas; for example, rupture into the posterior pharynx may lead to aspiration pneumonia and empyema. Extension may also occur to the lateral pharyngeal space and mediastinum, resulting in mediastinitis and pericarditis, or into nearby major blood vessels. All these events are associated with a high mortality rate.

32 Oral Manifestations of Disease

Samuel C. Durso

As primary care physicians and consultants, internists are often asked to evaluate patients with disease of the oral soft tissues, teeth, and pharynx. Knowledge of the oral milieu and its unique structures is necessary to guide preventive services and recognize oral manifestations of local or systemic disease (**Chap. e7**). Furthermore, internists frequently collaborate with dentists in the care of patients who have a variety of medical conditions that affect oral health or who undergo dental procedures that increase their risk of medical complications.

DISEASES OF THE TEETH AND PERIODONTAL STRUCTURES

TOOTH AND PERIODONTAL STRUCTURE

Tooth formation begins during the sixth week of embryonic life and continues through the first 17 years of age. Tooth development begins in utero and continues until after the tooth erupts. Normally all 20 deciduous teeth have erupted by age 3 and have been shed by age 13. Permanent teeth, eventually totaling 32, begin to erupt by age 6 and have completely erupted by age 14, though third molars (wisdom teeth) may erupt later.

The erupted tooth consists of the visible crown covered with enamel and the root submerged below the gum line and covered with bonelike cementum. *Dentin*, a material that is denser than bone and exquisitely sensitive to pain, forms the majority of the tooth substance. Dentin surrounds a core of myxomatous *pulp* containing the vascular and nerve supply. The tooth is held firmly in the alveolar socket by the *periodontium*, supporting structures that consist of the gingivae, alveolar bone, cementum, and periodontal ligament. The periodontal ligament tenaciously binds the tooth's cementum to the alveolar bone. Above this ligament is a collar of attached gingiva just below the crown. A few millimeters of unattached or free gingiva (1–3 mm) overlap the base of the crown, forming a shallow sulcus along the gum-tooth margin.

Dental Caries, Pulpal and Periapical Disease, and Complications Dental caries begin asymptomatically as a destructive process of the hard surface of the tooth. *Streptococcus mutans*, principally, along with other bacteria colonize the organic buffering film on the tooth surface to produce *plaque*. If not removed by brushing or the natural cleaning action of saliva and oral soft tissues, bacterial acids demineralize the enamel. Fissures and pits on the occlusion surfaces are the most frequent sites of decay. Surfaces adjacent to tooth restorations and exposed roots are also vulnerable, particularly as teeth are retained in an aging population. Over time, dental caries extend to the underlying dentin, leading to cavitation of the enamel and ultimately penetration to the tooth pulp, producing *acute pulpitis*. At this early stage, when the pulp infection is limited, the tooth becomes sensitive to percussion and hot or cold, and pain resolves immediately when the irritating stimulus is removed. Should the infection spread throughout the pulp, *irreversible pulpitis* occurs, leading to pulp necrosis. At this late stage pain is severe and has a sharp or throbbing visceral quality that may be worse when the patient lies down. Once pulp necrosis is complete, pain may be constant or intermittent, but cold sensitivity is lost.

Treatment of caries involves removal of the softened and infected hard tissue; sealing the exposed dentin; and restoration of the tooth structure with silver amalgam, composite plastic, gold, or porcelain. Once irreversible pulpitis occurs, root canal therapy is necessary, and the contents of the pulp chamber and root canals are removed, followed by thorough cleaning, antisepsis, and filling with an inert material. Alternatively, the tooth may be extracted.

Pulpal infection, if it does not egress through the decayed enamel, leads to *periapical abscess* formation, which produces pain on chewing. If the infection is mild and chronic, a *periapical granuloma* or eventually a *periapical cyst* forms, either of which produces radiolucency at the root apex. When unchecked, a periapical abscess can erode into the alveolar bone producing osteomyelitis, penetrate and drain through the gingivae (parulis or gumboil), or track along deep fascial planes, producing a virulent cellulitis (Ludwig's angina) involving the submandibular space and floor of the mouth (Chap. 157). Elderly patients, those with diabetes mellitus, and patients taking glucocorticoids may experience little or no pain and fever as these complications develop.

Periodontal Disease Periodontal disease accounts for more tooth loss than caries, particularly in the elderly. Like dental caries, chronic infection of the gingiva and anchoring structures of the tooth begins with formation of bacterial plaque. The process begins invisibly above the gum line and in the gingival sulcus. Plaque, including mineralized plaque (calculus), is preventable by appropriate dental hygiene, including periodic professional cleaning. Left undisturbed, chronic inflammation ensues and produces a painless hyperemia of the free and attached gingivae (*gingivitis*) that typically bleeds with brushing. If ignored, severe *periodontitis* occurs, leading to deepening of the physiologic sulcus and destruction of the periodontal ligament. Pockets develop around the teeth and become filled with pus and debris. As the periodontium is

destroyed, teeth loosen and exfoliate. Eventually there is resorption of the alveolar bone. A role for the chronic inflammation resulting from chronic periodontal disease in promoting coronary heart disease and stroke has been proposed. Epidemiologic studies demonstrate a moderate but significant association between chronic periodontal inflammation and atherogenesis, though a causal role remains unproven.

Acute and aggressive forms of periodontal disease are less common than the chronic forms described above. However, if the host is stressed or exposed to a new pathogen, rapidly progressive and destructive disease of the periodontal tissue can occur. A virulent example is *acute necrotizing ulcerative gingivitis* (ANUG), or *Vincent's infection*, characterized as "trench mouth" during World War I. Stress, poor oral hygiene, and tobacco and alcohol use are risk factors. The presentation includes sudden gingival inflammation, ulceration, bleeding, interdental gingival necrosis, and fetid halitosis. *Localized juvenile periodontitis*, seen in adolescents, is particularly destructive and appears to be associated with impaired neutrophil chemotaxis. *AIDS-related periodontitis* resembles ANUG in some patients or a more destructive form of adult chronic periodontitis in others. It may also produce a gangrene-like destructive process of the oral soft tissues and bone that resembles *noma*, seen in severely malnourished children in developing nations.

Prevention of Tooth Decay and Periodontal Infection Despite the reduced prevalence of dental caries and periodontal disease in the United States due in large part to water fluoridation and improved dental care, respectively, both diseases constitute a major public health problem worldwide and for certain groups. The internist should promote preventive dental care and hygiene as part of health maintenance. Special populations at high risk for dental caries and periodontal disease include those with xerostomia, diabetics, alcoholics, tobacco users, those with Down's syndrome, and those with gingival hyperplasia. Furthermore, patients lacking dental care access (low socioeconomic status) and those with reduced ability to provide self-care (e.g., nursing home residents, those with dementia or upper extremity disability) suffer at a disproportionate rate. It is important to provide counseling regarding regular dental hygiene and professional cleaning, use of fluoride-containing toothpaste, professional fluoride treatments, and use of electric toothbrushes for patients with limited dexterity and to give instruction to caregivers for those unable to perform self-care. Internists caring for international students studying in the United States should be aware of the high prevalence of dental decay in this population. Cost, fear of dental care, and language and cultural differences may create barriers that prevent some from seeking preventive dental services.

Developmental and Systemic Disease Affecting the Teeth and Periodontium Malocclusion is the most common developmental problem, which, in addition to a problem with cosmesis, can interfere with mastication unless corrected through orthodontic techniques. Impacted third molars are common and occasionally become infected. Acquired prognathism due to *acromegaly* may also lead to malocclusion, as may deformity of the maxilla and mandible due to *Paget's disease* of the bone. Delayed tooth eruption, receding chin, and a protruding tongue are occasional features of *cretinism* and *hypopituitarism*. Congenital syphilis produces tapering, notched (Hutchinson's) incisors and finely nodular (mulberry) molar crowns.

Enamel hypoplasia results in crown defects ranging from pits to deep fissures of primary or permanent teeth. Intrauterine infection (syphilis, rubella), vitamin deficiency (A, C, or D), disorders of calcium metabolism (malabsorption, vitamin D–resistant rickets, hypoparathyroidism), prematurity, high fever, or rare inherited defects (*amelogenesis imperfecta*) are all causes. Tetracycline, given in sufficiently high doses during the first 8 years, may produce enamel hypoplasia and discoloration. Exposure to endogenous pigments can discolor developing teeth: *erythroblastosis fetalis* (green or bluish-black), congenital liver disease (green or yellow-brown), and porphyria (red or brown that fluoresces with ultraviolet light). *Mottled enamel* occurs if excessive fluoride is ingested during development. Worn enamel is seen with age, bruxism, or excessive acid exposure (e.g., chronic gastric reflux or bulimia).

Premature tooth loss resulting from periodontitis is seen with cyclic neutropenia, Papillon-Lefèvre syndrome, Chédiak-Higashi syndrome, and leukemia. Rapid focal tooth loosening is most often due to infection, but rarer causes include histiocytosis X, Ewing's sarcoma, osteosarcoma, or Burkitt's lymphoma. Early loss of primary teeth is a feature of *hypophosphatasia*, a rare inborn error of metabolism.

Pregnancy may produce severe gingivitis and localized *pyogenic granulomas*. Severe periodontal disease occurs with Down's syndrome and diabetes mellitus. *Gingival hyperplasia* may be caused by phenytoin, calcium channel blockers (e.g., nifedipine), and cyclosporine. *Idiopathic familial gingival fibromatosis* and several syndrome-related disorders appear similar. Removal of the medication often reverses the drug-induced form, though surgery may be needed to control both. *Linear gingival erythema* is variably seen in patients with advanced HIV infection and probably represents immune deficiency and decreased neutrophil activity. Diffuse or focal gingival swelling may be a feature of early or late acute myelomonocytic leukemia (AML) as well as of other lymphoproliferative disorders. A rare, but pathognomonic, sign of Wegener's granulomatosis is a red-purplish, granular gingivitis (strawberry gums).

DISEASES OF THE ORAL MUCOSA

Infection Most oral mucosal diseases involve microorganisms (Table 32-1).

Pigmented Lesions See Table 32-2.

Dermatologic Diseases See Tables 32-1, 32-2, and 32-3 and Chaps. 52–56.

Diseases of the Tongue See Table 32-4.

HIV Disease and AIDS See Tables 32-1, 32-2, 32-3, and 32-5; Chap. 182; and Figs. 174-1 and 196-1.

Ulcers Ulceration is the most common oral mucosal lesion. Although there are many causes, the host and pattern of lesions, including the presence of systemic features, narrow the differential diagnosis (Table 32-1). Most acute ulcers are painful and self-limited. Recurrent aphthous ulcers and herpes simplex infection constitute the majority. Persistent and deep aphthous ulcers can be idiopathic or seen with HIV/AIDS. Aphthous lesions are often the presenting symptom in *Behçet's syndrome* (Chap. 320). Similar-appearing, though less painful, lesions may occur with Reiter's syndrome, and aphthous ulcers are occasionally present during phases of discoid or *systemic lupus erythematosus* (Chap. 316). Aphthous-like ulcers are seen in Crohn's disease (Chap. 289), but unlike the common aphthous variety, they may exhibit granulomatous inflammation histologically. Recurrent aphthae in some patients with *celiac disease* have been reported to remit with elimination of gluten.

Of major concern are chronic, relatively painless ulcers and mixed red/white patches (erythroplakia and leukoplakia) of more than 2 weeks' duration. Squamous cell carcinoma and premalignant dysplasia should be considered early and a diagnostic biopsy obtained. The importance is underscored because early-stage malignancy is vastly more treatable than late-stage disease. High-risk sites include the lower lip, floor of the mouth, ventral and lateral tongue, and soft palate–tonsillar pillar complex. Significant risk factors for oral cancer in Western countries include sun exposure (lower lip) and tobacco and alcohol use. In India and some other Asian countries, smokeless tobacco mixed with betel nut, slaked lime, and spices is a common cause of oral cancer. Less common etiologies include syphilis and Plummer-Vinson syndrome (iron deficiency).

Rarer causes of chronic oral ulcer such as tuberculosis, fungal infection, Wegener's granulomatosis, and midline granuloma may look identical to carcinoma. Making the correct diagnosis depends on recognizing other clinical features and biopsy of the lesion. The syphilitic chancre is typically painless and therefore easily missed. Regional lymphadenopathy is invariably present. Confirmation is achieved using appropriate bacterial and serologic tests.

TABLE 32-1 VESICULAR, BULLOUS, OR ULCERATIVE LESIONS OF THE ORAL MUCOSA

Condition	Usual Location	Clinical Features	Course
Viral Diseases			
Primary acute herpetic gingivostomatitis [herpes simplex virus (HSV) type 1, rarely type 2]	Lip and oral mucosa (buccal, gingival, lingual mucosa)	Labial vesicles that rupture and crust, and intraoral vesicles that quickly ulcerate; extremely painful; acute gingivitis, fever, malaise, foul odor, and cervical lymphadenopathy; occurs primarily in infants, children, and young adults	Heals spontaneously in 10–14 days. Unless secondarily infected, lesions lasting >3 weeks are not due to primary HSV infection.
Recurrent herpes labialis	Mucocutaneous junction of lip, perioral skin	Eruption of groups of vesicles that may coalesce, then rupture and crust; painful to pressure or spicy foods	Lasts about 1 week, but condition may be prolonged if secondarily infected. If severe, topical or oral antiviral may reduce healing time.
Recurrent intraoral herpes simplex	Palate and gingiva	Small vesicles on keratinized epithelium that rupture and coalesce; painful	Heals spontaneously in about 1 week. If severe, topical or oral antiviral may reduce healing time.
Chickenpox (varicella-zoster virus)	Gingiva and oral mucosa	Skin lesions may be accompanied by small vesicles on oral mucosa that rupture to form shallow ulcers; may coalesce to form large bullous lesions that ulcerate; mucosa may have generalized erythema	Lesions heal spontaneously within 2 weeks.
Herpes zoster (reactivation of varicella-zoster virus)	Cheek, tongue, gingiva, or palate	Unilateral vesicular eruptions and ulceration in linear pattern following sensory distribution of trigeminal nerve or one of its branches	Gradual healing without scarring unless secondarily infected; postherpetic neuralgia is common. Oral acyclovir, famcyclovir, or valacyclovir reduce healing time and postherpetic neuralgia
Infectious mononucleosis (Epstein-Barr virus)	Oral mucosa	Fatigue, sore throat, malaise, fever, and cervical lymphadenopathy; numerous small ulcers usually appear several days before lymphadenopathy; gingival bleeding and multiple petechiae at junction of hard and soft palates	Oral lesions disappear during convalescence; no treatment though glucocorticoids indicated if tonsillar swelling compromises airway
Herpangina (coxsackievirus A; also possibly coxsackie B and echovirus)	Oral mucosa, pharynx, tongue	Sudden onset of fever, sore throat, and oropharyngeal vesicles, usually in children under 4 years, during summer months; diffuse pharyngeal congestion and vesicles (1–2 mm), grayish-white surrounded by red areola; vesicles enlarge and ulcerate	Incubation period 2–9 days; fever for 1–4 days; recovery uneventful
Hand, foot, and mouth disease (coxsackievirus A16 most common)	Oral mucosa, pharynx, palms, and soles	Fever, malaise, headache with oropharyngeal vesicles that become painful, shallow ulcers; highly infectious; usually affects children under age 10	Incubation period 2–18 days; lesions heal spontaneously in 2–4 weeks
Primary HIV infection	Gingiva, palate, and pharynx	Acute gingivitis and oropharyngeal ulceration, associated with febrile illness resembling mononucleosis and including lymphadenopathy	Followed by HIV seroconversion, asymptomatic HIV infection, and usually ultimately by HIV disease
Bacterial or Fungal Diseases			
Acute necrotizing ulcerative gingivitis ("trench mouth," Vincent's infection)	Gingiva	Painful, bleeding gingiva characterized by necrosis and ulceration of gingival papillae and margins plus lymphadenopathy and foul odor	Debridement and diluted (1:3) peroxide lavage provide relief within 24 h; antibiotics in acutely ill patients; relapse may occur
Prenatal (congenital) syphilis	Palate, jaws, tongue, and teeth	Gummatous involvement of palate, jaws, and facial bones; Hutchinson's incisors, mulberry molars, glossitis, mucous patches, and fissures on corner of mouth	Tooth deformities in permanent dentition irreversible
Primary syphilis (chancre)	Lesion appears where organism enters body; may occur on lips, tongue, or tonsillar area	Small papule developing rapidly into a large, painless ulcer with indurated border; unilateral lymphadenopathy; chancre and lymph nodes containing spirochetes; serologic tests positive by third to fourth weeks	Healing of chancre in 1–2 months, followed by secondary syphilis in 6–8 weeks
Secondary syphilis	Oral mucosa frequently involved with mucous patches, primarily on palate, also at commissures of mouth	Maculopapular lesions of oral mucosa, 5–10 mm in diameter with central ulceration covered by grayish membrane; eruptions occurring on various mucosal surfaces and skin accompanied by fever, malaise, and sore throat	Lesions may persist from several weeks to a year
Tertiary syphilis	Palate and tongue	Gummatous infiltration of palate or tongue followed by ulceration and fibrosis; atrophy of tongue papillae produces characteristic bald tongue and glossitis	Gumma may destroy palate, causing complete perforation
Gonorrhea	Lesions may occur in mouth at site of inoculation or secondarily by hematogenous spread from a primary focus elsewhere	Most pharyngeal infection is asymptomatic; may produce burning or itching sensation; oropharynx and tonsils may be ulcerated and erythematous; saliva viscous and fetid	More difficult to eradicate than urogenital infection, though pharyngitis usually resolves with appropriate antimicrobial treatment

(continued)

TABLE 32-1 VESICULAR, BULLOUS, OR ULCERATIVE LESIONS OF THE ORAL MUCOSA (CONTINUED)

Condition	Usual Location	Clinical Features	Course
Tuberculosis	Tongue, tonsillar area, soft palate	A painless, solitary, 1–5 cm, irregular ulcer covered with a persistent exudate; ulcer has a firm undermined border	Autoinnoculation from pulmonary infection usual; lesions resolve with appropriate antimicrobial therapy
Cervicofacial actinomycosis	Swellings in region of face, neck, and floor of mouth	Infection may be associated with an extraction, jaw fracture, or eruption of molar tooth; in acute form resembles an acute pyogenic abscess, but contains yellow "sulfur granules" (gram-positive mycelia and their hyphae)	Typically swelling is hard and grows painlessly; multiple abscesses with draining tracks develop; penicillin first choice; surgery usually necessary
Histoplasmosis	Any area of the mouth, particularly tongue, gingiva, or palate	Nodular, verrucous, or granulomatous lesions; ulcers are indurated and painful; usual source hematogenous or pulmonary, but may be primary	Systemic antifungal therapy necessary to treat
Candidiasis (Table 32-3)			
Dermatologic Diseases			
Mucous membrane pemphigoid	Typically produces marked gingival erythema and ulceration; other areas of oral cavity, esophagus, and vagina may be affected	Painful, grayish-white collapsed vesicles or bullae of full-thickness epithelium with peripheral erythematous zone; gingival lesions desquamate, leaving ulcerated area	Protracted course with remissions and exacerbations; involvement of different sites occurs slowly; glucocorticoids may temporarily reduce symptoms but do not control the disease
Erythema multiforme minor and major (Stevens-Johnson syndrome)	Primarily the oral mucosa and the skin of hands and feet	Intraoral ruptured bullae surrounded by an inflammatory area; lips may show hemorrhagic crusts; the "iris," or "target," lesion on the skin is pathognomonic; patient may have severe signs of toxicity	Onset very rapid; usually idiopathic, but may be associated with trigger such as drug reaction; condition may last 3–6 weeks; mortality with EM major 5–15% if untreated
Pemphigus vulgaris	Oral mucosa and skin; sites of mechanical trauma (soft/hard palate, frenulum, lips, buccal mucosa)	Usually (>70%) presents with oral lesions; fragile, ruptured bullae and ulcerated oral areas; mostly in older adults	With repeated occurrence of bullae, toxicity may lead to cachexia, infection, and death within 2 years; often controllable with oral glucocorticoids
Lichen planus	Oral mucosa and skin	White striae in mouth; purplish nodules on skin at sites of friction; occasionally causes oral mucosal ulcers and erosive gingivitis	White striae alone usually asymptomatic; erosive lesions often difficult to treat, but may respond to glucocorticoids
Other Conditions			
Recurrent aphthous ulcers	Usually on nonkeratinized oral mucosa (buccal and labial mucosa, floor of mouth, soft palate, lateral and ventral tongue)	Single or clusters of painful ulcers with surrounding erythematous border; lesions may be 1–2 mm in diameter in crops (herpetiform), 1–5 mm (minor), or 5–15 mm (major)	Lesions heal in 1–2 weeks but may recur monthly or several times a year; protective barrier with orabase and topical steroids give symptomatic relief; systemic glucocorticoids may be needed in severe cases
Behçet's syndrome	Oral mucosa, eyes, genitalia, gut, and CNS	Multiple aphthous ulcers in mouth; inflammatory ocular changes, ulcerative lesions on genitalia; inflammatory bowel disease and CNS disease	Oral lesions often first manifestation; persist several weeks and heal without scarring
Traumatic ulcers	Anywhere on oral mucosa; dentures frequently responsible for ulcers in vestibule	Localized, discrete ulcerated lesions with red border; produced by accidental biting of mucosa, penetration by a foreign object, or chronic irritation by a denture	Lesions usually heal in 7–10 days when irritant is removed, unless secondarily infected
Squamous cell carcinoma	Any area in the mouth, most commonly on lower lip, tongue, and floor of mouth	Ulcer with elevated, indurated border; failure to heal, pain not prominent; lesions tend to arise in areas of erythro/leukoplakia or in smooth atrophic tongue	Invades and destroys underlying tissues; frequently metastasizes to regional lymph nodes
Acute myeloid leukemia (usually monocytic)	Gingiva	Gingival swelling and superficial ulceration followed by hyperplasia of gingiva with extensive necrosis and hemorrhage; deep ulcers may occur elsewhere on the mucosa complicated by secondary infection	Usually responds to systemic treatment of leukemia; occasionally requires local radiation therapy
Lymphoma	Gingiva, tongue, palate and tonsillar area	Elevated, ulcerated area that may proliferate rapidly, giving the appearance of traumatic inflammation	Fatal if untreated; may indicate underlying HIV infection
Chemical or thermal burns	Any area in mouth	White slough due to contact with corrosive agents (e.g., aspirin, hot cheese) applied locally; removal of slough leaves raw, painful surface	Lesion heals in several weeks if not secondarily infected

Note: CNS, central nervous system.

TABLE 32-2 PIGMENTED LESIONS OF THE ORAL MUCOSA

Condition	Usual Location	Clinical Features	Course
Oral melanotic macule	Any area of the mouth	Discrete or diffuse localized, brown to black macule	Remains indefinitely; no growth
Diffuse melanin pigmentation	Any area of the mouth	Diffuse pale to dark-brown pigmentation; may be physiologic ("racial") or due to smoking	Remains indefinitely
Nevi	Any area of the mouth	Discrete, localized, brown to black pigmentation	Remains indefinitely
Malignant melanoma	Any area of the mouth	Can be flat and diffuse, painless, brown to black, or can be raised and nodular	Expands and invades early; metastasis leads to death
Addison's disease	Any area of the mouth, but mostly buccal mucosa	Blotches or spots of bluish-black to dark-brown pigmentation occurring early in the disease, accompanied by diffuse pigmentation of skin; other symptoms of adrenal insufficiency	Condition controlled by adrenal steroid replacement
Peutz-Jeghers syndrome	Any area of the mouth	Dark-brown spots on lips, buccal mucosa, with characteristic distribution of pigment around lips, nose, eyes, and on hands; concomitant intestinal polyposis	Oral pigmented lesions remain indefinitely; gastrointestinal polyps may become malignant
Drug ingestion (neuroleptics, oral contraceptives, minocycline, zidovudine, quinine derivatives)	Any area of the mouth	Brown, black, or gray areas of pigmentation	Gradually disappears following cessation of drug
Amalgam tattoo	Gingiva and alveolar mucosa	Small blue-black pigmented areas associated with embedded amalgam particles in soft tissues; these may show up on radiographs as radiopaque particles in some cases	Remains indefinitely
Heavy metal pigmentation (bismuth, mercury, lead)	Gingival margin	Thin blue-black pigmented line along gingival margin; rarely seen except for children exposed to lead-based paint	Indicative of systemic absorption; no significance for oral health
Black hairy tongue	Dorsum of tongue	Elongation of filiform papillae of tongue, which become stained by coffee, tea, tobacco, or pigmented bacteria	Improves within 1–2 weeks with gentle brushing of tongue or discontinuation of antibiotic if due to bacterial overgrowth
Fordyce "spots"	Buccal and labial mucosa	Numerous small yellowish spots just beneath mucosal surface; no symptoms; due to hyperplasia of sebaceous glands	Benign; remains without apparent change
Kaposi's sarcoma	Palate most common, but may occur in any other site	Red or blue plaques of variable size and shape; often enlarge, become nodular and may ulcerate	Usually indicative of HIV infection or non-Hodgkin's lymphoma; rarely fatal, but may require treatment for comfort or cosmesis
Mucous retention cysts	Buccal and labial mucosa	Bluish-clear fluid-filled cyst due to extravasated mucous from injured minor salivary gland	Benign; painless unless traumatized; may be removed surgically

TABLE 32-3 WHITE LESIONS OF ORAL MUCOSA

Condition	Usual Location	Clinical Features	Course
Lichen planus	Buccal mucosa, tongue, gingiva, and lips; skin	Striae, white plaques, red areas, ulcers in mouth; purplish papules on skin; may be asymptomatic, sore, or painful; lichenoid drug reactions may look similar	Protracted; responds to topical glucocorticoids
White sponge nevus	Oral mucosa, vagina, anal mucosa	Painless white thickening of epithelium; adolescent/early adult onset; familial	Benign and permanent
Smoker's leukoplakia and smokeless tobacco lesions	Any area of oral mucosa, sometimes related to location of habit	White patch that may become firm, rough, or red-fissured and ulcerated; may become sore and painful but usually painless	May or may not resolve with cessation of habit; 2% develop squamous cell carcinoma; early biopsy essential
Erythroplakia with or without white patches	Floor of mouth common in men; tongue and buccal mucosa in women	Velvety, reddish plaque; occasionally mixed with white patches or smooth red areas	High risk of squamous cell cancer; early biopsy essential
Candidiasis	Any area in mouth	*Pseudomembranous type* ("thrush"): creamy white curdlike patches that reveal a raw, bleeding surface when scraped; found in sick infants, debilitated elderly patients receiving high doses of glucocorticoids or broad-spectrum antibiotics, or in patients with AIDS	Responds favorably to antifungal therapy and correction of predisposing causes where possible
		Erythematous type: flat, red, sometimes sore areas in same groups of patients	Course same as for pseudomembranous type
		Candidal leukoplakia: nonremovable white thickening of epithelium due to *Candida*	Responds to prolonged antifungal therapy
		Angular cheilitis: sore fissures at corner of mouth	Responds to topical antifungal therapy
Hairy leukoplakia	Usually lateral tongue, rarely elsewhere on oral mucosa	White areas ranging from small and flat to extensive accentuation of vertical folds; found in HIV carriers in all risk groups for AIDS	Due to EBV; responds to high dose acyclovir but recurs; rarely causes discomfort unless secondarily infected with *Candida*
Warts (papillomavirus)	Anywhere on skin and oral mucosa	Single or multiple papillary lesions, with thick, white keratinized surfaces containing many pointed projections; cauliflower lesions covered with normal-colored mucosa or multiple pink or pale bumps (focal epithelial hyperplasia)	Lesions grow rapidly and spread; consider squamous cell carcinoma and rule out with biopsy; excision or laser therapy; may regress in HIV infected patients on antiretroviral therapy

Note: EBV, Epstein-Barr virus.

TABLE 32-4 ALTERATIONS OF THE TONGUE

Type of Change	Clinical Features
Size or Morphology Changes	
Macroglossia	Enlarged tongue that may be part of a syndrome found in developmental conditions such as Down syndrome, Simpson-Golabi-Behmel syndrome, or Beckwith-Wiedemann syndrome may be due to tumor (hemangioma or lymphangioma), metabolic disease (such as primary amyloidosis), or endocrine disturbance (such as acromegaly or cretinism)
Fissured ("scrotal") tongue	Dorsal surface and sides of tongue covered by painless shallow or deep fissures that may collect debris and become irritated
Median rhomboid glossitis	Congenital abnormality of tongue with ovoid, denuded area in median posterior portion of the tongue; may be associated with candidiasis and may respond to antifungals
Color Changes	
"Geographic" tongue (benign migratory glossitis)	Asymptomatic inflammatory condition of the tongue, with rapid loss and regrowth of filiform papillae, leading to appearance of denuded red patches "wandering" across the surface of the tongue
Hairy tongue	Elongation of filiform papillae of the medial dorsal surface area due to failure of keratin layer of the papillae to desquamate normally; brownish-black coloration may be due to staining by tobacco, food, or chromogenic organisms
"Strawberry" and "raspberry" tongue	Appearance of tongue during scarlet fever due to the hypertrophy of fungiform papillae plus changes in the filiform papillae
"Bald" tongue	Atrophy may be associated with xerostomia, pernicious anemia, iron-deficiency anemia, pellagra, or syphilis; may be accompanied by painful burning sensation; may be an expression of erythematous candidiasis and respond to antifungals

Disorders of mucosal fragility often produce painful oral ulcers that fail to heal within 2 weeks. *Mucous membrane pemphigoid* and *pemphigus vulgaris* are the major acquired disorders. While clinical features are often distinctive, immunohistochemical examination should be performed for diagnosis and to distinguish these entities from *lichen planus* and drug reactions.

Hematologic and Nutritional Disease Internists are more likely to encounter patients with acquired, rather than congenital, bleeding disorders. Bleeding after minor trauma should stop after 15 min and within an hour of tooth extraction if local pressure is applied. More prolonged bleeding, if not due to continued injury or rupture of a large vessel, should lead to investigation for a clotting abnormality. In addition to bleeding, petechiae and ecchymoses are prone to occur at the line of vibration between the soft and hard palates in patients with platelet dysfunction or thrombocytopenia.

All forms of leukemia, but particularly acute myelomonocytic leukemia, can produce gingival bleeding, ulcers, and gingival enlargement. Oral ulcers are a feature of agranulocytosis, and ulcers and mucositis are often severe complications of chemotherapy and radiation therapy for hematologic and other malignancies. Plummer-Vinson syndrome (iron deficiency, angular stomatitis, glossitis, and dysphagia) raises the risk of oral squamous cell cancer and esophageal cancer at the postcricoidal tissue web. Atrophic papillae and a red, burning tongue may occur with pernicious anemia. B group vitamin deficiencies produce many of these same symptoms as well as oral ulceration and cheilosis. Cheilosis may also be seen in iron deficiency. Swollen, bleeding gums, ulcers, and loosening of the teeth are a consequence of scurvy.

NONDENTAL CAUSES OF ORAL PAIN

Most but not all oral pain emanates from inflamed or injured tooth pulp or periodontal tissues. Nonodontogenic causes may be overlooked. In most instances toothache is predictable and proportional to the stimulus applied, and an identifiable condition (e.g., caries, abscess) is found. Local anesthesia eliminates pain originating from dental or periodontal structures, but not referred pains. The most common nondental origin is myofascial pain referred from muscles of mastication, which become tender and ache with increased use. Many sufferers exhibit bruxism (the grinding of teeth, often during sleep) that is secondary to stress and anxiety. *Temporomandibular disorder* is closely related. It predominantly affects females ages 15–45. Features include pain, limited mandibular movement, and temporomandibular joint sounds. The etiologies are complex, and malocclusion does not play the primary role once attributed to it. *Osteoarthritis* is a common cause of masticatory pain. Anti-inflammatory medication, jaw rest, soft foods, and heat provide relief. The temporomandibular joint is involved in 50% of patients with *rheumatoid arthritis* and is usually a late feature of severe disease. Bilateral preauricular pain, particularly in the morning, limits range of motion.

Migrainous neuralgia may be localized to the mouth. Episodes of pain and remission without identifiable cause and absence of relief with local anesthesia are important clues. *Trigeminal neuralgia* (*tic douloureaux*) may involve the entire branch or part of the mandibular or maxillary branches of the fifth cranial nerve and produce pain in one or a few teeth. Pain may occur spontaneously or may be triggered by touching the lip or gingiva, brushing the teeth, or chewing. *Glossopharyngeal neuralgia* produces similar acute neuropathic symptoms in the distribution of the ninth cranial nerve. Swallowing, sneezing, coughing, or pressure on the tragus of the ear triggers pain that is felt in the base of the tongue, pharynx, and soft palate and may be referred to the temporomandibular joint. *Neuritis* involving the maxillary and mandibular divisions of the trigeminal nerve (e.g., maxillary sinusitis, neuroma, and leukemic infiltrate) is distinguished from ordinary toothache by the neuropathic quality of the pain. Occasionally *phantom pain* follows tooth extraction.

TABLE 32-5 ORAL LESIONS ASSOCIATED WITH HIV INFECTION

Lesion Morphology	Etiologies
Papules, nodules, plaques	Candidiasis (hyperplastic and pseudomembranous)[a] Condyloma acuminatum (human papillomavirus infection) Squamous cell carcinoma (preinvasive and invasive) Non-Hodgkin's lymphoma[a] Hairy leukoplakia[a]
Ulcers	Recurrent aphthous ulcers[a] Angular cheilitis Squamous cell carcinoma Acute necrotizing ulcerative gingivitis[a] Necrotizing ulcerative periodontitis[a] Necrotizing ulcerative stomatitis Non-Hodgkin's lymphoma[a] Viral infection (herpes simplex, herpes zoster, cytomegalovirus) *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare* Fungal infection (histoplasmosis, cryptococcosis, candidiasis, geotrichosis, aspergillosis) Bacterial infection (*Escherichia coli, Enterobacter cloacae, Klebsiella pneumoniae, Pseudomonas aeruginosa*) Drug reactions (single or multiple ulcers)
Pigmented lesions	Kaposi's sarcoma[a] Bacillary angiomatosis (skin and visceral lesions more common than oral) Zidovudine pigmentation (skin, nails, and occasionally oral mucosa) Addison's disease
Miscellaneous	Linear gingival erythema[a]

[a]Strongly associated with HIV infection.

Often the earliest symptom of Bell's palsy in the day or so before facial weakness develops is pain and hyperalgesia behind the ear and side of the face. Likewise, similar symptoms may precede visible lesions of herpes zoster infecting the seventh nerve (Ramsey-Hunt syndrome) or trigeminal nerve. *Postherpetic neuralgia* may follow either condition. *Coronary ischemia* may produce pain exclusively in the face and jaw and, like typical angina pectoris, is usually reproducible with increased myocardial demand. Aching in several upper molar or premolar teeth that is unrelieved by anesthetizing the teeth may point to *maxillary sinusitis*.

Giant cell arteritis is notorious for producing headache, but it may also produce facial pain or sore throat without headache. Jaw and tongue claudication with chewing or talking is relatively common. Tongue infarction is rare. Patients with subacute thyroiditis often experience pain referred to the face or jaw before the tender thyroid gland and transient hyperthyroidism are appreciated.

Burning mouth syndrome (glossodynia) is present in the absence of an identifiable cause (e.g., vitamin B_{12} deficiency, iron deficiency, Plummer-Vinson syndrome, diabetes mellitus, low-grade *Candida* infection, food sensitivity, or subtle xerostomia) and predominantly affects postmenopausal women. The etiology may be neuropathic. Clonazepam, alpha-lipoic acid and cognitive behavioral therapy have benefited some.

DISEASES OF THE SALIVARY GLANDS

Saliva is essential to oral health. Its major components, water and mucin, serve as a cleansing solvent and lubricating fluid. In addition, it contains antimicrobial factors (e.g., lysozyme, lactoperoxidase, secretory IgA), epidermal growth factor, minerals, and buffering systems. The major salivary glands secrete intermittently in response to autonomic stimulation, which is high during a meal but low otherwise. Hundreds of minor glands in the lips and cheeks secrete mucus continuously. Consequently, oral function becomes impaired when salivary function is reduced. Dry mouth (*xerostomia*) is perceived when salivary flow is reduced by 50%. The most common etiology is medication, especially drugs with anticholinergic properties, but also alpha and beta blockers, calcium channel blockers, and diuretics. Other causes include Sjögren's syndrome, chronic parotitis, salivary duct obstruction, diabetes mellitus, HIV/AIDS, and irradiation for head and neck cancer. Management involves eliminating or limiting drying medications, preventive dental care, and supplementing oral liquid. Sugarless mints or chewing gum may stimulate salivary secretion if dysfunction is mild. When sufficient exocrine tissue remains, pilocarpine or cevimeline has been shown to increase secretions. Commercial saliva substitutes or gels relieve dryness but must be supplemented with fluoride applications to prevent caries.

Sialolithiasis presents most often as painful swelling but in some instances as just swelling or pain. The obstructing stone produces spasm upon eating. Conservative therapy consists of local heat, massage, and hydration. Promotion of salivary secretion with mints or lemon drops may flush out small stones. Antibiotic treatment is necessary when bacterial infection in suspected. In adults, *acute bacterial parotitis* is typically unilateral and most commonly affects postoperative patients within the first 2 weeks of surgery. *Staphylococcus aureus* is the most common bacterial agent. Dehydration, advanced age, and chronic debilitating disease are major risks. Chronic bacterial sialadenitis results from lowered salivary secretion and recurrent bacterial infection. When suspected bacterial infection is not responsive to therapy, the differential diagnosis should be expanded to include benign and malignant neoplasms, lymphoproliferative disorders, Sjögren's syndrome, sarcoidosis, tuberculosis, lymphadenitis, actinomycosis, and Wegener's granulomatosis. Bilateral nontender parotid enlargement occurs with diabetes mellitus, cirrhosis, bulimia, HIV/AIDS, and drugs (e.g., iodide, propylthiouracil).

Pleomorphic adenoma comprises two-thirds of all salivary neoplasms. The parotid is the principal salivary gland affected, and the tumor presents as a firm, slow-growing mass. Though benign, recurrence is common if resection is incomplete. Malignant tumors such as mucoepidermoid carcinoma, adenoid cystic carcinoma, and adenocarcinoma tend to grow relatively fast, depending upon grade. They may ulcerate and invade nerves, producing numbness and facial paralysis. Neutron-beam radiation therapy is an effective treatment; 5-year survival is about 68% for malignant salivary gland tumors.

DENTAL CARE OF MEDICALLY COMPLEX PATIENTS

Routine dental care (e.g., extraction, scaling and cleaning, tooth restoration, and root canal) is remarkably safe. The most common concerns regarding care of dental patients with medical disease are fear of excessive bleeding for patients on anticoagulants, infection of the heart valves and prosthetic devices from hematogenous seeding of oral flora, and cardiovascular complications resulting from vasopressors used with local anesthetics during dental treatment. Experience confirms that the risks of any of these complications are very low.

Patients undergoing tooth extraction or alveolar and gingival surgery rarely experience uncontrolled bleeding when warfarin anticoagulation is maintained within the therapeutic range currently recommended for prevention of venous thrombosis, atrial fibrillation, or mechanical heart valve. Embolic complications and death, however, have been reported during subtherapeutic anticoagulation. Therapeutic anticoagulation should be confirmed before and continued through the procedure. Likewise, low-dose aspirin (e.g., 81–325 mg) can be safely continued.

Patients at high or moderate risk for bacterial endocarditis (Chap. 118) should maintain optimal oral hygiene, including flossing, and have regular professional cleaning. Prophylactic antibiotics are recommended for all at-risk patients who undergo dental and oral procedures likely to cause significant bleeding and bacteremia. Should unexpected bleeding occur, antibiotics given within 2 h following the procedure provide effective prophylaxis.

Hematogenous bacterial seeding from oral infection can undoubtedly produce late prosthetic joint infection and therefore requires removal of the infected tissue (e.g., drainage, extraction, root canal) and appropriate antibiotic therapy. However, evidence that late prosthetic joint infection occurs following routine dental procedures is lacking. For this reason, antibiotic prophylaxis is not recommended before dental surgery in patients with orthopedic pins, screws, and plates. It is, however, advised within the first 2 years after joint replacement for patients who have inflammatory arthropathies, immunosuppression, type 1 diabetes mellitus, previous prosthetic joint infection, hemophilia, or malnourishment.

Concern often arises regarding the use of vasoconstrictors in patients with hypertension and heart disease. Vasoconstrictors enhance the depth and duration of local anesthesia, thus reducing the anesthetic dose and potential toxicity. If intravascular injection is avoided, 2% lidocaine with 1:100,000 epinephrine (limited to a total of 0.036 mg epinephrine) can be used safely in those with controlled hypertension and stable coronary heart disease, arrhythmia, or congestive heart failure. Precaution should be taken with patients taking tricyclic antidepressants and nonselective beta blockers as these drugs may potentiate the effect of epinephrine.

Elective dental treatments should be postponed for at least 1 month after myocardial infarction, after which the risk of reinfarction is low provided the patient is medically stable (e.g., stable rhythm, stable angina, and free of heart failure). Patients who have suffered a stroke should have elective dental care deferred for 6 months. In both situations, effective stress reduction requires good pain control, including the use of the minimal amount of vasoconstrictor necessary to provide good hemostasis and local anesthesia.

Bisphosphonate therapy can be associated with *osteonecrosis* of the jaw. Most patients affected have received high dose aminobisphosphonate therapy for multiple myeloma or metastatic breast cancer and have undergone tooth extraction or dental surgery. Intra-oral lesions appear as exposed yellow-white hard bone involving the mandible or maxilla. Two-thirds are painful. Patients about to receive aminobisphosphonate therapy should receive preventive dental care that reduces the risk of infection and need for future dentoalveolar surgery.

HALITOSIS

Halitosis typically emanates from the oral cavity or nasal passages. Volatile sulfur compounds resulting from bacterial decay of food and cellular de-

bris account for the malodor. Periodontal disease, caries, acute forms of gingivitis, poorly fitting dentures, oral abscess, and tongue coating are usual causes. Treatment includes correcting poor hygiene, treating infection, and tongue brushing. Xerostomia can produce and exacerbate halitosis. Pockets of decay in the tonsillar crypts, esophageal diverticulum, esophageal stasis (e.g., achalasia, stricture), sinusitis, and lung abscess account for some instances. A few systemic diseases produce distinctive odors: renal failure (ammoniacal), hepatic (fishy), and ketoacidosis (fruity). *Helicobacter pylori* gastritis can also produce ammoniac breath. If no odor is detectable, then pseudohalitosis or even halitophobia must be considered. These conditions represent varying degrees of psychiatric illness.

AGING AND ORAL HEALTH

While tooth loss and dental disease are not normal consequences of aging, a complex array of structural and functional changes occurs with age that can affect oral health. Subtle changes in tooth structure (e.g., diminished pulp space and volume, sclerosis of dentinal tubules, altered proportions of nerve and vascular pulp content) result in diminished or altered pain sensitivity, reduced reparative capacity, and increased tooth brittleness. In addition, age-associated fatty replacement of salivary acini may reduce physiologic reserve, thus increasing the risk of xerostomia.

Poor oral hygiene often results when vision fails or when patients lose manual dexterity and upper extremity flexibility. This is particularly common for nursing home residents and must be emphasized since regular oral cleaning and dental care has been shown to reduce the incidence of pneumonia. Other risks for dental decay include limited lifetime fluoride exposure and preference by some older adults for intensely sweet foods when taste and olfaction wane. These factors occur in an increasing proportion of persons over age 75 who retain teeth that have extensive restorations and exposed roots. Without assiduous care, decay can become quite advanced yet remain asymptomatic. Consequently, much or all of the tooth can be destroyed before the process is detected.

Periodontal disease, a leading cause of tooth loss, is indicated by loss of alveolar bone height. Over 90% of Americans have some degree of periodontal disease by age 50. Healthy adults who have not experienced significant alveolar bone loss by the sixth decade do not typically develop significant worsening with advancing age.

Complete edentulousness with advanced age, though less common than in previous decades, is still present in approximately 50% of Americans age ≥85. Speech, mastication, and facial contours are dramatically affected. Edentulousness may also worsen obstructive sleep apnea, particularly in those without symptoms while wearing dentures. Dentures can improve speech articulation and restore diminished facial contours. Mastication is restored less predictably, and those expecting dentures to improve oral intake are often disappointed. Dentures require periodic adjustment to accommodate inevitable remodeling that leads to a diminished volume of the alveolar ridge. Pain can result from friction or traumatic lesions produced by loose dentures. Poor fit and poor oral hygiene may permit candidiasis to develop. This may be asymptomatic or painful and is indicated by erythematous smooth or granular tissue conforming to an area covered by the appliance.

SECTION 5 ALTERATIONS IN CIRCULATORY AND RESPIRATORY FUNCTIONS

33 Dyspnea and Pulmonary Edema

Richard M. Schwartzstein

DYSPNEA

The American Thoracic Society defines *dyspnea* as a "subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity. The experience derives from interactions among multiple physiological, psychological, social, and environmental factors, and may induce secondary physiological and behavioral responses." Dyspnea, a symptom, must be distinguished from the signs of increased work of breathing.

MECHANISMS OF DYSPNEA

Respiratory sensations are the consequence of interactions between the *efferent*, or outgoing, motor output from the brain to the ventilatory muscles (feed-forward) and the *afferent*, or incoming, sensory input from receptors throughout the body (feedback), as well as the integrative processing of this information that we infer must be occurring in the brain (Fig. 33-1). A given disease state may lead to dyspnea by one or more mechanisms, some of which may be operative under some circumstances but not others.

Motor Efferents Disorders of the ventilatory pump are associated with increased work of breathing or a sense of an increased effort to breathe. When the muscles are weak or fatigued, greater effort is required, even though the mechanics of the system are normal. The increased neural output from the motor cortex is thought to be sensed due to a corollary discharge that is sent to the sensory cortex at the same time that signals are sent to the ventilatory muscles.

Sensory Afferents Chemoreceptors in the carotid bodies and medulla are activated by hypoxemia, acute hypercapnia, and acidemia. Stimulation of these receptors, as well as others that lead to an increase in ventilation, produce a sensation of air hunger. Mechanoreceptors in the lungs, when stimulated by bronchospasm, lead to a sensation of chest tightness. J-receptors, sensitive to interstitial edema, and pulmonary vascular receptors, activated by acute changes in pulmonary artery pressure, appear to contribute to air hunger. Hyperinflation is associated with the sensation of an inability to get a deep breath or of an unsatisfying breath. It is not clear if this sensation arises from receptors in the lungs or chest wall, or if it is a variant of the sensation of air hunger. Metaboreceptors, located in skeletal muscle, are believed to be activated by changes in the local biochemical milieu of the tissue active during exercise and, when stimulated, contribute to the breathing discomfort.

e7 Atlas of Oral Manifestations of Disease

Samuel C. Durso, Janet A. Yellowitz, Jane C. Atkinson

The health status of the oral cavity is linked to cardiovascular disease, diabetes, and other systemic illnesses. Thus, there is significant clinical value in examining the oral cavity for signs of disease. This chapter presents numerous outstanding clinical photographs illustrating many of the conditions discussed in Chap. 32, Oral Manifestations of Disease. Conditions affecting the teeth, periodontal tissues, and oral mucosa are all represented.

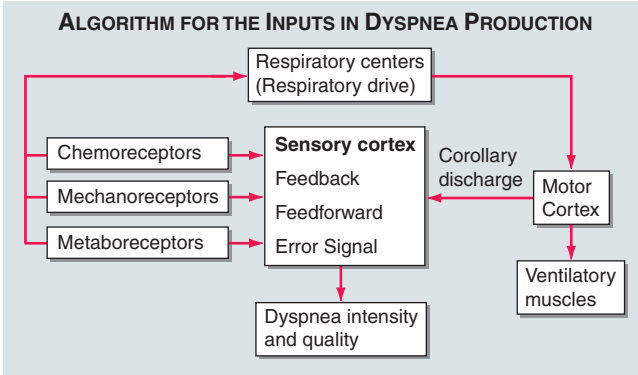

FIGURE 33-1 Hypothetical model for integration of sensory inputs in the production of dyspnea. Afferent information from the receptors throughout the respiratory system projects directly to the sensory cortex to contribute to primary qualitative sensory experiences and provide feedback on the action of the ventilatory pump. Afferents also project to the areas of the brain responsible for control of ventilation. The motor cortex, responding to input from the control centers, sends neural messages to the ventilatory muscles and a corollary discharge to the sensory cortex (feed-forward with respect to the instructions sent to the muscles). If the feed-forward and feedback messages do not match, an error signal is generated and the intensity of dyspnea increases. *(Adapted from Gillette and Schwartzstein.)*

Integration: Efferent-Reafferent Mismatch A discrepancy or mismatch between the feed-forward message to the ventilatory muscles and the feedback from receptors that monitor the response of the ventilatory pump increases the intensity of dyspnea. This is particularly important when there is a mechanical derangement of the ventilatory pump, such as in asthma or chronic obstructive pulmonary disease (COPD).

Anxiety Acute anxiety may increase the severity of dyspnea either by altering the interpretation of sensory data or by leading to patterns of breathing that heighten physiologic abnormalities in the respiratory system. In patients with expiratory flow limitation, for example, the increased respiratory rate that accompanies acute anxiety leads to hyperinflation, increased work of breathing, a sense of an increased effort to breathe, and a sense of an unsatisfying breath.

ASSESSING DYSPNEA

Quality of Sensation As with pain, dyspnea assessment begins with a determination of the quality of the discomfort (Table 33-1). Dyspnea questionnaires, or lists of phrases commonly used by patients, assist those who have difficulty describing their breathing sensations.

Sensory Intensity A modified Borg scale or visual analogue scale can be utilized to measure dyspnea at rest, immediately following exercise, or on recall of a reproducible physical task, e.g., climbing the stairs at home. An alternative approach is to inquire about the activities a patient can do, i.e., to gain a sense of the patient's disability. The Baseline Dyspnea Index and the Chronic Respiratory Disease Questionnaire are commonly used tools for this purpose.

TABLE 33-1 ASSOCIATION OF QUALITATIVE DESCRIPTORS AND PATHOPHYSIOLOGIC MECHANISMS OF SHORTNESS OF BREATH

Descriptor	Pathophysiology
Chest tightness or constriction	Bronchoconstriction, interstitial edema (asthma, myocardial ischemia)
Increased work or effort of breathing	Airway obstruction, neuromuscular disease (COPD, moderate to severe asthma, myopathy, kyphoscoliosis)
Air hunger, need to breathe, urge to breathe	Increased drive to breathe (CHF, pulmonary embolism, moderate to severe airflow obstruction)
Cannot get a deep breath, unsatisfying breath	Hyperinflation (asthma, COPD) and restricted tidal volume (pulmonary fibrosis, chest wall restriction)
Heavy breathing, rapid breathing, breathing more	Deconditioning

Note: CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease.
Source: From Schwartzstein and Feller-Kopman.

Affective Dimension For a sensation to be reported as a symptom, it must be perceived as unpleasant and interpreted as abnormal. We are still in the early stages of learning the best ways to assess the affective dimension of dyspnea. Some therapies for dyspnea, such as pulmonary rehabilitation, may reduce breathing discomfort, in part, by altering this dimension.

DIFFERENTIAL DIAGNOSIS
