A typical PCI may take 60–90 min, and utilize 150–250 mL of radiographic contrast, depending on the number and complexity of the lesions to be treated. At the end of the procedure, no further antithrombin therapy (heparin or bivalirudin) is given, although a IIb/IIIa receptor blocker may be continued for up to 18 h. The intraarterial sheath may be removed with manual pressure once the anticoagulated state has subsided (usually 2–4 after the procedure) or may be removed immediately through the aid of a vascular entry sealing device (one of several collagen plugs, suture, or external clip devices). The patient is returned to an inpatient unit for overnight observation, before discharge the following day on dual antiplatelet therapy. A predischarge electrocardiogram (ECG) and biomarkers (CK-MB fraction) assessment are obtained to monitor for the occurrence of periprocedural non-Q wave myocardial necrosis. Elevation of CK-MB <5 times the laboratory upper limit of normal occur in 3–5% of procedures and should be noted, but it generally does not require changes in subsequent therapy. Larger elevations or the development of ECG changes, particularly if in the setting of ongoing or recurrent postprocedural chest pain, suggest a procedural complication such as vessel closure or loss of a side branch within the stented segment and may mandate repeat diagnostic coronary angiography to evaluate, exclude, or treat such problems.

Upon discharge, the need for ongoing dual antiplatelet therapy is reemphasized to the patient, who can generally return to work within 2–3 days. No specific follow-up of the interventional result is usually performed in the absence of a recurrence in chest pain suggestive of myocardial ischemia, but it is crucial to modify any existing coronary risk factors (generally including optimization of lipid status). The

FIGURE 240-6 Diagnosis and treatment of an acute anterior wall myocardial infarction. In this patient, there is a subocclusive filling defect in the left anterior descending artery (***left***), which is removed by thrombectomy to show the underlying lesion (***center***), which is then treated by bifurcation stenting in the left anterior descending artery and the involved diagonal branch (***right***).

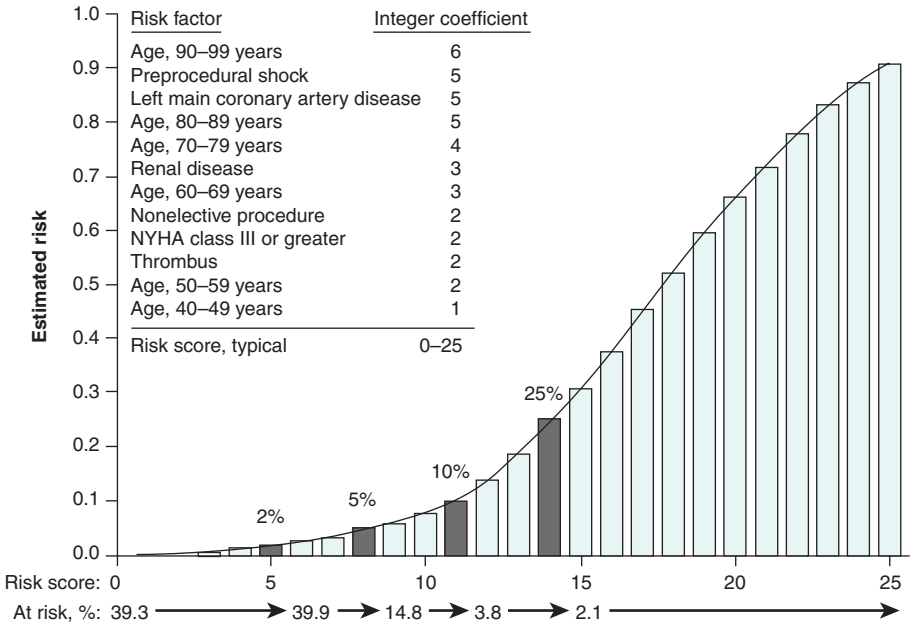

FIGURE 240-7 The Mayo Clinic risk score for mortality. This score assigns integer coefficients for each named clinical variable so that one can read the estimated mortality risk that corresponds to the total of the integer coefficients from the curve and the value on the *y* axis. The 2% of patients with a total score >14 thus have an expected procedural mortality of 25%. *(From M Singh et al, J Am Coll Cardiol 40:387, 2002, with permission.)*

main cause of recurrent events in the 5 years after a successful stent-based PCI is, in fact, progression of disease at other (non-stented) coronary sites.

Serious complications of modern PCI are uncommon, with a mortality < 0.3% for elective procedures (Fig. 240-7). As intervention has moved into more complex situations (multivessel disease, bifurcation lesions, vein graft, or unprotected left main lesions) in patients with acute coronary syndromes or poor baseline ventricular function, the average mortality of PCI has remained 1–1.5%. Abrupt vessel closure with emergency surgery has fallen to 0.1%, but current PCI guidelines still call for elective PCI to be performed in institutions that have on-site cardiac surgery support. Perforation of a coronary artery was an extremely rare complication of conventional balloon angioplasty but may occur in up to 1% of patients undergoing aggressive atherectomy procedures and may be seen with stenting. Even small perforations of the distal vessel by the angioplasty guidewire may lead to significant hemopericardium, requiring urgent pericardiocentesis in the setting of intense anticoagulant and antiplatelet therapy. PCI operators should thus be skilled in the management of such perforations using immediate balloon tamponade, placement of embolic vascular coils for small branch perforations, and placement of membrane-covered stents for perforations of major vessels. Finally, catheter-based interventions are subject to all of the complications of diagnostic catheterization, including local entry site complications, stroke, and contrast nephropathy in sensitive patients. For most patients, however, catheter-based coronary revascularization offers a safe and effective alternative to surgical revascularization.

NONCORONARY INTERVENTIONS

Because atherosclerosis is a systemic disease (i.e., not limited to the coronary arteries), it is increasingly common for analogous percutaneous interventions to be performed in the carotid, renal, or lower extremity arteries. These procedures may be combined with PCI when clinically indicated. Catheter-based interventions may also be used to treat structural cardiac defects (e.g., atrial septal defect, patent foramen ovale) or valvular heart disease. Balloon valvuloplasty is now the dominant treatment for rheumatic mitral stenosis (Chap. 230), and various catheter-based modalities are being developed for percutaneous mitral valve repair for mitral regurgitation and for percutaneous aortic valve replacement for severe aortic stenosis in patients at prohibitive risk for surgical aortic valve replacement.

SUMMARY

The past 30 years have seen the development of new techniques (such as stent placement), new drug regimens, and refinements in practice driven by "evidence-based" medicine, allowing catheter-based revascularization (PCI) to develop from a procedural curiosity to what is now the dominant form of coronary revascularization. As short- and long-term results have improved and the number of procedures has continued to grow, the pace of development continues to accelerate. Similar catheter techniques are now being used elsewhere in the arterial circulation and for the correction of structural heart disease in selected patients.

e23 Atlas of Percutaneous Revascularization

Donald S. Baim*

As indicated in Chap. 240, percutaneous coronary intervention (PCI) has assumed a major role in the management of coronary artery disease. It is used most commonly in patients with chronic stable angina, unstable angina, and primary therapy in acute ST segment elevation myocardial infarction.

This chapter illustrates some complex uses of percutaneous techniques, including management of cardiogenic shock, stent thrombosis, management of distal coronary vascular disease, and stenting of a chronic totally occluded vessel. In addition, pressure tracings obtained at left heart catheterization in the diagnosis of obstructive hypertrophic cardiomyopathy are shown, as is the percutaneous insertion of an experimental aortic valve. The latter has not yet been approved for clinical use but demonstrates one of the future extensions of percutaneous techniques.

CASE 1: CARDIOGENIC SHOCK WITH LEFT MAIN CORONARY ARTERY OBSTRUCTION

(Figs. e23-1 to e23-5; Videos e23-1 to e23-10)

- A 93-year-old man presented to the emergency room with 9 h of dyspnea and a sense of "dread"
- Prior subendocardial MI 2 months earlier managed medically (no catheterization done)
- Entry systolic pressure 70 mmHg, rales 2/3 way up, cool clammy extremities, arterial saturation 85% on 100% oxygen rebreathing mask
- Brought emergently to the catheterization laboratory—right heart catheterization performed

VIDEO e23-1 (Play video) Baseline left coronary angiogram shows severe ulcerated stenosis of the distal left main coronary artery.

FIGURE e23-2 Cardiogenic shock is present. The mean pulmonary capillary wedge (PCW) pressure is elevated at 23 mmHg, with prominent *v* waves (peaking after the ECG T wave), suggestive of mitral regurgitation. Arterial pressure is reduced (91/55 mmHg) despite dopamine infusion, and the respiratory rate (24/min) plus arterial desaturation (93%) on 100% O_2 suggest incipient pulmonary edema.

VIDEO e23-2 (Play video) As seen also in this right anterior oblique projection.
VIDEO e23-3 (Play video) There is also significant stenosis in the midportion of the dominant right coronary artery.
VIDEO e23-4 (Play video) Intraaortic balloon pump placed via contralateral groin. 8 Fr guiding catheter is used to place separate wires into the left anterior descending (LAD) and circumflex (CX) arteries.
VIDEO e23-5 (Play video) Simultaneous inflation of two 3.0-mm adjacent "kissing" balloons.
VIDEO e23-6 (Play video) Simultaneous kissing stent deployment in the LAD and Cx.
VIDEO e23-7 (Play video) Post-stent result.
VIDEO e23-8 (Play video) Post-stent result.

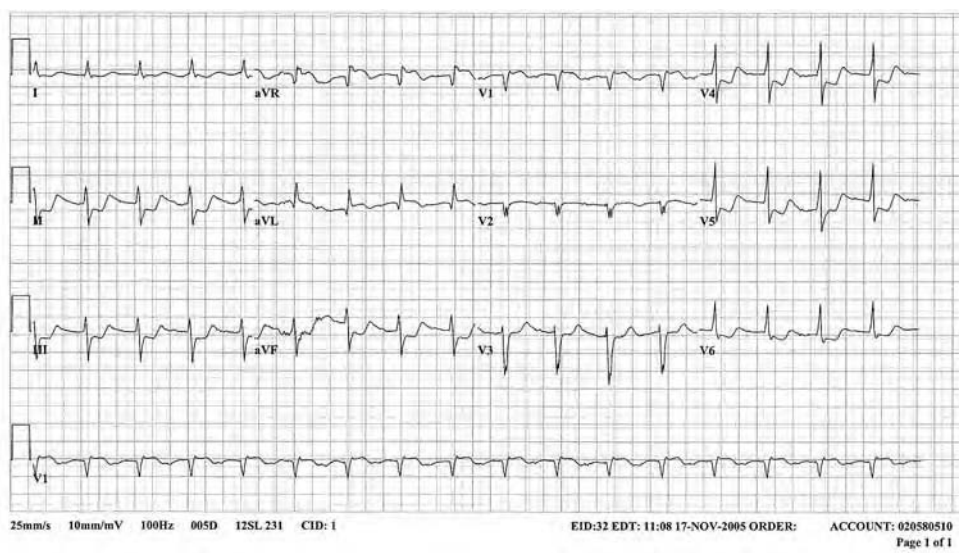

FIGURE e23-1 Presenting ECG—marked inferior and anterolateral ST depression.

*At the time that Dr. Baim prepared this chapter, he was a Professor of Medicine at Harvard Medical School and Senior Physician at Brigham and Women's Hospital. Since then, he has assumed the position of Chief Medical and Scientific Officer at Boston Scientific Co.

FIGURE e23-3 The aortic (Ao) pressure is reduced (78/52 mmHg), the pulmonary artery (PA) pressure is elevated (59/32 mmHg) and the Pa_{O_2} saturation (32%) corresponds to a cardiac index of 1.4 (L/min)/m^2, confirming the cardiogenic shock state.

FIGURE e23-5 The PCW fell from 34 mmHg preintervention to 20 mmHg post-intervention with resolution of the tall *v* waves, and PA saturation increased from 32 to 52%, while cardiac index (CI) rose from 1.4 to 2.1 (L/min)/m^2.

VIDEO e23-9 (Play video) Shock persists, so the right coronary artery lesion was also stented.
VIDEO e23-10 (Play video) Result.

LEFT MAIN CORONARY ARTERY STENOSIS WITH CARDIOGENIC SHOCK

- Cardiogenic shock requires emergent revascularization
- Right heart catheterization is useful to assess and monitor hemodynamics, in this case showing profound shock and probable ischemic mitral regurgitation
- Coronary angio showed the cause—a critical ulcerated stenosis of the distal left main and right coronary artery (RCA)
- With intraaortic balloon pump insertion via the contralateral groin, and double wire, "kissing" balloon and kissing stent implantation were performed via 8 Fr guide
- Because of ongoing shock, RCA stenting also performed
- This stabilized hemodynamics with PCW falling to 10 mmHg, and cardiac output normalizing over first 8 h in CCU
- Patient recovered despite a peak CPK of 2300, CKMB 274
- Discharged on day 7, despite a pre-procedure 85% estimated PCI mortality!

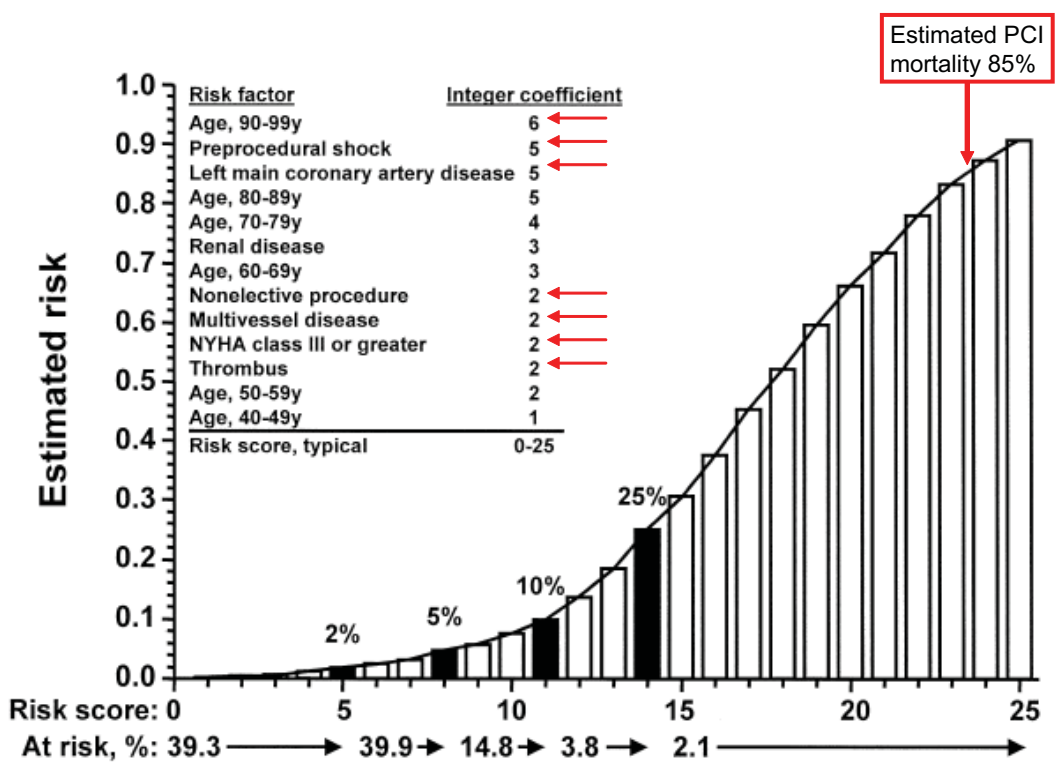

FIGURE e23-4 Estimation of risk of mortality of percutaneous coronary intervention (PCI). *(From M Singh et al: J Am Coll Cardiol 40:387, 2002.)*

CASE 2: INFERIOR MI WITH CARDIOGENIC SHOCK

(Figs. e23-6 and e23-7; Videos e23-11 to e23-19)

- A 67-year-old man with no prior cardiac history has 20 min of chest pain
- He is hypotensive and hypoxic (oxygen saturation 85% on 100% O_2)

VIDEO e23-11 (Play video) Angiography of the non-infarct left coronary shows unexpected distal left main bifurcation stenosis with possible superimposed thrombus.
VIDEO e23-12 (Play video) The right coronary artery is occluded proximally.
VIDEO e23-13 (Play video) Guidewire passage restores antegrade flow, exposing extensive linear thrombus and stenosis in the mid-RCA. Elapsed time since arrival in the catheterization laboratory—10 min.
VIDEO e23-14 (Play video) Some improvement in the filling defect after suction thrombectomy.
VIDEO e23-15 (Play video) Positioning a 3.5 × 32 mm drug-eluting stent to cover the culprit lesion.
VIDEO e23-16 (Play video) Stent deployment.
VIDEO e23-17 (Play video) Post-stent.
VIDEO e23-18 (Play video) Post-stent in shallow RAO cranial projection shows brisk flow in a very dominant right coronary artery. Elapsed time since catheterization laboratory arrival < 20 min.
VIDEO e23-19 (Play video) Sheath injection shows entry into the common femoral artery just above a moderate lesion. An intraaortic balloon pump was placed to stabilize the patient for bypass surgery of the left coronary artery the following day. Peak CPK was 337 (upper limit of normal = 200), indicating an aborted myocardial infarction with this very early reperfusion.

INFERIOR MI WITH CARDIOGENIC SHOCK

- Inferior MIs are usually more benign than anterior MIs
- When there *is* hypotension in an inferior MI, it may reflect right ventricular involvement as might have been the case here with the very proximal right coronary occlusion
- The severity of the hypotension and coexistent hypoxia here, however, suggest associated global ischemia due to the left main disease
- The patient was clinically stable after the intervention on the right coronary artery, and an intraaortic balloon was placed preparatory to bypass surgery of the left system
- The very early presentation and rapid intervention virtually completely aborted this life-threatening MI

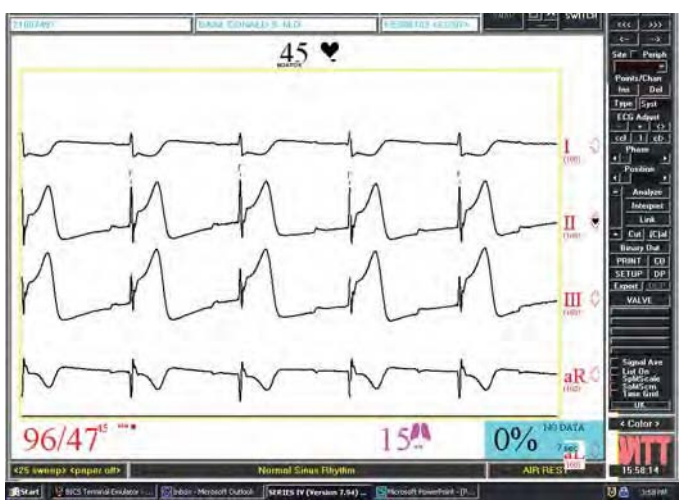

FIGURE e23-6 ECG shows sinus bradycardia, an accelerated idioventricular rhythm and isorhythmic dissociation, and profound inferior ST elevation.

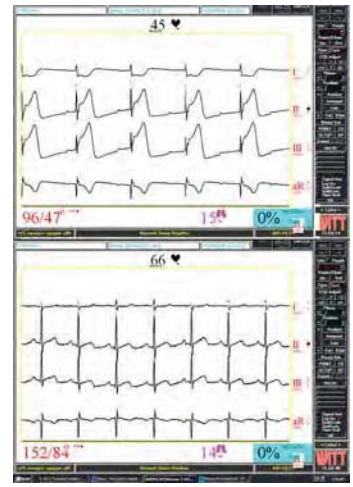

FIGURE e23-7 ***Top:*** Preintervention. ***Bottom:*** Postintervention. As soon as flow was restored, rhythm returned to normal sinus, ST elevation resolved, blood pressure rose to 152/84 mmHg despite discontinuation of dopamine, and oxygen saturation normalized (not shown). Right heart catheterization post-stent (not shown) revealed normal hemodynamics with wedge pressure of 12 mmHg and cardiac index of 2.4 (L/min)/m^2.

CASE 3: ANTERIOR MI STENT, WITH STENT THROMBOSIS

(Videos e23-20 to e23-25)

- A 37-year-old admitted cocaine user presented with severe chest pain and an anterior wall myocardial infarction
- Baseline angiography showed LAD thrombus, which was treated with thrombectomy
- The LAD and diagonal were then treated with "kissing" Cypher drug-eluting stents

VIDEO e23-20 Baseline angiography showing bifurcation thrombus in the LAD. ***A.*** (Play video) ***B.*** (Play video)
VIDEO e23-21 Rheolytic thrombectomy, with post-thrombectomy result. ***A.*** (Play video) ***B.*** (Play video)
VIDEO e23-22 Simultaneous drug-eluting stenting of the LAD-diagonal bifurcation (***A***) (Play video), with an excellent result (***B***) (Play video).
VIDEO e23-23 (Play video) The patient self-discontinued clopidogrel at 2 months after stenting, and developed recurrent pain 10 days later. Emergency coronary angiography shows recurrent LAD occlusion due to subacute stent thrombosis.
VIDEO e23-24 The stent thrombosis was crossed with wires into the distal LAD and diagonal (***A***) (Play video), restoring flow but showing filling defects representing thrombus. This was again treated with thrombectomy (***B***) (Play video).
VIDEO e23-25 (Play video) The result after thrombectomy was again excellent, although a small filling defect remains.

MYOCARDIAL INFARCTION STENTING, WITH STENT THROMBOSIS

- Coronary occlusions causing myocardial infarction usually contain some thrombus
- Although *routine* thrombectomy has not been shown to produce benefit, large thrombi respond well to thrombectomy
- The underlying, presumably atherosclerotic bifurcation lesion was then treated with "kissing" drug-eluting stents (DES) with a good result
- It is imperative that dual antiplatelet therapy be continued for at least 6 months post DES, since early discontinuation increases the risk of subacute stent thrombosis (SAT)
- In this case, as in most, SAT was associated with a substantial myocardial infarction

This case was contributed by Dr. James Kirshenbaum, Brigham and Women's Hospital, Boston; with permission.

CASE 4: DISTAL CORONARY DISEASE IN A DIABETIC PATIENT

(Videos e23-26 to e23-32)

- This 67-year-old non-insulin dependent diabetic developed refractory angina
- The culprit lesions were in the posterior descending and posterolateral branches of the dominant right coronary artery
- While bypass surgery is still the standard of care in diabetic patients with multivessel coronary disease, drug-eluting stenting may be an option in selected patients
- They present challenges for intervention because of distal location, small vessel diameter, diffuse disease, and a high restenosis rate due to diabetes mellitus

VIDEO e23-26 (Play video) Baseline angiogram in the shallow right anterior oblique view with cranial angulation shows the culprit lesions.
VIDEO e23-27 (Play video) Dilation of the posterior descending artery (PDA) with a 2-mm balloon.
VIDEO e23-28 (Play video) Post-angioplasty result shows significant residual stenosis.
VIDEO e23-29 Positioning a 2.5 × 24 mm drug-eluting stent in the distal posterior descending artery (PDA) (***A***) (Play video) and a 2.5 × 16 mm stent in the proximal PDA (***B***) (Play video).
VIDEO e23-30 (Play video) After documenting an excellent result in the PDA, the guidewire is relocated to the posterolateral branch, which is also predilated with a 2-mm balloon.
VIDEO e23-31 (Play video) Stent deployment.
VIDEO e23-32 (Play video) Excellent result in both vessels poststenting.

STENTING DISTAL CORONARY ARTERY DISEASE IN DIABETIC PATIENTS

- Diffuse distal disease in diabetics remains very challenging for both PCI and bypass surgery (due to poor distal targets)
- In this patient, poor prospects for a favorable outcome with surgery swung the balance to PCI
- The availability of flexible stents for small vessels has made treatment of such vessels possible
- Drug-eluting stents also reduce the incidence of restenosis (increased in patients with diabetes) to roughly 7% compared to roughly 25% with bare metal stents

CASE 5: CHRONIC TOTAL OCCLUSION STIFF GUIDEWIRE

(Videos e23-33 to e23-41)

- 75-year-old man with angina and inferior ischemia on exercise thallium-201 scan
- Catheterization shows moderate left anterior descending (LAD) coronary artery lesion, and chronic total occlusion of the circumflex (Cx) and right coronary arteries (RCA)

VIDEO e23-33 (Play video) Baseline left coronary injection shows LAD disease and occluded Cx-OM, plus left-to-right collaterals from AV groove Cx.
VIDEO e23-34 (Play video) Double (also known as "simultaneous") injection of the left and right coronaries demonstrates area of distal occlusion.
VIDEO e23-35 (Play video) Stiff guidewire slightly below trajectory.
VIDEO e23-36 (Play video) Stiff guidewire now across the occlusion and in a small branch of the PDA.
VIDEO e23-37 (Play video) After stenting, the RCA is widely patent, and now supplies right to left collaterals to the Cx.
VIDEO e23-38 (Play video) Poststenting view in AP cranial projection.
VIDEO e23-39 (Play video) Return of angina 10 months later—restudy shows widely patent RCA.
VIDEO e23-40 (Play video) Progression of the proximal LAD lesion, with slow flow at the apex.
VIDEO e23-41 (Play video) Post LAD stenting.

TOTAL OCCLUSION—STIFF WIRES

- The presence of one or more chronic total occlusions often leads to referral to surgery
- Using stiff (3.0–9 g) specialty guidewires, double injection, and painstaking technique, roughly 70% of these lesions can be crossed and, once crossed, stented with good long-term results.
- This patient declined to return for an attempt on the occluded Cx and did well for 10 months. Then he returned with a patent RCA and progressive disease in the LAD, which was in turn stented.
- If the RCA had not been opened, and the stents had not remained patent, the consequences of the severe LAD lesion progression might well have been more risky.

See Chaps. 22, 24, and 29.

CASE 6: HYPERTROPHIC CARDIOMYOPATHY (HCM) WITH OBSTRUCTION

HYPERTROPHIC CARDIOMYOPATHY (HCM) WITH OBSTRUCTION

(Figs. e23-8 to e23-11)

- Asymmetric hypertrophy of the upper septum can cause an intracavitary gradient within the LV due to contact of the anterior leaflet with the septum during systole

FIGURE e23-8 Simultaneous recording of the left ventricular (yellow) and femoral artery (orange) pressures shows a 60 mmHg pressure gradient. This could represent aortic stenosis, but this patient had a normal aortic valve on echo and asymmetric thickening of the upper left ventricular septum.

FIGURE e23-9 A spontaneous ventricular premature beat is followed by an augmented sinus beat marked by increased LV pressure and LV-Ao gradient, but a *decrease* in femoral artery pulse pressure, consistent with HCM with obstruction (Braunwald-Brockenbrough sign).

Copyright © 2008 The McGraw-Hill Companies. All rights reserved.

FIGURE e23-10 Slow pull-back of the end-hole catheter from the apex of the LV to the area just under the aortic valve shows disappearance of the pressure gradient.

FIGURE e23-11 Continued pull-back into the aorta shows another VPB with reduced aortic pulse pressure and a "spike and dome" central aortic pressure tracing, again consistent with HCM with obstruction. Note that the femoral artery systolic pressure is slightly higher than the central aortic pressure due to peripheral augmentation.

- While the LV-Ao pressure gradient may look superficially like that seen in aortic stenosis, the characteristic decrease in aortic or peripheral arterial pulse pressure and spike-and-dome pattern in a post-ventricular premature contraction are seen only in HCM with obstruction
- An end-hole catheter positioned towards the LV apex allows recording this dynamic gradient, and intracavitary localization of the gradient during pull-back
- The diagnosis and evaluation of this disease, however, is more often made by echocardiography in current practice

CASE 7: PERCUTANEOUS AORTIC VALVE REPLACEMENT

(Figs. e23-12 to e23-15)

- The preferred treatment for severe aortic stenosis is surgical replacement of the aortic valve
- Although the average surgical mortality for this procedure is ~4%, some patients are at significantly higher risk due to advanced age, poor LV function, or other comorbidities
- Percutaneous balloon valvuloplasty was evaluated in the late 1980s, and provided limited benefit
- A new class of investigational percutaneous aortic valve replacement techniques, using pericardial valves mounted in an outer stent, are now under investigation

The case and data shown here were provided by Dr. Eberhard Grube of Sieburg, Germany; with permission.

241 Hypertensive Vascular Disease

Theodore A. Kotchen

Hypertension doubles the risk of cardiovascular diseases, including coronary heart disease (CHD), congestive heart failure (CHF), ischemic and hemorrhagic stroke, renal failure, and peripheral arterial disease. Hypertension is often associated with additional cardiovascular disease risk factors, and the risk of cardiovascular disease increases with the total burden of risk factors. Although antihypertensive therapy clearly reduces the risks of cardiovascular and renal disease, large segments of the hypertensive population are either untreated or inadequately treated.

EPIDEMIOLOGY

Blood pressure levels, the rate of age-related blood pressure increase, and the prevalence of hypertension vary among countries and among subpopulations within a country. Hypertension is present in all populations except for a small number of individuals living in primitive, culturally isolated societies. It has been estimated that hypertension accounts for 6% of deaths worldwide. In industrialized societies, blood pressure increases steadily during the first two decades. In children and adolescents, blood pressure is associated with growth and maturation. Blood pressure "tracks" over time in children and between adolescence and young adulthood. In the United States, average systolic blood pressure is higher for men than for women during early adulthood, although among older individuals the age-related rate of rise is steeper for women. Consequently, among individuals age 60 and older, systolic blood pressures of women are higher than those of men. Among adults, diastolic blood pressure also increases progressively with age until ~55 years, after which it tends to decrease. The consequence is a widening of pulse pressure (the difference between systolic and diastolic blood pressure) beyond age 60.

In the United States, based on results of the National Health and Nutrition Examination Survey (NHANES), 28.7% (age-adjusted prevalence) of U.S. adults, or ~58.4 million individuals, have hypertension (defined as any one of the following: systolic blood pressure ≥140 mmHg; diastolic blood pressure ≥90 mmHg; taking antihypertensive medications). Hypertension prevalence is 33.5% in non-Hispanic blacks, 28.9% in non-Hispanic whites, and 20.7% in Mexican Americans. The burden of hypertension increases with age, and among individuals aged ≥60, hypertension prevalence is 65.4%. Recent evidence suggests that the prevalence of hypertension in the United States may be increasing, possibly as a consequence of increasing obesity. The prevalence of hypertension and stroke mortality rates are higher in the southeastern United States than in other regions. In African Americans, hypertension appears earlier, is generally more severe, and results in higher rates of morbidity and mortality from stroke, left ventricular hypertrophy, CHF, and end-stage renal disease (ESRD) than in Caucasian Americans.

Both environmental and genetic factors may contribute to regional and racial variations of blood pressure and hypertension prevalence. Studies of societies undergoing "acculturation" and studies of migrants from a less to a more urbanized setting indicate a profound environmental contribution to blood pressure. Obesity and weight gain are strong, independent risk factors for hypertension. It has been estimated that 60% of hypertensives are >20% overweight. Among populations, hypertension prevalence is related to dietary NaCl intake, and the age-related increase of blood pressure may be augmented by a high NaCl intake. Low dietary intakes of calcium and potassium may also contribute to the risk of hypertension. Additional environmental factors that may contribute to hypertension include alcohol consumption, psychosocial stress, and low levels of physical activity.

Adoption, twin, and family studies document a significant heritable component to blood pressure levels and hypertension. Family studies

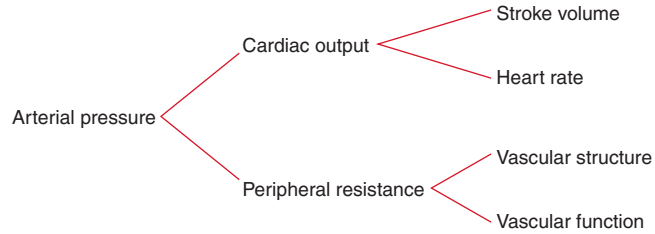

FIGURE 241-1 Determinants of arterial pressure.

controlling for a common environment indicate that blood pressure heritabilities are in the range of 15–35%. In twin studies, heritability estimates of blood pressure are ~60% for males and 30–40% for females. High blood pressure before age 55 occurs 3.8 times more frequently among persons with a positive family history of hypertension. Although specific genetic etiologies have been identified for relatively rare causes of hypertension, this has not been the case for the large majority of hypertensive patients. For most individuals, it is likely that hypertension represents a polygenic disorder in which a single gene or combination of genes act in concert with environmental exposures to contribute only a modest effect on blood pressure.

GENETIC CONSIDERATIONS Although specific genetic variants have been identified in rare Mendelian forms of hypertension (Table 241-5), these variants are not applicable to the vast majority (>98%) of patients with essential hypertension. Blood pressure levels reflect the contributions of many susceptibility genes interacting with each other and with the environment. Essential hypertension is a polygenic disorder, and different patients may carry different subsets of genes that lead to elevated blood pressure and to different phenotypes associated with hypertension, e.g., obesity, dyslipidemia, insulin resistance.

Several strategies are being utilized in the search for specific hypertension-related genes. Animal models (including selectively bred rats and congenic rat strains) provide a powerful approach for evaluating genetic loci and genes associated with hypertension. Comparative mapping strategies allow for the identification of syntenic genomic regions between the rat and human genome that may be involved in blood pressure regulation. In linkage studies, polymorphic genetic markers are examined at regular distances along each chromosome. Linkage information is gathered family by family, and the minimum family unit comprises at least two relatives, often a pair of siblings. To date, genome scans for hypertension have yielded inconsistent results. In complementary association studies, different alleles (or combinations of alleles at different loci) of specific genes or chromosomal regions are compared in hypertensive patients and normotensive control subjects. Current evidence suggests that genes encoding components of the renin-angiotensin-aldosterone system, and angiotensinogen and angiotensin-converting enzyme (ACE) polymorphisms, may be related to hypertension and to blood pressure sensitivity to dietary NaCl. The alpha-adducin gene is also thought to be associated with increased renal tubular absorption of sodium, and variants of this gene may also be associated with hypertension and salt sensitivity of blood pressure. Other genes possibly related to hypertension include genes encoding the AT_1 receptor, aldosterone synthase, and the β_2-adrenoreceptor.

Preliminary evidence suggests that there may also be genetic determinants of target organ damage attributed to hypertension. Family studies indicate significant heritability of left ventricular mass, and there is considerable individual variation in the responses of the heart to hypertension. Family studies and variations in candidate genes associated with renal damage suggest that genetic factors may also contribute to hypertensive nephropathy. Specific genetic variants have been linked to CHD and stroke.

In the future, it is possible that DNA analysis will predict individual risk for hypertension and target organ damage and will identify responders to specific classes of antihypertensive agents. However, with the exception of the rare, monogenic hypertensive diseases, the genetic variants

associated with hypertension remain to be confirmed, and the intermediate steps by which these variants affect blood pressure remain to be determined.

MECHANISMS OF HYPERTENSION

To provide a framework for understanding the pathogenesis and treatment options of hypertensive disorders, it is useful to understand factors involved in the regulation of both normal and elevated arterial pressure. Cardiac output and peripheral resistance are the two determinants of arterial pressure (Fig. 241-1). Cardiac output is determined by stroke volume and heart rate; stroke volume is related to myocardial contractility and to the size of the vascular compartment. Peripheral resistance is determined by functional and anatomic changes in small arteries (lumen diameter 100–400 μm) and arterioles.

INTRAVASCULAR VOLUME

Vascular volume is a primary determinant of arterial pressure over the long term. Although the extracellular fluid space is composed of vascular and interstitial spaces, in general, alterations in total extracellular fluid volume are associated with proportional changes of blood volume. Sodium is predominantly an extracellular ion and is a primary determinant of the extracellular fluid volume. When NaCl intake exceeds the capacity of the kidney to excrete sodium, vascular volume initially expands and cardiac output increases. However, many vascular beds (including kidney and brain) have the capacity to autoregulate blood flow, and if constant blood flow is to be maintained in the face of increased arterial pressure, resistance within that bed must increase, since:

$$\text{Blood flow} = \frac{\text{pressure across the vascular bed}}{\text{vascular resistance}}$$

The initial elevation of blood pressure in response to vascular volume expansion is related to an increase of cardiac output; however, over time, peripheral resistance increases and cardiac output reverts toward normal. The effect of sodium on blood pressure is related to the provision of sodium with chloride; non-chloride salts of sodium have little or no effect on blood pressure. As arterial pressure increases in response to a high NaCl intake, urinary sodium excretion increases and sodium balance is maintained at the expense of an increase in arterial pressure. The mechanism for this "pressure-natriuresis" phenomenon may involve a subtle increase of glomerular filtration rate, decreased absorbing capacity of the renal tubules, and possibly hormonal factors such as atrial natriuretic factor. In individuals with an impaired capacity to excrete sodium, greater increases of arterial pressure are required to achieve natriuresis and sodium balance.

NaCl-dependent hypertension may be a consequence of a decreased capacity of the kidney to excrete sodium, due to either intrinsic renal disease or to increased production of a salt-retaining hormone (mineralocorticoid) resulting in increased renal tubular reabsorption of sodium. Renal tubular sodium reabsorption may also be augmented by increased neural activity to the kidney. In each of these situations, a higher arterial pressure may be required to achieve sodium balance, i.e., the pressure-natriuresis phenomenon. Conversely, salt-wasting disorders are associated with low blood pressure levels. ESRD is an extreme example of volume-dependent hypertension. In ~80% of these patients, vascular volume and hypertension can be controlled with adequate dialysis; in the other 20%, the mechanism of hypertension is related to increased activity of the renin-angiotensin system and is likely to be responsive to pharmacologic blockade of renin-angiotensin.

AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system maintains cardiovascular homeostasis via pressure, volume, and chemoreceptor signals. Adrenergic reflexes modulate blood pressure over the short term, and adrenergic function, in concert with hormonal and volume-related factors, contributes to the long-term regulation of arterial pressure. The three endogenous catecholamines are norepinephrine, epinephrine, and dopamine. All three play important roles in tonic and phasic cardiovascular regulation. Adrenergic neurons synthesize norepinephrine and dopamine (a precursor of norepinephrine), which are stored in vesicles within the neuron. When the neuron is stimulated, these neurotransmitters are released into the synaptic cleft and to receptor sites on target tissues. Subsequently, the transmitter is either metabolized or taken up into the neuron by an active reuptake process. Epinephrine is synthesized in the adrenal medulla and released into the circulation upon adrenal stimulation.

The activities of the adrenergic receptors are mediated by guanosine nucleotide-binding regulatory proteins (G proteins) and by intracellular concentrations of downstream second messengers. In addition to receptor affinity and density, physiologic responsiveness to catecholamines may also be altered by the efficiency of receptor-effector coupling at a site "distal" to receptor binding. The receptor sites are relatively specific both for the transmitter substance and for the response that occupancy of the receptor site elicits. Norepinephrine and epinephrine are agonists for all adrenergic receptor subtypes, although with varying affinities. Based on their physiology and pharmacology, adrenergic receptors have been divided into two principal types: α and β. These types have been further differentiated into α_1, α_2, β_1, and β_2 receptors. Recent molecular cloning studies have identified several additional subtypes. α Receptors are more avidly occupied and activated by norepinephrine than by epinephrine, and the reverse is true for β receptors. α_1 Receptors are located on postsynaptic cells in smooth muscle and elicit vasoconstriction. α_2 Receptors are localized on presynaptic membranes of postganglionic nerve terminals that synthesize norepinephrine. When activated by catecholamines, α_2 receptors act as negative feedback controllers, inhibiting further norepinephrine release. Different classes of antihypertensive agents either inhibit α_1 receptors or act as agonists of α_2 receptors and reduce systemic sympathetic outflow. Activation of myocardial β_1 receptors stimulates the rate and strength of cardiac contraction, and consequently increases cardiac output. β_1 Receptor activation also stimulates renin release from the kidney. Another class of antihypertensive agents acts by inhibiting β_1 receptors. Activation of β_2 receptors by epinephrine relaxes vascular smooth muscle and results in vasodilation.

Circulating catecholamine concentrations may affect the number of adrenoreceptors in various tissues. Downregulation of receptors may be a consequence of sustained high levels of catecholamines and provides an explanation for decreasing responsiveness, or tachyphylaxis, to catecholamines. For example, orthostatic hypotension is frequently observed in patients with pheochromocytoma, possibly due to the lack of norepinephrine-induced vasoconstriction with assumption of the upright posture. Conversely, with chronic reduction of neurotransmitter substances, adrenoreceptors may increase in number, or be upregulated, resulting in increased responsiveness to the neurotransmitter. Chronic administration of agents that block adrenergic receptors may result in upregulation, and withdrawal of these agents may produce a condition of temporary hypersensitivity to sympathetic stimuli. For example, clonidine is an antihypertensive agent that is a centrally acting α_2 agonist that inhibits sympathetic outflow. Rebound hypertension may occur with the abrupt cessation of clonidine therapy, probably as a consequence of upregulation of α_1 receptors.

Several reflexes modulate blood pressure on a minute-to-minute basis. One arterial baroreflex is mediated by stretch-sensitive sensory nerve endings located in the carotid sinuses and the aortic arch. The rate of firing of these baroreceptors increases with arterial pressure, and the net effect is a decrease of sympathetic outflow, resulting in decreases of arterial pressure and heart rate. This is a primary mechanism for rapid buffering of acute fluctuations of arterial pressure that may occur during postural changes, behavioral or physiologic stress, and changes in blood volume. However, the activity of the baroreflex declines or adapts to sustained increases of arterial pressure such that the baroreceptors are reset to higher pressures. Patients with autonomic neuropathy and impaired baroreflex function may have extremely labile blood pressures with difficult-to-control episodic blood pressure spikes.

Pheochromocytoma is the most obvious example of hypertension related to increased catecholamine production, in this instance by a

tumor. Blood pressure can be reduced by surgical excision of the tumor or by pharmacologic treatment with an α_1 receptor antagonist or with an inhibitor of tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. Increased sympathetic activity may contribute to other forms of hypertension. Drugs that block the sympathetic nervous system are potent antihypertensive agents, indicating that the sympathetic nervous system plays a permissive, although perhaps not a causative, role in the maintenance of increased arterial pressure.

RENIN-ANGIOTENSIN-ALDOSTERONE

The renin-angiotensin-aldosterone system contributes to the regulation of arterial pressure primarily via the vasoconstrictor properties of angiotensin II and the sodium-retaining properties of aldosterone. Renin is an aspartyl protease that is synthesized as an enzymatically inactive precursor, prorenin. Most renin in the circulation is synthesized in the segment of the renal afferent renal arteriole (juxtaglomerular cells) that abuts the glomerulus and a group of sensory cells located at the distal end of the loop of Henle, the macula densa. Prorenin may be secreted directly into the circulation or may be activated within secretory cells and released as active renin. Although human plasma contains two- to fivefold times more prorenin than renin, there is no evidence that prorenin contributes to the physiologic activity of this system. There are three primary stimuli for renin secretion: (1) decreased NaCl transport in the thick ascending limb of the loop of Henle (macula densa mechanism), (2) decreased pressure or stretch within the renal afferent arteriole (baroreceptor mechanism), and (3) sympathetic nervous system stimulation of renin-secreting cells via β_1 adrenoreceptors. Conversely, renin secretion is inhibited by increased NaCl transport in the thick ascending limb of the loop of Henle, by increased stretch within the renal afferent arteriole, and by β_1 receptor blockade. In addition, renin secretion may be modulated by a number of humoral factors, including angiotensin II. Angiotensin II directly inhibits renin secretion due to angiotensin II type 1 receptors on juxtaglomerular cells, and renin secretion increases in response to pharmacologic blockade of either ACE or angiotensin II receptors.

Once released into the circulation, active renin cleaves a substrate, angiotensinogen, to form an inactive decapeptide, angiotensin I (Fig. 241-2). A converting enzyme, located primarily but not exclusively in the pulmonary circulation, converts angiotensin I to the active octapeptide, angiotensin II, by releasing the C-terminal histidyl-leucine dipeptide. The same converting enzyme cleaves a number of other peptides, including and thereby inactivating the vasodilator bradykinin. Acting primarily through angiotensin II type 1 (AT_1) receptors located on cell membranes, angiotensin II is a potent pressor substance, the primary trophic factor for the secretion of aldosterone by the adrenal zona glomerulosa, and a potent mitogen stimulating vascular smooth-muscle cell and myocyte growth. Independent of its hemodynamic effects, angiotensin II may play a role in the pathogenesis of atherosclerosis through a direct cellular action on the vessel wall. An angiotensin II type 2 (AT_2) receptor has been characterized. It is widely distributed in the kidney and has the opposite functional effects of the AT_1 receptor. The AT_2 receptor induces vasodilation, sodium excretion, and inhibition of cell growth and matrix formation. Experimental evidence suggests that the AT_2 receptor improves vascular remodeling by stimulating smooth-muscle cell apoptosis and contributes to the regulation of glomerular filtration rate. AT_1 receptor blockade induces an increase in AT_2 receptor activity. Currently, the AT_2 receptor has a less well defined functional role than the AT_1 receptor.

Renin-secreting tumors are clear examples of renin-dependent hypertension. In the kidney, these include benign hemangiopericytomas of the juxtaglomerular apparatus, and infrequently renal carcinomas, including Wilms' tumors. Renin-producing carcinomas have also been described in lung, liver, pancreas, colon, and adrenals. In these instances, in addition to excision and/or ablation of the tumor, treatment of hypertension includes pharmacologic therapies targeted to inhibit angiotensin II production or action. Renovascular hypertension is another renin-mediated form of hypertension. Obstruction of the renal artery leads to decreased renal perfusion pressure, thereby stimulating

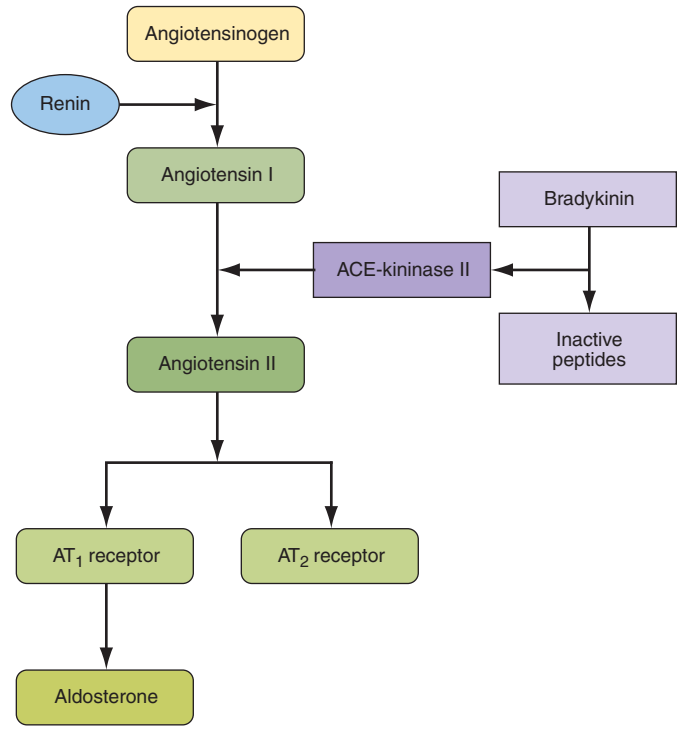

FIGURE 241-2 Renin-angiotensin-aldosterone axis.

renin secretion. Over time, as a consequence of secondary renal damage, this form of hypertension may become less renin dependent.

Angiotensinogen, renin, and angiotensin II are also synthesized locally in many tissues, including the brain, pituitary, aorta, arteries, heart, adrenal glands, kidneys, adipocytes, leukocytes, ovaries, testes, uterus, spleen, and skin. Angiotensin II in tissues may be formed by the enzymatic activity of renin or by other proteases, e.g., tonin, chymase, and cathepsins. In addition to regulating local blood flow, tissue angiotensin II is a mitogen that stimulates growth and contributes to modeling and repair. Excess tissue angiotensin II may contribute to atherosclerosis, cardiac hypertrophy, and renal failure and consequently may be a target for pharmacologic therapy to prevent target organ damage.

Angiotensin II is the primary trophic factor regulating the synthesis and secretion of aldosterone by the zona glomerulosa of the adrenal cortex. Aldosterone synthesis is also dependent on potassium, and aldosterone secretion may be decreased in potassium-depleted individuals. Although acute elevations of adrenocorticotropic hormone (ACTH) levels also increase aldosterone secretion, ACTH is not an important trophic factor for the chronic regulation of aldosterone.

Aldosterone is a potent mineralocorticoid that increases sodium reabsorption by amiloride-sensitive epithelial sodium channels (ENaC) on the apical surface of the principal cells of the renal cortical collecting duct (Chap. 271). Electric neutrality is maintained by exchanging sodium for potassium and hydrogen ions. Consequently, increased aldosterone secretion may result in hypokalemia and alkalosis. Because potassium depletion may inhibit aldosterone synthesis, clinically, hypokalemia should be corrected before evaluating a patient for hyperaldosteronism.

Mineralocorticoid receptors are also expressed in the colon, salivary glands, and sweat glands. Cortisol also binds to these receptors but normally functions as a less potent mineralocorticoid than aldosterone because cortisol is converted to cortisone by the enzyme 11 β-hydroxysteroid dehydrogenase type 2. Cortisone has no affinity for the mineralocorticoid receptor. Primary aldosteronism is a compelling example of mineralocorticoid-mediated hypertension. In this disorder, adrenal aldosterone synthesis and release are independent of renin-angiotensin, and renin release is suppressed by the resulting volume expansion.

Aldosterone also has effects on nonepithelial targets. Independent of a potential effect on blood pressure, aldosterone may also play a role in cardiac hypertrophy and CHF. Aldosterone acts via mineralocorticoid receptors within the myocardium to enhance extracellular matrix and collagen deposition. In animal models, high circulating aldosterone levels stimulate cardiac fibrosis and left ventricular hypertrophy, and spironolactone (an aldosterone antagonist) prevents aldosterone-induced myocardial fibrosis. Pathologic patterns of left ventricular geometry have also been associated with elevations of plasma aldosterone concentration in patients with essential hypertension, as well as in patients with primary aldosteronism. In patients with CHF, low-dose spironolactone reduces the risk of progressive heart failure and sudden death from cardiac causes by 30%. Owing to a renal hemodynamic effect, in patients with primary aldosteronism, high circulating levels of aldosterone may also cause glomerular hyperfiltration and albuminuria. These renal effects are reversible after removal of the effects of excess aldosterone by adrenalectomy or spironolactone.

Increased activity of the renin-angiotensin-aldosterone axis is not invariably associated with hypertension. In response to a low-NaCl diet or to volume contraction, arterial pressure and volume homeostasis may be maintained by increased activity of the renin-angiotensin-aldosterone axis. Secondary aldosteronism (i.e., increased aldosterone secondary to increased renin-angiotensin), but not hypertension, is also observed in edematous states such as CHF and liver disease.

VASCULAR MECHANISMS

Vascular radius and compliance of resistance arteries are also important determinants of arterial pressure. Resistance to flow varies inversely with the fourth power of the radius, and consequently small decreases in lumen size significantly increase resistance. In hypertensive patients, structural, mechanical, or functional changes may reduce lumen diameter of small arteries and arterioles. Remodeling refers to geometric alterations in the vessel wall without changing vessel volume. Hypertrophic (increased cell number, increased cell size, and increased deposition of intercellular matrix) or eutrophic (no change in the amount of material in the vessel wall) vascular remodeling results in decreased lumen size and hence contributes to increased peripheral resistance. Apoptosis, low-grade inflammation, and vascular fibrosis also contribute to remodeling. Lumen diameter is also related to elasticity of the vessel. Vessels with a high degree of elasticity can accommodate an increase of volume with relatively little change of pressure, whereas in a semi-rigid vascular system, a small increment in volume induces a relatively large increment of pressure.

Hypertensive patients have stiffer arteries, and arteriosclerotic patients may have particularly high systolic blood pressures and wide pulse pressures as a consequence of decreased vascular compliance due to structural changes in the vascular wall. Recent evidence suggests that arterial stiffness has independent predictive value for cardiovascular events. Clinically, a number of devices are available to evaluate arterial stiffness or compliance, including ultrasound and MRI.

Ion transport by vascular smooth-muscle cells may contribute to hypertension-associated abnormalities of vascular tone and vascular growth, both of which are modulated by intracellular pH (pH_i). Three ion transport mechanisms participate in the regulation of pH_i: (1) Na^+-H^+ exchange, (2) Na^+-dependent HCO_3^--Cl^- exchange, and (3) cation-independent HCO_3^--Cl^- exchange. Based on measurements in cell types that are more accessible than vascular smooth muscle (e.g., leukocytes, erythrocytes, platelets, skeletal muscle), activity of the Na^+-H^+ exchanger is increased in hypertension, and this may result in increased vascular tone by two mechanisms. First, increased sodium entry may lead to increased vascular tone by activating Na^+-Ca^{2+} exchange and thereby increasing intracellular calcium. Second, increased pH_i enhances calcium sensitivity of the contractile apparatus, leading to an increase in contractility for a given intracellular calcium concentration. Additionally, increased Na^+-H^+ exchange might stimulate vascular smooth-muscle cell growth by enhancing sensitivity to mitogens.

Vascular endothelial function also modulates vascular tone. The vascular endothelium synthesizes and releases a spectrum of vasoactive substances, including nitric oxide, a potent vasodilator. Endothelium-dependent vasodilation is impaired in hypertensive patients. This impairment is often assessed with high-resolution ultrasonography as flow-mediated vasodilation of the brachial artery. Alternatively, endothelium-dependent vasodilation may be assessed with venous occlusion plethysmography in response to an intraarterially infused endothelium-dependent vasodilator, e.g., acetylcholine.

Presently, it is not known if these hypertension-related vascular abnormalities of ion transport and endothelial function are primary alterations or secondary consequences of elevated arterial pressure. Limited evidence suggests that vascular compliance and endothelium-dependent vasodilation may be improved by aerobic exercise, weight loss, and antihypertensive agents. It remains to be determined whether these interventions affect arterial structure and stiffness via a blood pressure–independent mechanism and whether different classes of antihypertensive agents preferentially affect vascular structure and function.

PATHOLOGIC CONSEQUENCES OF HYPERTENSION

Hypertension is a risk factor for all clinical manifestations of atherosclerosis. It is an independent predisposing factor for heart failure, coronary artery disease, stroke, renal disease, and peripheral arterial disease (PAD).

HEART

Heart disease is the most common cause of death in hypertensive patients. Hypertensive heart disease is the result of structural and functional adaptations leading to left ventricular hypertrophy, diastolic dysfunction, CHF, abnormalities of blood flow due to atherosclerotic coronary artery disease and microvascular disease, and cardiac arrhythmias.

Both genetic and hemodynamic factors contribute to left ventricular hypertrophy. Clinically, left ventricular hypertrophy can be diagnosed by electrocardiogram, although echocardiography provides a more sensitive measure of left ventricular wall thickness. Individuals with left ventricular hypertrophy are at increased risk for CHD, stroke, CHF, and sudden death. Aggressive control of hypertension can regress or reverse left ventricular hypertrophy and reduce the risk of cardiovascular disease. It is not clear if different classes of antihypertensive agents have an added impact on reducing left ventricular mass, independent of their blood pressure–lowering effect.

Abnormalities of diastolic function, ranging from asymptomatic heart disease to overt heart failure, are common in hypertensive patients. Patients with diastolic heart failure have a preserved ejection fraction, which is a measure of systolic function. Approximately one-third of patients with CHF have normal systolic function but abnormal diastolic function. Diastolic dysfunction is an early consequence of hypertension-related heart disease and is exacerbated by left ventricular hypertrophy and ischemia. Clinically, cardiac catheterization provides the most accurate assessment of diastolic function; however, this is an invasive procedure and generally not indicated for the assessment of diastolic function. Alternatively, diastolic function can be evaluated by several noninvasive methods, including echocardiography and radionuclide angiography.

BRAIN

Hypertension is an important risk factor for brain infarction and hemorrhage. Approximately 85% of strokes are due to infarction and the remainder are due to hemorrhage, either intracerebral hemorrhage or subarachnoid hemorrhage. The incidence of stroke rises progressively with increasing blood pressure levels, particularly systolic blood pressure in individuals >65 years. Treatment of hypertension convincingly decreases the incidence of both ischemic and hemorrhagic strokes.

Hypertension is also associated with impaired cognition in an aging population, and longitudinal studies support an association between mid-life hypertension and late-life cognitive decline. Hypertension-related cognitive impairment and dementia may be a consequence of a single infarct due to occlusion of a "strategic" larger vessel or multiple

lacunar infarcts due to occlusive small vessel disease resulting in subcortical white matter ischemia. Several clinical trials suggest that antihypertensive therapy has a beneficial effect on cognitive function, although this remains an active area of investigation.

Cerebral blood flow remains unchanged over a wide range of arterial pressures (mean arterial pressure of 50–150 mmHg) through a process termed *autoregulation* of blood flow. In patients with the clinical syndrome of malignant hypertension, encephalopathy is related to failure of autoregulation of cerebral blood flow at the upper pressure limit, resulting in vasodilation and hyperperfusion. Signs and symptoms of hypertensive encephalopathy may include severe headache, nausea and vomiting (often of a projectile nature), focal neurologic signs, and alterations in mental status. Untreated, hypertensive encephalopathy may progress to stupor, coma, seizures, and death within hours. It is important to distinguish hypertensive encephalopathy from other neurologic syndromes that may be associated with hypertension, e.g., cerebral ischemia, hemorrhagic or thrombotic stroke, seizure disorder, mass lesions, pseudotumor cerebri, delirium tremens, meningitis, acute intermittent porphyria, traumatic or chemical injury to the brain, and uremic encephalopathy.

KIDNEY

Primary renal disease is the most common etiology of secondary hypertension. Conversely, hypertension is a risk factor for renal injury and ESRD. The increased risk associated with high blood pressure is graded, continuous, and present throughout the entire distribution of blood pressure above optimal. Renal risk appears to be more closely related to systolic than to diastolic blood pressure, and black men are at greater risk than white men for developing ESRD at every level of blood pressure.

The atherosclerotic, hypertension-related vascular lesions in the kidney primarily affect the preglomerular arterioles, resulting in ischemic changes in the glomeruli and postglomerular structures. Glomerular injury may also be a consequence of direct damage to the glomerular capillaries due to glomerular hyperperfusion. Glomerular pathology progresses to glomerulosclerosis, and eventually the renal tubules may also become ischemic and gradually atrophic. The renal lesion associated with malignant hypertension consists of fibrinoid necrosis of the afferent arterioles, sometimes extending into the glomerulus, and may result in focal necrosis of the glomerular tuft.

Clinically, macroalbuminuria (a random urine albumin/creatinine ratio > 300 mg/g) or microalbuminuria (a random urine albumin/creatinine ratio 30–300 mg/g) are early markers of renal injury. These are also risk factors for renal disease progression and for cardiovascular disease.

PERIPHERAL ARTERIES

In addition to contributing to the pathogenesis of hypertension, blood vessels may be a target organ for atherosclerotic disease secondary to long-standing elevated blood pressure. Hypertensive patients with arterial disease of the lower extremities are at increased risk for future cardiovascular disease. Although patients with stenotic lesions of the lower extremities may be asymptomatic, intermittent claudication is the classic symptom of PAD. This is characterized by aching pain in the calves or buttocks while walking that is relieved by rest. The ankle-brachial index is a useful approach for evaluating PAD and is defined as the ratio of noninvasively assessed ankle to brachial (arm) systolic blood pressure. An ankle-brachial index < 0.90 is considered diagnostic of PAD and is associated with >50% stenosis in at least one major lower limb vessel. Several studies suggest that an ankle-brachial index < 0.80 is associated with elevated blood pressure, particularly systolic blood pressure.

DEFINING HYPERTENSION

From an epidemiologic perspective, there is no obvious level of blood pressure that defines hypertension. In adults, there is a continuous, incremental risk of cardiovascular disease, stroke, and renal disease across levels of both systolic and diastolic blood pressure. The Multiple Risk Factor Intervention Trial (MRFIT), which included >350,000 male participants, demonstrated a continuous and graded influence of both systolic and diastolic blood pressure on CHD mortality, extending down to systolic blood pressures of 120 mmHg. Similarly, results of a meta-analysis involving almost 1 million participants indicate that ischemic heart disease mortality, stroke mortality, and mortality from other vascular causes are directly related to the height of the blood pressure, beginning at 115/75 mmHg, without evidence of a threshold. Cardiovascular disease risk doubles for every 20-mmHg increase in systolic and 10-mmHg increase in diastolic pressure. Among older individuals, systolic blood pressure and pulse pressure are more powerful predictors of cardiovascular disease than diastolic blood pressure.

TABLE 241-1 BLOOD PRESSURE CLASSIFICATION

Blood Pressure Classification	Systolic, mmHg	Diastolic, mmHg
Normal	<120	*and* <80
Prehypertension	120–139	*or* 80–89
Stage 1 hypertension	140–159	*or* 90–99
Stage 2 hypertension	≥160	*or* ≥100
Isolated systolic hypertension	≥140	*and* <90

Source: Adapted from Chobanian et al.

Clinically, hypertension might be defined as that level of blood pressure at which the institution of therapy reduces blood pressure–related morbidity and mortality. Current clinical criteria for defining hypertension are generally based on the average of two or more seated blood pressure readings during each of two or more outpatient visits. A recent classification recommends blood pressure criteria for defining normal blood pressure, prehypertension, hypertension (stages I and II), and isolated systolic hypertension, which is a common occurrence among the elderly (Table 241-1). In children and adolescents, hypertension is generally defined as systolic and/or diastolic blood pressure consistently >95th percentile for age, gender, and height. Blood pressures between the 90th and 95th percentiles are considered prehypertensive and are an indication for lifestyle interventions.

Home blood pressure and average 24-h ambulatory blood pressure measurements are generally lower than clinic blood pressures. Because ambulatory blood pressure recordings yield multiple readings throughout the day and night, they provide a more comprehensive assessment of the vascular burden of hypertension than a limited number of office readings. Increasing evidence suggests that home blood pressures, including 24-h blood pressure recordings, more reliably predict target organ damage than office blood pressures. Blood pressure tends to be higher in the early morning hours, soon after waking, than at other times of day. Myocardial infarction and stroke are more frequent in the early morning hours. Nighttime blood pressures are generally 10–20% lower than daytime blood pressures, and an attenuated nighttime blood pressure "dip" is associated with increased cardiovascular disease risk. Blunting of the day-night blood pressure pattern occurs in several clinical conditions, including sleep apnea and autonomic neuropathy, and in certain populations, including African Americans. Recommended criteria for a diagnosis of hypertension are average awake blood pressure ≥135/85 mmHg and asleep blood pressure ≥120/75 mmHg. These levels approximate a clinic blood pressure of 140/90 mmHg.

Approximately 15–20% of patients with stage 1 hypertension (as defined in Table 241-1) based on office blood pressures have average ambulatory readings <135/85 mmHg. This phenomenon, so-called white coat hypertension, may also be associated with an increased risk of target organ damage (e.g., left ventricular hypertrophy, carotid atherosclerosis, overall cardiovascular morbidity), although to a lesser extent than individuals with elevated office and ambulatory readings. Individuals with white coat hypertension are also at increased risk for developing sustained hypertension.

CLINICAL DISORDERS OF HYPERTENSION

Depending on methods of patient ascertainment, ~80–95% of hypertensive patients are diagnosed as having "essential" hypertension (also

TABLE 241-2 SYSTOLIC HYPERTENSION WITH WIDE PULSE PRESSURE

1. Decreased vascular compliance (arteriosclerosis)
2. Increased cardiac output
   a. Aortic regurgitation
   b. Thyrotoxicosis
   c. Hyperkinetic heart syndrome

TABLE 241-3 SECONDARY CAUSES OF SYSTOLIC AND DIASTOLIC HYPERTENSION

Renal	Parenchymal diseases, renal cysts (including polycystic kidney disease), renal tumors (including renin-secreting tumors), obstructive uropathy
Renovascular	Arteriosclerotic, fibromuscular dysplasia
Adrenal	Primary aldosteronism, Cushing's syndrome, 17α-hydroxylase deficiency, 11β-hydroxylase deficiency, 11-hydroxysteroid dehydrogenase deficiency (licorice), pheochromocytoma
Aortic coarctation	
Obstructive sleep apnea	
Preeclampsia/eclampsia	
Neurogenic	Psychogenic, diencephalic syndrome, familial dysautonomia, polyneuritis (acute porphyria, lead poisoning), acute increased intracranial pressure, acute spinal cord section
Miscellaneous endocrine	Hypothyroidism, hyperthyroidism, hypercalcemia, acromegaly
Medications	High-dose estrogens, adrenal steroids, decongestants, appetite suppressants, cyclosporine, tricyclic antidepressants, monamine oxidase inhibitors, erythropoietin, nonsteroidal anti-inflammatory agents, cocaine
Mendelian forms of hypertension	See Table 241-4

referred to as primary or idiopathic hypertension). In the remaining 5–20% of hypertensive patients, a specific underlying disorder causing the elevation of blood pressure can be identified (Tables 241-2 and 241-3). In individuals with "secondary" hypertension, a specific mechanism for the blood pressure elevation is often more apparent.

ESSENTIAL HYPERTENSION

Essential hypertension tends to be familial and is likely to be the consequence of an interaction between environmental and genetic factors. The prevalence of essential hypertension increases with age, and individuals with relatively high blood pressures at younger ages are at increased risk for the subsequent development of hypertension. It is likely that essential hypertension represents a spectrum of disorders with different underlying pathophysiologies. In the majority of patients with established hypertension, peripheral resistance is increased and cardiac output is normal or decreased; however, in younger patients with mild or labile hypertension, cardiac output may be increased and peripheral resistance may be normal.

When plasma renin activity (PRA) is plotted against 24-h sodium excretion, ~10–15% of hypertensive patients have high PRA and 25% have low PRA. High-renin patients may have a vasoconstrictor form of hypertension, whereas low-renin patients may have a volume-dependent hypertension. Inconsistent associations between plasma aldosterone and blood pressure have been described in patients with essential hypertension. The association between aldosterone and blood pressure is more striking in African Americans, and PRA tends to be low in hypertensive African Americans. This raises the possibility that subtle increases of aldosterone may contribute to hypertension in at least some groups of patients who do not have overt primary aldosteronism. Furthermore, spironolactone, an aldosterone antagonist, may be a particularly effective antihypertensive agent for some patients with essential hypertension, including some patients with "drug-resistant" hypertension.

METABOLIC SYNDROME

(See also Chap. 236) Hypertension and dyslipidemia frequently occur together and in association with resistance to insulin-stimulated glucose uptake. This clustering of risk factors is often, but not invariably, associated with obesity, particularly abdominal obesity. Insulin resistance is also associated with an unfavorable imbalance in the endothelial production of mediators that regulate platelet aggregation, coagulation, fibrinolysis, and vessel tone. When these risk factors cluster, the risks for CHD, stroke, diabetes, and cardiovascular disease mortality are further increased.

Depending on the populations studied and the methodologies for defining insulin resistance, ~25–50% of non-obese, non-diabetic hypertensive persons are insulin resistant. The constellation of insulin resistance, hypertension, and dyslipidemia has been designated as the *metabolic syndrome*. As a group, first-degree relatives of patients with essential hypertension are also insulin resistant, and hyperinsulinemia (a surrogate marker of insulin resistance) may predict the eventual development of hypertension and cardiovascular disease. Although the metabolic syndrome may in part be heritable as a polygenic condition, the expression of the syndrome is modified by environmental factors, such as degree of physical activity and diet. Insulin sensitivity increases and blood pressure decreases in response to weight loss. The recognition that cardiovascular disease risk factors tend to cluster within individuals has important implications for the evaluation and treatment of hypertension. Evaluation of both hypertensive patients and individuals at risk for developing hypertension should include assessment of overall cardiovascular disease risk. Similarly, introduction of lifestyle modification strategies and drug therapies should address overall risk, and not simply focus on hypertension.

RENAL PARENCHYMAL DISEASES

Virtually all disorders of the kidney may cause hypertension (Table 241-3), and renal disease is the most common cause of secondary hypertension. Hypertension is present in >80% of patients with chronic renal failure. In general, hypertension is more severe in glomerular diseases than in interstitial diseases, such as chronic pyelonephritis. Conversely, hypertension may cause nephrosclerosis, and in some instances it may be difficult to determine whether hypertension or renal disease was the initial disorder. Proteinuria > 1000 mg/day and an active urine sediment are indicative of primary renal disease. In either instance, the goals are to control blood pressure and retard the rate of progression of renal dysfunction.

Renovascular Hypertension Hypertension due to obstruction of a renal artery, renovascular hypertension, is a potentially curable form of hypertension. The mechanism of hypertension is generally related to activation of the renin-angiotensin system. Two groups of patients are at risk for this disorder: older arteriosclerotic patients who have a plaque obstructing the renal artery, frequently at its origin, and patients with fibromuscular dysplasia. Although fibromuscular dysplasia may occur at any age, it has a strong predilection for young Caucasian women. The prevalence in females is eightfold that in males. There are several histologic variants of fibromuscular dysplasia, including medial fibroplasia, perimedial fibroplasia, medial hyperplasia, and intimal fibroplasia. Medial fibroplasia is the most common variant and accounts for approximately two-thirds of patients. The lesions of fibromuscular dysplasia are frequently bilateral, and in contrast to atherosclerotic renovascular disease, tend to affect more distal portions of the renal artery.

In addition to the age and gender of the patient, several clues from the history and physical examination suggest a diagnosis of renovascular hypertension. Patients should first be evaluated for evidence of atherosclerotic vascular disease. Although response to antihypertensive therapy does not exclude the diagnosis, severe or refractory hypertension, recent loss of hypertension control or recent onset of moderately severe hypertension, and unexplained deterioration of renal function or deteri-

oration of renal function associated with an ACE inhibitor should raise the possibility of renovascular hypertension. Approximately 50% of patients with renovascular hypertension have an abdominal or flank bruit, and the bruit is more likely to be hemodynamically significant if it lateralizes or extends throughout systole into diastole.

If blood pressure is adequately controlled with a simple antihypertensive regimen and renal function remains stable, there may be little impetus to pursue an evaluation for renal artery stenosis, particularly in an older patient with atherosclerotic disease and comorbid conditions. Patients with long-standing hypertension, advanced renal insufficiency, or diabetes mellitus are less likely to benefit from renal vascular repair. The most effective medical therapies include an ACE inhibitor or an angiotensin II receptor blocker; however, these agents decrease glomerular filtration rate in the stenotic kidney owing to efferent renal arteriolar dilation. In the presence of bilateral renal artery stenosis or renal artery stenosis to a solitary kidney, progressive renal insufficiency may result from the use of these agents. Importantly, the renal insufficiency is generally reversible following discontinuation of the offending drug.

If renal artery stenosis is suspected, and if the clinical condition warrants an intervention such as percutaneous transluminal renal angioplasty (PTRA), placement of a vascular endoprosthesis (stent), or surgical renal revascularization, imaging studies should be the next step in the evaluation. As a screening test, renal blood flow may be evaluated with a radionuclide [^{131}I]-orthoiodohippurate (OIH) scan or glomerular filtration rate may be evaluated with [^{99m}Tc]-diethylenetriamine pentaacetic acid (DTPA) scan, before and after a single dose of captopril (or other ACE inhibitor). The following are consistent with a positive study: (1) decreased relative uptake by the involved kidney, which contributes <40% of total renal function; (2) delayed uptake on the affected side; or (3) delayed washout on the affected side. In patients with normal, or near-normal, renal function, a normal captopril renogram essentially excludes functionally significant renal artery stenosis; however its usefulness is limited in patients with renal insufficiency (creatinine clearance < 20 mL/min) or bilateral renal artery stenosis. Additional imaging studies are indicated if the scan is positive. Doppler ultrasound of the renal arteries produces reliable estimates of renal blood flow velocity and offers the opportunity to track a lesion over time. Positive studies are usually confirmed at angiography, whereas false-negative results occur frequently, particularly in obese patients. Gadolinium-contrast magnetic resonance angiography offers clear images of the proximal renal artery but may miss distal lesions. An advantage is the opportunity to image the renal arteries with an agent that is not nephrotoxic. Contrast arteriography remains the "gold standard" for evaluation and identification of renal artery lesions. Potential risks include nephrotoxicity, particularly in patients with diabetes mellitus or preexisting renal insufficiency.

Some degree of renal artery obstruction may be observed in almost 50% of patients with atherosclerotic disease, and there are several approaches for evaluating the functional significance of such a lesion to predict the effect of vascular repair on blood pressure control and renal function. Each approach has varying degrees of sensitivity and specificity, and no single test is sufficiently reliable to determine a causal relationship between a renal artery lesion and hypertension. On angiography, the presence of collateral vessels to the ischemic kidney suggests a functionally significant lesion. A lateralizing renal vein renin ratio (ratio > 1.5 of affected side/contralateral side) has a 90% predictive value for a lesion that would respond to vascular repair; however, the false-negative rate for blood pressure control is 50–60%. Measurement of the pressure gradient across a renal artery lesion does not reliably predict the response to vascular repair.

In the final analysis, a decision concerning vascular repair vs. medical therapy and the type of repair procedure should be individualized for each patient. Patients with fibromuscular disease have more favorable outcomes than patients with atherosclerotic lesions, presumably owing to their younger age, shorter duration of hypertension, and less systemic disease. Because of its low risk-versus-benefit ratio and high success rate (improvement or cure of hypertension in 90% of patients and restenosis rate of 10%), PTRA is the initial treatment of choice for these patients. Surgical revascularization may be undertaken if PTRA is unsuccessful or if a branch lesion is present. In atherosclerotic patients, vascular repair should be considered if blood pressure cannot be adequately controlled with medical therapy or if renal function deteriorates. Surgery may be the preferred initial approach for younger atherosclerotic patients without comorbid conditions; however, for most atherosclerotic patients, depending on the location of the lesion, the initial approach may be PTRA and/or stenting. Surgical revascularization may be indicated if these approaches are unsuccessful, if the vascular lesion is not amenable to PTRA or stenting, or if concomitant aortic surgery is required, e.g., to repair an aneurysm.

PRIMARY ALDOSTERONISM

Excess aldosterone production due to primary aldosteronism is a potentially curable form of hypertension. In patients with primary aldosteronism, increased aldosterone production is independent of the renin-angiotensin system, and the consequences are sodium retention, hypertension, hypokalemia, and low PRA. The reported prevalence of this disorder varies from <2% to ~15% of hypertensive individuals. In part, this variation is related to the intensity of screening and to the criteria for establishing the diagnosis.

History and physical examination provide little information about the diagnosis. The age at the time of diagnosis is generally in the third through fifth decades. Hypertension is usually mild to moderate but occasionally may be severe; primary aldosteronism should be considered in all patients with refractory hypertension. Hypertension in these patients may be associated with glucose intolerance. Most patients are asymptomatic, although, infrequently, polyuria, polydypsia, paresthesias, or muscle weakness may be present as a consequence of hypokalemic alkalosis. The simplest screening test is measurement of serum potassium concentration. In a hypertensive patient with unprovoked hypokalemia (i.e., unrelated to diuretics, vomiting, or diarrhea), the prevalence of primary aldosteronism approaches 40–50%. In patients on diuretics, serum potassium <3.1 mmol/L (<3.1 meq/L) also raises the possibility of primary aldosteronism; however, serum potassium is an insensitive and nonspecific screening test. On initial presentation, serum potassium is normal in ~25% of patients subsequently found to have an aldosterone-producing adenoma, and higher percentages of patients with other etiologies of primary aldosteronism are not hypokalemic. Additionally, hypokalemic hypertension may be a consequence of secondary aldosteronism, other mineralocorticoid- and glucocorticoid-induced hypertensive disorders, and pheochromocytoma.

The ratio of plasma aldosterone to plasma renin activity (PA/PRA) is a useful screening test. These measurements are preferably obtained in ambulatory patients in the morning. A ratio >30:1 in conjunction with a plasma aldosterone concentration > 555 pmol/L (>20 ng/dL) reportedly has a sensitivity of 90% and a specificity of 91% for an aldosterone-producing adenoma. In a Mayo Clinic series, an aldosterone-producing adenoma was subsequently surgically confirmed in >90% of hypertensive patients with a PA/PRA ratio ≥20 and a plasma aldosterone concentration ≥415 pmol/L (≥15 ng/dL). There are, however, several caveats to interpreting the ratio. The cutoff for a "high" ratio is laboratory- and assay-dependent. Although some antihypertensive agents may affect the ratio (e.g., aldosterone antagonists, angiotensin receptor antagonists, and ACE inhibitors may increase renin; aldosterone antagonists may increase aldosterone), the ratio has been reported to be useful as a screening test in measurements obtained with patients taking their usual antihypertensive medications. A high ratio in the absence of an elevated plasma aldosterone level is considerably less specific for primary aldosteronism since many patients with essential hypertension have low renin levels in this setting, particularly African Americans and elderly patients. In patients with renal insufficiency, the ratio may also be elevated because of decreased aldosterone clearance. In patients with an elevated PA/PRA ratio, the diagnosis of primary aldosteronism can be confirmed by demonstrating failure to suppress plasma aldosterone to <277 pmol/L (<10 ng/dL) after IV infusion of 2 L of isotonic saline over 4 h.

Several adrenal abnormalities may culminate in the syndrome of primary aldosteronism, and appropriate therapy depends on the specific etiology. Some 60–70% of patients have an aldosterone-producing adrenal adenoma. The tumor is almost always unilateral, and most measure <3 cm in diameter. Most of the remainder have bilateral adrenocortical hyperplasia (idiopathic hyperaldosteronism). Rarely, primary aldosteronism may be caused by an adrenal carcinoma or an ectopic malignancy, e.g., ovarian arrhenoblastoma. Most aldosterone-producing carcinomas, in contrast to adrenal adenomas and hyperplasia, produce excessive amounts of other adrenal steroids in addition to aldosterone. Functional differences in hormone secretion may assist in the differential diagnosis. Aldosterone biosynthesis is more responsive to ACTH in patients with adenoma and more responsive to angiotensin in patients with hyperplasia. Consequently, patients with adenoma tend to have higher plasma aldosterone in the early morning that decreases during the day, reflecting the diurnal rhythm of ACTH, whereas plasma aldosterone tends to increase with upright posture in patients with hyperplasia, reflecting the normal postural response of the renin-angiotensin-aldosterone axis.

Adrenal CT or MRI should be carried out in all patients diagnosed with primary aldosteronism. High-resolution CT may identify tumors as small as 0.3 cm and is positive for an adrenal tumor 90% of the time. If the CT or MRI is not diagnostic, an adenoma may be detected by adrenal scintigraphy with 6 β-[I^{131}]iodomethyl-19-norcholesterol after dexamethasone suppression (0.5 mg every 6 h for 7 days); however, this technique has decreased sensitivity for adenomas < 1 cm. When results of functional and anatomic studies are inconclusive, bilateral adrenal venous sampling for aldosterone and cortisol levels in response to ACTH stimulation should be carried out. An ipsilateral/contralateral aldosterone ratio >10, with symmetric ACTH-stimulated cortisol levels, is diagnostic of an aldosterone-producing adenoma.

Hypertension is generally responsive to surgery in patients with adenoma but not in patients with bilateral adrenal hyperplasia. Unilateral adrenalectomy, often done via a laparoscopic approach, is curative in 40–70% of patients with an adenoma. Surgery should be undertaken after blood pressure has been controlled and hypokalemia corrected. Transient hypoaldosteronism may occur for up to 3 months postoperatively, resulting in hyperkalemia. Potassium should be monitored during this time, and hyperkalemia should be treated with potassium-wasting diuretics and with fludrocortisone, if needed. Patients with bilateral hyperplasia should be treated medically. The drug regimen for these patients, as well as for patients with an adenoma who are poor surgical candidates, should include an aldosterone antagonist and, if necessary, other potassium-sparing diuretics.

Glucocorticoid-remediable hyperaldosteronism is a rare, monogenic autosomal dominant disorder characterized by moderate to severe hypertension, often at an early age. Hypokalemia is usually mild or absent. Normally, angiotensin II stimulates aldosterone production by the adrenal zona glomerulosa, whereas ACTH stimulates cortisol production in the zona fasciculata. Owing to a chimeric gene on chromosome 8, ACTH also regulates aldosterone secretion by the zona fasciculata in patients with glucocorticoid-remediable hyperaldosteronism. The consequence is overproduction in the zona fasciculata of both aldosterone and hybrid steroids (18-hydroxycortisol and 18-oxocortisol) due to oxidation of cortisol. The diagnosis may be established by urine excretion rates of these hybrid steroids that are twenty to thirty times normal or by direct genetic testing. Therapeutically, suppression of ACTH with low-dose glucocorticoids corrects the hyperaldosteronism, hypertension, and hypokalemia. Spironolactone is also a therapeutic option.

CUSHING'S SYNDROME

(See also Chap. 336) Hypertension occurs in 75–80% of patients with Cushing's syndrome. The mechanism of hypertension may be related to stimulation of mineralocorticoid receptors by cortisol and increased secretion of other adrenal steroids. If clinically suspected, in patients not taking exogenous glucocorticoids, laboratory screening may be carried out with measurement of 24-h excretion rates of urine free cortisol or an overnight dexamethasone-suppression test. Recent evidence suggests that late night salivary cortisol is a sensitive and convenient screening test. Further evaluation is required to confirm the diagnosis and to identify the specific etiology of Cushing's syndrome. Appropriate therapy depends on the etiology.

PHEOCHROMOCYTOMA

(See also Chap. 337) Catecholamine-secreting tumors are located in the adrenal medulla (pheochromocytoma) or in extra-adrenal paraganglion tissue (paraganglioma) and account for hypertension in ~0.05% of patients. Approximately 20% of pheochromocytomas are familial with an autosomal dominant inheritance. Inherited pheochromocytomas may be associated with multiple endocrine neoplasia (MEN) type 2A and type 2B (Table 241-4). If unrecognized, pheochromocytoma may result in lethal cardiovascular consequences. Clinical manifestations, including hypertension, are primarily related to increased circulating catecholamines, although some of these tumors may secrete a number of other vasoactive substances. In a small percent of patients, epinephrine is the predominant catecholamine secreted by the tumor, and these patients may present with hypotension rather than hypertension. The initial suspicion of the diagnosis is based on symptoms and/or the association of pheochromocytoma with other disorders (Table 241-4). Laboratory testing consists of measuring catecholamines in either urine or plasma. Genetic screening is also available for evaluating patients and relatives suspected of harboring a pheochromocytoma associated with a familial syndrome. Surgical excision is the definitive treatment of pheochromocytoma and results in cure in ~90% of patients.

MISCELLANEOUS CAUSES OF HYPERTENSION

Hypertension due to *obstructive sleep apnea* is being recognized with increasing frequency (Chap. 259). Independent of obesity, hypertension occurs in >50% of individuals with obstructive sleep apnea, the severe end of the sleep-disordered breathing syndrome. The severity of hypertension correlates with the severity of sleep apnea. Approximately 70% of patients with obstructive sleep apnea are obese. Hypertension related to obstructive sleep apnea should also be considered in patients with drug-resistant hypertension and in patients with a history of snoring. The diagnosis can be confirmed by polysomnography. In obese patients, weight loss may alleviate or cure sleep apnea and related hypertension. Continuous positive airway pressure (CPAP) administered during sleep is an effective therapy for obstructive sleep apnea. With CPAP, patients with apparently drug-resistant hypertension may be more responsive to antihypertensive agents.

Coarctation of the aorta is the most common congenital cardiovascular cause of hypertension (Chap. 229). The incidence is 1–8 per 1000 live births. It is usually sporadic but occurs in 35% of children with Turner's syndrome. Even when the anatomic lesion is surgically corrected in infancy, up to 30% of patients develop subsequent hypertension and are at risk of accelerated coronary artery disease and cerebrovascular events. Patients with less severe lesions may not be diagnosed until young adulthood. The physical findings are diagnostic, and include diminished and delayed femoral pulses and a systolic pressure gradient between the right arm and the legs, and, depending on the location of the coarctation, between the right and left arms. A blowing systolic murmur may be heard in the posterior left interscapular areas. The diagnosis may be confirmed by chest x-ray and transesophageal echocardiogram. Therapeutic options include surgical repair or balloon angioplasty, with or without placement of an intravascular stent. Subsequently, many patients do not have a normal life expectancy but may have persistent hypertension with death due to ischemic heart disease, cerebral hemorrhage, or aortic aneurysm.

Several additional endocrine disorders, including *thyroid diseases* and *acromegaly*, cause hypertension. Mild diastolic hypertension may be a consequence of hypothyroidism, whereas hyperthyroidism may result in systolic hypertension. *Hypercalcemia* of any etiology, the most common being primary hyperparathyroidism, may result in hypertension. Hypertension may also be related to a number of prescribed or over-the-counter *medications*.

TABLE 241-4 RARE MENDELIAN FORMS OF HYPERTENSION

Disease	Phenotype	Genetic Cause
Glucocorticoid-remediable hyperaldosteronism	Autosomal dominant Absent or mild hypokalemia	Chimeric 11β-hydroxylase/aldsoterone gene on chromosome 8
17α-hydroxylase deficiency	Autosomal recessive Males: pseudohermaphroditism Females: primary amenorrhea, absent secondary sexual characteristics	Random mutations of the *CYP17* gene on chromosome 10
11β-hydroxylase deficiency	Autosomal recessive Masculinization	Mutations of the *CYP11B1* gene on chromosome 8q21-q22
11β-hydroxysteroid dehydrogenase deficiency (apparent mineralocorticoid excess syndrome)	Autosomal recessive Hypokalemia, low renin, low aldosterone	Mutations in the 11β-hydroxysteroid dehydrogenase gene
Liddle's syndrome	Autosomal dominant Hypokalemia, low renin, low aldosterone	Mutation subunits of the epithelial sodium channel *SCNN1B* and *SCNN1C* genes
Pseudohypoaldosteronism type II (Gordon's syndrome)	Autosomal dominant Hyperkalemia, normal glomerular filtration rate	Linkage to chromosomes 1q31-q42 and 17p11-q21
Hypertension exacerbated in pregnancy	Autosomal dominant Severe hypertension in early pregnancy	Missense mutation with substitution of leucine for serine at codon 810 (MR_{L810})
Polycystic kidney disease	Autosomal dominant Large cystic kidneys, renal failure, liver cysts, cerebral aneurysms, valvular heart disease	Mutations in the *PKD1* gene on chromosome 16 and *PKD2* gene on chromosome 4
Pheochromocytoma	Autosomal dominant	
	(a) Multiple endocrine neoplasia, type 2A Medullary thyroid carcinoma, hyperparathyroidism	(a) Mutations in the RET protooncogene
	(b) Multiple endocrine neoplasia, type 2B Medullary thyroid carcinoma, mucosal neuromas, thickened corneal nerves, alimentary ganglioneuromatoses, marfanoid habitus	(b) Mutations in the RET protooncogene
	(c) von Hippel–Lindau disease Retinal angiomas, hemangioblastomas of the cerebellum and spinal cord, renal cell carcinoma	(c) Mutations in the VHL tumor-suppressor gene
	(d) Neurofibromatosis type 1 Multiple neurofibromas, café au lait spots	(d) Mutations in the NF1 tumor-suppressor gene

MONOGENIC HYPERTENSION

A number of rare forms of monogenic hypertension have been identified (Table 241-4). These disorders may be recognized by their characteristic phenotypes, and in many instances the diagnosis may be confirmed by genetic analysis. Several inherited defects in adrenal steroid biosynthesis and metabolism result in mineralocorticoid-induced hypertension and hypokalemia. In patients with a 17α-hydroxylase deficiency, synthesis of sex hormones and cortisol is decreased (Fig. 241-3). Consequently, these individuals do not mature sexually; males may present with pseudohermaphroditism and females with primary amenorrhea and absent secondary sexual characteristics. Because cortisol-induced negative feedback on pituitary ACTH production is diminished, ACTH-stimulated adrenal steroid synthesis proximal to the enzymatic block is increased. Hypertension and hypokalemia are consequences of increased synthesis of mineralocorticoids proximal to the enzymatic block, particularly desoxycorticosterone. Increased steroid production and, hence, hypertension may be treated with low-dose glucocorticoids. An 11β-hydroxylase deficiency results in a salt-retaining adrenogenital syndrome, occurring in 1 in 100,000 live births. This enzymatic defect results in decreased cortisol synthesis, increased synthesis of mineralocorticoids (e.g., desoxycorticosterone), and shunting of steroid biosynthesis into the androgen pathway. In the severe form, the syndrome may present early in life, including the newborn period, with virilization and ambiguous genitalia in females and penile enlargement in males, or in older children as precocious puberty and short stature. Acne, hirsutism, and menstrual irregularities may be the presenting features when the disorder is first recognized in adolescence or early adulthood. Hypertension is less common in the late-onset forms. Patients with an 11β-hydroxysteroid dehydrogenase deficiency have an impaired capacity to metabolize cortisol to its inactive metabolite, cortisone, and hypertension is related to activation of mineralocorticoid receptors by cortisol. This defect may be inherited or acquired, due to licorice-containing glyccherizic acid. This same substance is present in the paste of several brands of chewing tobacco. The defect in Liddle's syndrome (Chaps. 46 and 336) results from constitutive activation of amiloride-sensitive epithelial sodium channels (ENaC) on the distal renal tubule, resulting in excess sodium reabsorption; the syndrome is ameliorated by amiloride. Hypertension exacerbated in pregnancy (Chap. 7) is due to activation of the mineralocorticoid receptor by progesterone. Approximately 20% of pheochromocytomas are familial and may be associated with distinctive phenotypes.

APPROACH TO THE PATIENT: Hypertension

HISTORY The initial assessment of the hypertensive patient should include a complete history and physical examination to confirm a diagnosis of hypertension, screen for other cardiovascular disease risk factors, screen for secondary causes of hypertension, identify cardiovascular consequences of hypertension and other comorbidities, assess blood pressure–related lifestyles, and determine the potential for intervention.

Most patients with hypertension have no specific symptoms referable to their blood pressure elevation. Although popularly considered a symptom of elevated arterial pressure, headache generally occurs only in patients with severe hypertension. Characteristically, a "hypertensive headache" occurs in the morning and is localized to the occipital region. Other nonspecific symptoms that may be related to elevated blood pressure include dizziness, palpitations, easy fatigability, and impotence. When symptoms are present, they are generally related to hypertensive cardiovascular disease or to manifestations of secondary hypertension. Table 241-5 lists salient features that should be addressed in obtaining a history from a hypertensive patient.

MEASUREMENT OF BLOOD PRESSURE Reliable measurements of blood pressure depend on attention to the details of the technique and conditions of the measurement. Owing to recent regulations preventing the use of mercury because of concerns about its potential toxicity, most office measurements are made with aneroid instruments. The accuracy of automated blood pressure instruments should be confirmed. Before taking the blood pressure measurement, the individual should be seated quietly for 5 min in a private, quiet setting with a comfortable room temperature. The center of

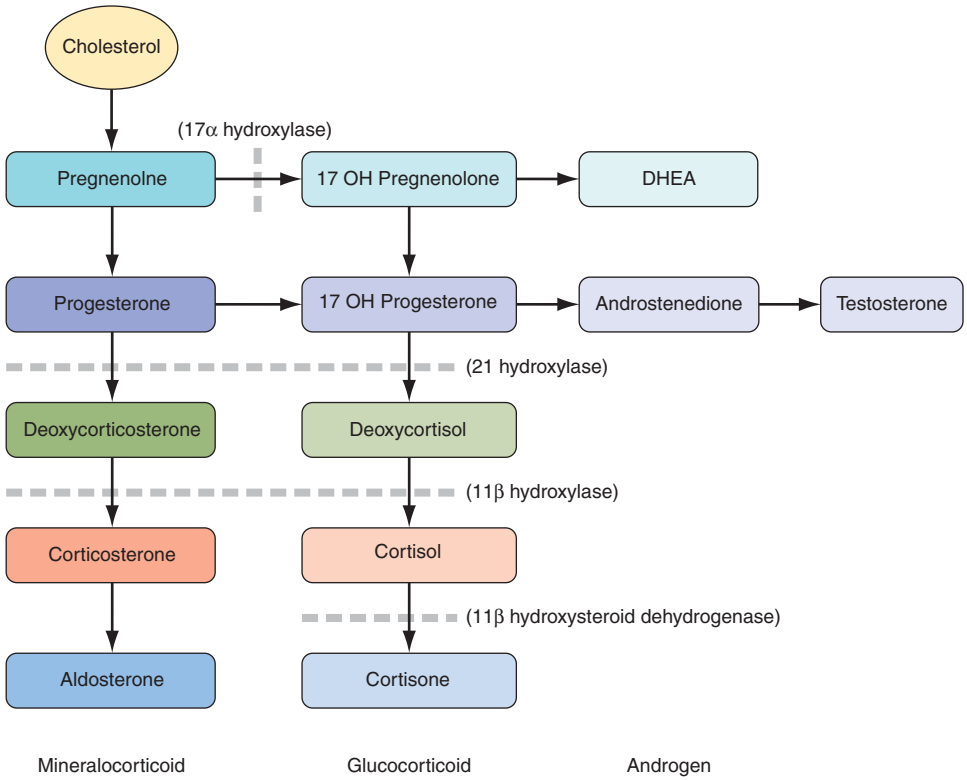

FIGURE 241-3 Adrenal enzymatic defects.

the cuff should be at heart level, and the width of the bladder cuff should equal at least 40% of the arm circumference; the length of the cuff bladder should encircle at least 80% of the arm circumference. It is important to pay attention to cuff placement, stethoscope placement, and the rate of deflation of the cuff (2 mmHg/s). Systolic blood pressure is the first of at least two regular "tapping" Korotkoff sounds, and diastolic blood pressure is the point at which the last regular Korotkoff sound is heard. In current practice, a diagnosis of hypertension is generally based on seated, office measurements.

Currently available ambulatory monitors are fully automated, use the oscillometric technique, and typically are programmed to take readings every 15–30 min. Ambulatory blood pressure monitoring is not, however, routinely used in clinical practice and is generally reserved for patients in whom white coat hypertension is suspected. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) has also recommended ambulatory monitoring for treatment resistance, symptomatic hypotension, autonomic failure, and episodic hypertension.

TABLE 241-5 PATIENT'S RELEVANT HISTORY

Duration of hypertension
Previous therapies: responses and side effects
Family history of hypertension and cardiovascular disease
Dietary and psychosocial history
Other risk factors: weight change, dyslipidemia, smoking, diabetes, physical inactivity
Evidence of secondary hypertension: history of renal disease; change in appearance; muscle weakness; spells of sweating, palpitations, tremor; erratic sleep, snoring, daytime somnolence; symptoms of hypo- or hyperthyroidism; use of agents that may increase blood pressure
Evidence of target organ damage: history of TIA, stroke, transient blindness; angina, myocardial infarction, congestive heart failure; sexual function
Other comorbidities

Note: TIA, transient ischemic attack.

PHYSICAL EXAMINATION Body habitus, including weight and height, should be noted. At the initial examination, blood pressure should be measured in both arms, and preferably in the supine, sitting, and standing positions to evaluate for postural hypotension. Even if the femoral pulse is normal to palpation, arterial pressure should be measured at least once in the lower extremity in patients in whom hypertension is discovered before age 30. Heart rate should also be recorded. Hypertensive individuals have an increased prevalence of atrial fibrillation. The neck should be palpated for an enlarged thyroid gland, and patients should be assessed for signs of hypo- and hyperthyroidism. Examination of blood vessels may provide clues about underlying vascular disease and should include funduscopic examination, auscultation for bruits over the carotid and femoral arteries, and palpation of femoral and pedal pulses. The retina is the only tissue in which arteries and arterioles can be examined directly. With increasing severity of hypertension and atherosclerotic disease, progressive funduscopic changes include increased arteriolar light reflex, arteriovenous crossing defects, hemorrhages and exudates, and, in patients with malignant hypertension, papilledema. Examination of the heart may reveal a loud second heart sound due to closure of the aortic valve and an S_4 gallop, attributed to atrial contraction against a noncompliant left ventricle. Left ventricular hypertrophy may be detected by an enlarged, sustained, and laterally displaced apical impulse. An abdominal bruit, particularly a bruit that lateralizes and extends throughout systole into diastole, raises the possibility of renovascular hypertension. Kidneys of patients with polycystic kidney disease may be palpable in the abdomen. The physical examination should also include evaluation for signs of CHF and a neurologic examination.

LABORATORY TESTING Table 241-6 lists recommended laboratory tests in the initial evaluation of hypertensive patients. Repeat measurements of renal function, serum electrolytes, fasting glucose, and lipids may be obtained after introducing a new antihypertensive agent and then annually, or more frequently if clinically indicated. More extensive laboratory testing is appropriate for patients with apparent drug-resistant hypertension or when the clinical evaluation suggests a secondary form of hypertension.

TABLE 241-6 BASIC LABORATORY TESTS FOR INITIAL EVALUATION

System	Test
Renal	Microscopic urinalysis, albumin excretion, serum BUN and/or creatinine
Endocrine	Serum sodium, potassium, calcium, ?TSH
Metabolic	Fasting blood glucose, total cholesterol, HDL and LDL (often computed) cholesterol, triglycerides
Other	Hematocrit, electrocardiogram

Note: BUN, blood urea nitrogen; TSH, thyroid-stimulating hormone; HDL, LDL, high-/low-density lipoprotein.

TABLE 241-7 LIFESTYLE MODIFICATIONS TO MANAGE HYPERTENSION

Weight reduction	Attain and maintain BMI < 25 kg/m^2
Dietary salt reduction	< 6 g NaCl/d
Adapt DASH-type dietary plan	Diet rich in fruits, vegetables, and low-fat dairy products with reduced content of saturated and total fat
Moderation of alcohol consumption	For those who drink alcohol, consume ≤2 drinks/day in men and ≤1 drink/day in women
Physical activity	Regular aerobic activity, e.g., brisk walking for 30 min/d

Note: BMI, body mass index; DASH, Dietary Approaches to Stop Hypertension (trial).

℞ HYPERTENSION

LIFESTYLE INTERVENTIONS Implementation of lifestyles that favorably affect blood pressure has implications for both the prevention and treatment of hypertension. Health-promoting lifestyle modifications are recommended for individuals with pre-hypertension and as an adjunct to drug therapy in hypertensive individuals. These interventions should address overall cardiovascular disease risk. Although the impact of lifestyle interventions on blood pressure is more pronounced in persons with hypertension, in short-term trials, weight loss and reduction of dietary NaCl have also been shown to prevent the development of hypertension. In hypertensive individuals, even if these interventions do not produce a sufficient reduction of blood pressure to avoid drug therapy, the number of medications or dosages required for blood pressure control may be reduced. Dietary modifications that effectively lower blood pressure are weight loss, reduced NaCl intake, increased potassium intake, moderation of alcohol consumption, and an overall healthy dietary pattern **(Table 241-7)**.

Prevention and treatment of obesity are important for reducing blood pressure and cardiovascular disease risk. In short-term trials, even modest weight loss can lead to a reduction of blood pressure and an increase of insulin sensitivity. Average blood pressure reductions of 6.3/3.1 mmHg have been observed with a reduction in mean body weight of 9.2 kg. Regular physical activity facilitates weight loss, decreases blood pressure, and reduces the overall risk of cardiovascular disease. Blood pressure may be lowered by 30 min of moderately intense physical activity, such as brisk walking, 6–7 days a week, or by more intense, less frequent workouts.

There is individual variability in the sensitivity of blood pressure to NaCl, and this variability may have a genetic basis. Based on results of meta-analyses, lowering of blood pressure by limiting daily NaCl intake to 4.4–7.4 g (75–125 meq) results in blood pressure reductions of 3.7–4.9/0.9–2.9 mmHg in hypertensive and lesser reductions in normotensive individuals. Diets deficient in potassium, calcium, and magnesium are associated with higher blood pressures and a higher prevalence of hypertension. The urine sodium-to-potassium ratio is a stronger correlate of blood pressure than either sodium or potassium alone. Potassium and calcium supplementation have inconsistent, modest antihypertensive effects, and, independent of blood pressure, potassium supplementation may be associated with reduced stroke mortality. Alcohol use in persons consuming three or more drinks per day (a standard drink contains ~14 g ethanol) is associated with higher blood pressures, and a reduction of alcohol consumption is associated with a reduction of blood pressure. Mechanisms by which dietary potassium, calcium, or alcohol may affect blood pressure have not been established.

The DASH (Dietary Approaches to Stop Hypertension) trial convincingly demonstrated that over an 8-week period a diet high in fruits, vegetables, and low-fat dairy products lowers blood pressure in individuals with high-normal blood pressures or mild hypertension. Reduction of daily NaCl intake to <6 g (100 meq) augmented the effect of this diet on blood pressure. Fruits and vegetables are enriched sources of potassium, magnesium, and fiber, and dairy products are an important source of calcium.

PHARMACOLOGIC THERAPY Drug therapy is recommended for individuals with blood pressures ≥140/90 mmHg. The degree of benefit derived from antihypertensive agents is related to the magnitude of the blood pressure reduction. Lowering systolic blood pressure by 10–12 mmHg and diastolic blood pressure by 5–6 mmHg confers relative risk reductions of 35–40% for stroke and 12–16% for CHD within 5 years of initiating treatment. Risk of heart failure is reduced by >50%. There is considerable variation in individual responses to different classes of antihypertensive agents, and the magnitude of response to any single agent may be limited by activation of counterregulatory mechanisms that oppose the hypotensive effect of the agent. Selection of antihypertensive agents, and combinations of agents, should be individualized, taking into account age, severity of hypertension, other cardiovascular disease risk factors, comorbid conditions, and practical considerations related to cost, side effects, and frequency of dosing **(Table 241-8)**.

Diuretics Low-dose thiazide diuretics are often used as first-line agents, alone or in combination with other antihypertensive drugs. Thiazides inhibit the Na^+/Cl^- pump in the distal convoluted tubule and, hence, increase sodium excretion. Long term, they may also act as vasodilators. Thiazides are safe, efficacious, and inexpensive and reduce clinical events. They provide additive blood pressure–lowering effects when combined with beta blockers, ACE inhibitors, or angiotensin receptor blockers. In contrast, addition of a diuretic to a calcium channel blocker is less effective. Usual doses of hydrochlorothiazide range from 6.25–50 mg/d. Owing to an increased incidence of metabolic side effects (hypokalemia, insulin resistance, increased cholesterol), higher doses are generally not recommended. Two potassium-sparing diuretics, amiloride and triamterene, act by inhibiting epithelial sodium channels in the distal nephron. These agents are weak antihypertensive agents but may be used in combination with a thiazide to protect against hypokalemia. The main pharmacologic target for loop diuretics is the Na^+-K^+-$2Cl^-$ cotransporter in the thick ascending limb of the loop of Henle. Loop diuretics are generally reserved for hypertensive patients with reduced glomerular filtration rates [reflected in serum creatinine > 220 μmol/L (>2.5 mg/dL)], CHF, or sodium retention and edema for some other reason such as treatment with a potent vasodilator, e.g., minoxidil.

Blockers of the Renin-Angiotensin System ACE inhibitors decrease the production of angiotensin II, increase bradykinin levels, and reduce sympathetic nervous system activity. Angiotensin II receptor blockers provide selective blockade of AT_1 receptors, and the effect of angiotensin II on unblocked AT_2 receptors may augment the hypotensive effect. Both classes of agents are effective antihypertensive agents that may be used as monotherapy or in combination with diuretics, calcium antagonists, and alpha-blocking agents. Side effects of ACE inhibitors and angiotensin receptor blockers include functional renal insufficiency due to efferent renal arteriolar dilatation in a kidney with a stenotic lesion of the renal artery. Additional predisposing conditions to renal insufficiency induced by these agents include dehydration, CHF, and use of nonsteroidal anti-inflammatory drugs. Dry cough occurs in ~15% of patients, and angioedema occurs in <1% of patients taking ACE inhibitors. Angioedema occurs most commonly in individuals of Asian origin and more commonly in African Americans than in Caucasians. Hyperkalemia due to hypoaldosteronism is an occasional side effect of both ACE inhibitors and angiotensin receptor blockers.

Aldosterone Antagonists Spironolactone is a nonselective aldosterone antagonist that may be used alone or in combination with a thiazide diuretic. It may be a particularly effective agent in patients with low-renin essential hypertension, resistant hypertension, and primary aldosteronism. In patients with CHF, low-dose spironolactone reduces mortality and hospitalizations for heart failure when given in addition to conventional therapy with ACE inhibitors, digoxin, and loop diuretics. Because spironolactone binds to progesterone and androgen receptors, side effects may include gynecomastia, impotence, and menstrual abnormalities. These side effects are circumvented by a newer agent, eplerenone, which is a selective aldosterone antagonist. Eplerenone has recently been approved in the United States for the treatment of hypertension.

Beta Blockers β-Adrenergic receptor blockers lower blood pressure by decreasing cardiac output, due to a reduction of heart rate and contractility. Other proposed mechanisms by which beta blockers lower blood pressure include a central nervous system effect, and inhibition of renin release. Beta blockers are particularly effective in hypertensive patients with tachycardia, and their hypotensive potency is enhanced by coadministration with a diuretic. In lower doses, some beta blockers selectively inhibit cardiac β_1 receptors and have less influence on β_2 receptors on bronchial and vascular smooth muscle cells; however, there seems to be no difference in

TABLE 241-8 EXAMPLES OF ORAL DRUGS USED IN TREATMENT OF HYPERTENSION

Drug Class	Examples	Usual Total Daily Dose[a] (Dosing Frequency/Day)	Other Indications	Contraindications/ Cautions
Diuretics				
Thiazides	Hydrochlorothiazide	6.25–50 mg (1–2)		Diabetes, dyslipidemia, hyperuricemia, gout, hypokalemia
	Chlorthalidone	25–50 mg (1)		
Loop diuretics	Furosemide	40–80 mg (2–3)	CHF, renal failure	Diabetes, dyslipidemia, hyperuricemia, gout, hypokalemia
	Ethacrynic acid	50–100 mg (2–3)		
Aldosterone antagonists	Spironolactone	25–100 mg (1–2)	CHF, primary aldosteronism	Renal failure, hyperkalemia
	Eplerenone	50–100 mg (1–2)		
K^+ retaining	Amiloride	5–10 mg (1–2)		Renal failure, hyperkalemia
	Triamterene	50–100 mg (1–2)		
Beta blockers				Asthma, COPD, 2nd or 3rd degree heart block, sick-sinus syndrome
Cardioselective	Atenolol	25–100 mg (1)	Angina, CHF, post-MI, sinus tachycardia, ventricular tachyarrhythmias	
	Metoprolol	25–100 mg (1–2)		
Nonselective	Propranolol	40–160 mg (2)		
	Propranolol LA	60–180 (1)		
Combined alpha/beta	Labetalol	200–800 mg (2)	? Post-MI, CHF	
	Carvedilol	12.5–50 mg (2)		
Alpha antagonists				
Selective	Prazosin	2–20 mg (2–3)	Prostatism	
	Doxazosin	1–16 mg (1)		
	Terazosin	1–10 mg (1–2)		
Nonselective	Phenoxybenzamine	20–120 mg (2–3)	Pheochromocytoma	
Sympatholytics				
Central	Clonidine	0.1–0.6 mg (2)		
	Clonidine patch	0.1–0.3 mg (1/week)		
	Methyldopa	250–1000 mg (2)		
	Reserpine	0.05–0.25 mg (1)		
	Guanfacine	0.5–2 mg (1)		
ACE inhibitors	Captopril	25–200 mg (2)	Post-MI, CHF, nephropathy	Renal failure, bilateral renal artery stenosis, pregnancy, hyperkalemia
	Lisinopril	10–40 mg (1)		
	Ramipril	2.5–20 mg (1–2)		
Angiotensin II antagonists	Losartan	25–100 mg (1–2)	CHF, diabetic nephropathy, ACE inhibitor cough	Renal failure, bilateral renal artery stenosis, pregnancy, hyperkalemia
	Valsartan	80–320 mg (1)		
	Candesartan	2–32 mg (1–2)		
Calcium antagonists				Heart failure, 2d or 3d degree heart block
Dihydropyridines	Nifedipine (long acting)	30–60 mg (1)	Angina	
Nondihydropyridines	Verapamil (long acting)	120–360 mg (1–2)	Post-MI, supraventricular tachycardias, angina	
	Diltiazem (long-acting)	180-420 mg (1)		
Direct vasodilators	Hydralazine	25–100 mg (2)		Severe coronary artery disease
	Minoxidil	2.5–80 mg (1–2)		

[a]At the initiation of therapy, lower doses may be preferable for elderly patients and for select combinations of antihypertensive agents.

Note: CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; MI, myocardial infarction; ACE, angiotensin-converting enzyme.

the antihypertensive potencies of cardio-selective and non-selective beta blockers. Certain beta blockers have intrinsic sympathomimetic activity, and it is uncertain whether this constitutes an overall advantage or disadvantage in cardiac therapy. Beta blockers without intrinsic sympathomimetic activity decrease the rate of sudden death, overall mortality, and recurrent myocardial infarction. In patients with CHF, beta blockers have been shown to reduce the risks of hospitalization and mortality. Carvedilol and labetalol block both β receptors and peripheral α-adrenergic receptors. The potential advantages of combined β- and α-adrenergic blockade in treating hypertension remain to be determined.

α-Adrenergic Blockers Postsynaptic, selective α-adrenoreceptor antagonists lower blood pressure by decreasing peripheral vascular resistance. They are effective antihypertensive agents, used either as monotherapy or in combination with other agents. However, in clinical trials of hypertensive patients, alpha blockade has not been shown to reduce cardiovascular morbidity and mortality or to provide as much protection against CHF as other classes of antihypertensive agents. These agents are also effective in treating lower urinary tract symptoms in men with prostatic hypertrophy. Nonselective α-adrenoreceptor antagonists bind to postsynaptic and presynaptic receptors and are primarily used for the management of patients with pheochromocytoma.

Sympatholytic Agents Centrally acting α_2 sympathetic agonists decrease peripheral resistance by inhibiting sympathetic outflow. They may be particularly useful in patients with autonomic neuropathy who have wide variations in blood pressure due to baroreceptor denervation. Drawbacks include somnolence, dry mouth, and rebound hypertension on withdrawal. Peripheral sympatholytics decrease peripheral resistance and venous constriction by depleting nerve terminal norepinephrine. Although potentially effective antihypertensive agents, their usefulness is limited by orthostatic hypotension, sexual dysfunction, and numerous drug-drug interactions.

Calcium Channel Blockers Calcium antagonists reduce vascular resistance through L-channel blockade, which reduces intracellular calcium and blunts vasoconstriction. This is a heterogeneous group of agents that includes drugs in the following three classes: phenylalkylamines (verapamil), benzothiazepines (diltiazem), and 1,4-dihydropyridines (nifedipine-like). Used alone and in combination with other agents (ACE inhibitors, beta blockers, α_1-adrenergic blockers), calcium antagonists effectively lower blood pressure; however, it is unclear if adding a diuretic to a calcium blocker results in a further lowering of blood pressure. Side effects of flushing, headache, and edema with dihydropyridine use are related to their potencies as arteriolar dilators; edema is due to an increase in transcapillary pressure gradients, not to net salt and water retention.

Direct Vasodilators These agents decrease peripheral resistance and concomitantly activate mechanisms that defend arterial pressure, notably the sympathetic nervous system, the renin-angiotensin-aldosterone system, and sodium retention. Usually, they are not considered first-line agents but are most effective when added to a combination that includes a diuretic and a beta blocker. Hydralazine is a potent direct vasodilator that has antioxidant and nitric-oxide enhancing actions, and minoxidil is a particularly potent agent and is most frequently used in patients with renal insufficiency who are refractory to all other drugs. Hydralazine may induce a lupus-like syndrome, and side effects of minoxidil include hypertrichosis and pericardial effusion.

COMPARISONS OF ANTIHYPERTENSIVES Based on pooling results from clinical trials, meta-analyses of the efficacy of different classes of antihypertensive agents suggest essentially equivalent blood pressure–lowering effects of the following six major classes of antihypertensive agents when used as monotherapy: thiazide diuretics, beta blockers, ACE

inhibitors, angiotensin II receptor blockers, calcium antagonists, and α_2 blockers. On average, standard doses of most antihypertensive agents reduce blood pressure by 8–10/4–7 mmHg; however, there may be subgroup differences in responsiveness. Younger patients may be more responsive to beta blockers and ACE inhibitors, whereas patients over age 50 may be more responsive to diuretics and calcium antagonists. There is a limited relationship between plasma renin and blood pressure response. Patients with high-renin hypertension may be more responsive to ACE inhibitors and angiotensin II receptor blockers than to other classes of agents, whereas patients with low-renin hypertension are more responsive to diuretics and calcium antagonists. Hypertensive African Americans tend to have low renin and may require higher doses of ACE inhibitors and angiotensin II receptor blockers than whites for optimal blood pressure control, although this difference is abolished when these agents are combined with a diuretic. Beta blockers also appear to be less effective than thiazide diuretics in African Americans than in non-African Americans.

A number of clinical trials have evaluated the possibility that different classes of antihypertensive agents have cardiovascular and renal protective effects not totally accounted for by their capacity to lower blood pressure. ACE inhibitors may have particular advantages, beyond that of blood pressure control, in reducing cardiovascular and renal outcomes. ACE inhibitors and angiotensin II receptor blockers decrease proteinuria and retard the rate of progression of renal insufficiency in both diabetic and nondiabetic renal diseases. The renoprotective effect of these agents, compared with other antihypertensive drugs, is less obvious at lower blood pressures. In both hypertensive and normotensive individuals, ACE inhibitors improve symptomatology and risk of death from CHF and reduce morbidity and mortality in the post-myocardial infarction patient. Similar benefits in cardiovascular morbidity and mortality in patients with CHF have also been observed with the use of angiotensin II receptor blockers. ACE inhibitors provide better coronary protection than calcium channel blockers, whereas calcium channel blockers provide more stroke protection than either ACE inhibitors or beta blockers.

In most patients with hypertension and heart failure due to systolic and/or diastolic dysfunction, the use of diuretics, ACE inhibitors or angiotensin II receptor antagonists, and beta blockers is recommended to improve survival. Although the optimal target blood pressure in patients with heart failure has not been established, a reasonable goal is the lowest blood pressure that is not associated with evidence of hypoperfusion.

A recent summary compared the results of 15 large clinical trials on the effects of antihypertensive treatment with different classes of agents on cardiovascular morbidity and mortality. In 13 of these trials, the incidence of cardiovascular events was similar between treatment groups, and in the remaining 2 trials, the difference was only marginally significant. It is possible that drug-related differences in cardiovascular outcomes are minimized in these large trials because of patient dropout, unplanned crossover of patients between groups, and insufficient statistical power to detect subgroup differences. Nevertheless, it is clear that the greatest cardiovascular and renal protective effects of antihypertensive therapy are related to adequate control of hypertension.

BLOOD PRESSURE GOALS OF ANTIHYPERTENSIVE THERAPY

Based on clinical trial data, the maximum protection against combined cardiovascular endpoints is achieved with pressures <135–140 mmHg for systolic blood pressure and <80–85 mmHg for diastolic blood pressure; however, treatment has not reduced cardiovascular disease risk to the level in nonhypertensive individuals. More aggressive blood pressure targets for blood pressure control (e.g., office or clinic blood pressure < 130/80 mmHg) may be appropriate for patients with diabetes, CHD, chronic kidney disease, or with additional cardiovascular disease risk factors. In diabetic patients, effective blood pressure control reduces the risk of cardiovascular events and death as well as the risk for microvascular disease (nephropathy, retinopathy). Risk reduction is greater in diabetic than in nondiabetic individuals.

To achieve recommended blood pressure goals, the majority of individuals with hypertension will require treatment with more than one drug. Three or more drugs are frequently needed in patients with diabetes and renal insufficiency. For most agents, reduction of blood pressure at half-standard doses is only ~20% less than at standard doses. Appropriate combinations of agents at these lower doses may have additive or almost additive effects on blood pressure with a lower incidence of side effects.

Despite theoretical concerns about decreasing cerebral, coronary, and renal blood flow by overly aggressive antihypertensive therapy, clinical trials have found no evidence for a "J-curve" phenomenon, i.e., at blood pressure reductions achieved in clinical practice, there does *not* appear to be a lower threshold for increasing cardiovascular risk. Even among patients with isolated systolic hypertension, further lowering of the diastolic blood pressure does not result in harm. However, relatively little information is available concerning the risk/benefit ratio of antihypertensive therapy in individuals >80 years, and, in this population, gradual blood pressure reduction to less aggressive target levels of control may be appropriate.

The term *resistant hypertension* refers to patients with blood pressures persistently >140/90 mmHg despite taking three or more antihypertensive agents, including a diuretic, in reasonable combination and at full doses. Resistant or difficult-to-control hypertension is more common in patients >60 years than in younger patients. Resistant hypertension may be related to "pseudoresistance" (high office blood pressures and lower home blood pressures), nonadherence to therapy, identifiable causes of hypertension (including obesity and excessive alcohol intake), and use of any of a number of nonprescription and prescription drugs (Table 241-3). Rarely, in older patients, pseudohypertension may be related to the inability to measure blood pressure accurately in severely sclerotic arteries. This condition is suggested if the radial pulse remains palpable despite occlusion of the brachial artery by the cuff (Osler maneuver). The actual blood pressure can be determined by direct intraarterial measurement. Evaluation of patients with resistant hypertension might include home blood pressure monitoring to determine if office blood pressures are representative of the usual blood pressure. A more extensive evaluation for a secondary form of hypertension should be undertaken if no other explanation for hypertension resistance becomes apparent.

HYPERTENSIVE EMERGENCIES Probably due to the widespread availability of antihypertensive therapy, in the United States there has been a decline in the numbers of patients presenting with "crisis levels" of blood pressure. Most patients who present with severe hypertension are chronically hypertensive, and in the absence of acute, end-organ damage, precipitous lowering of blood pressure may be associated with significant morbidity and should be avoided. The key to successful management of severe hypertension is to differentiate hypertensive crises from hypertensive urgencies. The degree of target organ damage, rather than the level of blood pressure alone, determines the rapidity with which blood pressure should be lowered. **Tables 241-9** and **241-10** list a number of hypertension-related emergencies and recommended therapies.

Malignant hypertension is a syndrome associated with an abrupt increase of blood pressure in a patient with underlying hypertension or related to the sudden onset of hypertension in a previously normotensive individual. The absolute level of blood pressure is not as important as its rate of rise. Pathologically, the syndrome is associated with diffuse necrotizing vasculitis, arteriolar thrombi, and fibrin deposition in arteriolar walls. Fibrinoid necrosis has been observed in arterioles of kidney, brain, retina, and other organs. Clinically, the syndrome is recognized by progressive retinopathy (arteriolar spasm, hemorrhages, exudates, and papilledema), deteriorating renal function with proteinuria, microangiopathic hemolytic anemia, and encephalopathy. In these patients, historic inquiry should include questions about the use of monamine oxidase inhibitors and recreational drugs (e.g., cocaine, amphetamines).

TABLE 241-9 PREFERRED PARENTERAL DRUGS FOR SELECTED HYPERTENSIVE EMERGENCIES

Hypertensive encephalopathy	Nitroprusside, nicardipine, labetalol
Malignant hypertension (when IV therapy is indicated)	Labetalol, nicardipine, nitroprusside, enalaprilat
Stroke	Nicardipine, labetalol, nitroprusside
Myocardial infarction/unstable angina	Nitroglycerin, nicardipine, labetalol, esmolol
Acute left ventricular failure	Nitroglycerin, enalaprilat, loop diuretics
Aortic dissection	Nitroprusside, esmolol, labetalol
Adrenergic crisis	Phentolamine, nitroprusside
Postoperative hypertension	Nitroglycerin, nitroprusside, labetalol, nicardipine
Preeclampsia/eclampsia of pregnancy	Hydralazine, labetalol, nicardipine

Source: Adapted from DG Vidt, in S Oparil, MA Weber (eds): *Hypertension*, 2d ed. Philadelphia, Elsevier Saunders, 2005.

TABLE 241-10 USUAL INTRAVENOUS DOSES OF ANTIHYPERTENSIVE AGENTS USED IN HYPERTENSIVE EMERGENCIES[a]

Antihypertensive Agent	Intravenous Dose
Nitroprusside	Initial 0.3 (μg/kg)/min; usual 2–4 (μg/kg)/min; maximum 10 (μg/kg)/min for 10 min
Nicardipine	Initial 5 mg/h; titrate by 2.5 mg/h at 5–15 min intervals; max 15 mg/h
Labetalol	2 mg/min up to 300 mg *or* 20 mg over 2 min, then 40–80 mg at 10-min intervals up to 300 mg total
Enalaprilat	Usual 0.625–1.25 mg over 5 min every 6–8 h; maximum 5 mg/dose
Esmolol	Initial 80–500 μg/kg over 1 min, then 50–300 (μg/kg)/min
Phentolamine	5–15 mg bolus
Nitroglycerin	Initial 5 μg/min, then titrate by 5 μg/min at 3–5 min intervals; if no response is seen at 20 μg/min, incremental increases of 10–20 μg/min may be used
Hydralazine	10–50 mg at 30-min intervals

[a]Constant blood pressure monitoring is required. Start with the lowest dose. Subsequent doses and intervals of administration should be adjusted according to the blood pressure response and duration of action of the specific agent.

Although blood pressure should be lowered rapidly in patients with hypertensive encephalopathy, there are inherent risks of overly aggressive therapy. In hypertensive individuals, the upper and lower limits of autoregulation of cerebral blood flow are shifted to higher levels of arterial pressure, and rapid lowering of blood pressure to below the lower limit of autoregulation may precipitate cerebral ischemia or infarction as a consequence of decreased cerebral blood flow. Renal and coronary blood flows may also decrease with overly aggressive acute therapy. The initial goal of therapy is to reduce mean arterial blood pressure by no more than 25% within minutes to 2 h or to a blood pressure in the range of 160/100–110 mmHg. This may be accomplished with IV nitroprusside, a short-acting vasodilator with a rapid onset of action that allows for minute-to-minute control of blood pressure. Parenteral labetalol and nicardipine are also effective agents for the treatment of hypertensive encephalopathy.

In patients with malignant hypertension without encephalopathy or some other catastrophic event, it is preferable to reduce blood pressure over hours or longer rather than minutes. This goal may effectively be achieved initially with frequent dosing of short-acting oral agents, such as captopril, clonidine, or labetalol.

Acute, transient blood pressure elevations, lasting days to weeks, frequently occur following thrombotic and hemorrhagic strokes. Autoregulation of cerebral blood flow is impaired in ischemic cerebral tissue, and higher arterial pressures may be required to maintain cerebral blood flow. Although specific blood pressure targets have not been defined for patients with acute cerebrovascular events, aggressive reductions of blood pressure are to be avoided. With the increasing availability of improved methods for measuring cerebral blood flow (using CT technology), studies are in progress to evaluate the effects of different classes of antihypertensive agents on both blood pressure and cerebral blood flow following an acute stroke. Currently, in the absence of other indications for acute therapy, for patients with cerebral infarction who are not candidates for thrombolytic therapy, one recommended guideline is to institute antihypertensive therapy only for those patients with a systolic blood pressure > 220 mmHg or a diastolic blood pressure > 130 mmHg. If thrombolytic therapy is to be used, the recommended goal blood pressure is <185 mmHg systolic pressure and <110 mmHg diastolic pressure. In patients with hemorrhagic stroke, suggested guidelines for initiating antihypertensive therapy are systolic > 180 mmHg or diastolic pressure > 130 mmHg. The management of hypertension after subarachnoid hemorrhage is controversial. Cautious reduction of blood pressure is indicated if mean arterial pressure is >130 mmHg.

In addition to pheochromocytoma, an adrenergic crisis due to catecholamine excess may be related to cocaine or amphetamine overdose, clonidine withdrawal, acute spinal cord injuries, and an interaction of tyramine-containing compounds with monamine oxidase inhibitors. These patients may be treated with phentolamine or nitroprusside.

Treatment of hypertension in patients with acute aortic dissection is discussed in Chap. 242, and treatment of hypertension in pregnancy is discussed in Chap. 7.

242 Diseases of the Aorta

Mark A. Creager, Joseph Loscalzo

The aorta is the conduit through which the blood ejected from the left ventricle is delivered to the systemic arterial bed. In adults, its diameter is approximately 3 cm at the origin and in the ascending portion, 2.5 cm in the descending portion in the thorax, and 1.8–2 cm in the abdomen. The aortic wall consists of a thin intima composed of endothelium, subendothelial connective tissue, and an internal elastic lamina; a thick tunica media composed of smooth-muscle cells and extracellular matrix; and an adventitia composed primarily of connective tissue enclosing the vasa vasorum and nervi vascularis. In addition to its conduit function, the viscoelastic and compliant properties of the aorta also subserve a buffering function. The aorta is distended during systole to enable a portion of the stroke volume and elastic energy to be stored, and it recoils during diastole so that blood continues to flow to the periphery. Because of its continuous exposure to high pulsatile pressure and shear stress, the aorta is particularly prone to injury and disease resulting from mechanical trauma (Table 242-1). The aorta is also more prone to rupture than any other vessel, especially with the development of aneurysmal dilatation, since its wall tension, as governed by Laplace's law (i.e., proportional to the product of pressure and radius), will be increased.

AORTIC ANEURYSM

An *aneurysm* is defined as a pathologic dilatation of a segment of a blood vessel. A *true aneurysm* involves all three layers of the vessel wall and is distinguished from a *pseudoaneurysm*, in which the intimal and medial layers are disrupted and the dilatation is lined by adventitia only and, at times, by perivascular clot. Aneurysms may also be classified according to their gross appearance. A *fusiform aneurysm* affects the entire circumference of a segment of the vessel, resulting in a diffusely dilated artery. In contrast, a *saccular aneurysm* involves only a portion of the circumference, resulting in an outpouching of the vessel wall. Aortic aneurysms are also classified according to location, i.e., abdominal versus thoracic. Aneurysms of the descending thoracic aorta are usually contiguous with infradiaphragmatic aneurysms and are referred to as *thoracoabdominal aortic aneurysms*.

TABLE 242-1 DISEASES OF THE AORTA: ETIOLOGY AND ASSOCIATED FACTORS

Aortic aneurysm
Degenerative/atherosclerosis
Aging
Cigarette smoking
Male gender
Family history
Cystic medial necrosis
Marfan syndrome
Ehlers-Danlos syndrome type IV
Familial etiology
Bicuspid aortic valve
Chronic aortic dissection
Infective (see below)
Trauma
Acute aortic syndromes (aortic dissection, acute intramural hematoma, penetrating atherosclerotic ulcer)
Atherosclerosis
Cystic medial necrosis (see above)
Hypertension
Vasculitis (see below)
Pregnancy
Trauma
Aortic occlusion
Atherosclerosis
Thromboembolism
Aortitis
Vasculitis
Takayasu's arteritis
Giant cell arteritis
Rheumatic
HLA-B27–associated spondyloarthropathies
Behçet's syndrome
Cogan's syndrome
Idiopathic retroperitoneal fibrosis
Infective
Syphilis
Tuberculosis
Mycotic (*Salmonella*, staphylococcal, streptococcal, fungal)

ETIOLOGY

Aortic aneurysms result from conditions that cause degradation or abnormal production of the aortic wall's structural components, elastin and collagen. The causes of aortic aneurysms may be broadly categorized as degenerative diseases, inherited or developmental diseases, infections, vasculitis, and trauma (Table 242-1). Inflammation, proteolysis, and biomechanical wall stress contribute to the degenerative processes that characterize most aneurysms of the abdominal and descending thoracic aorta. These are mediated by B and T cell lymphocytes, macrophages, inflammatory cytokines, and matrix metalloproteinases that degrade elastin and collagen and alter the tensile strength and ability of the aorta to accommodate pulsatile stretch. The associated histopathology demonstrates destruction of elastin and collagen, decreased vascular smooth muscle, ingrowth of new blood vessels, and inflammation. Factors associated with degenerative aortic aneurysms include aging, cigarette smoking, hypercholesterolemia, male gender, and a family history of aortic aneurysms.

The most common pathologic condition associated with degenerative aortic aneurysms is *atherosclerosis*. Many patients with aortic aneurysms have coexisting risk factors for atherosclerosis (Chap. 235), as well as atherosclerosis in other blood vessels.

Cystic medial necrosis is the histopathologic term used to describe the degeneration of collagen and elastic fibers in the tunica media of the aorta, as well as the loss of medial cells that are replaced by multiple clefts of mucoid material. Cystic medial necrosis characteristically affects the proximal aorta, results in circumferential weakness and dilatation, and leads to the development of fusiform aneurysms involving the ascending aorta and the sinuses of Valsalva. This condition is particularly prevalent in patients with Marfan syndrome, Ehlers-Danlos syndrome type IV (Chap. 357), hypertension, congenital bicuspid aortic valves, and familial thoracic aortic aneurysm syndromes. Sometimes it appears as an isolated condition in patients without any other apparent disease.

Familial clusterings of aortic aneurysms occur in 20% of patients, suggesting a hereditary basis for the disease. Mutations of the genes encoding fibrillin-1 and type III procollagen have been implicated in some cases of Marfan and Ehlers-Danlos type IV syndromes, respectively. Linkage analysis has identified loci on chromosomes 5q13–14, 11q23.3–q24, and 3p24–25 in several families, although the specific alleles have not been described.

The infectious causes of aortic aneurysms include syphilis, tuberculosis, and other bacterial infections. *Syphilis* (Chap. 162) is a relatively uncommon cause of aortic aneurysm. Syphilitic periaortitis and mesoaortitis damage elastic fibers, resulting in thickening and weakening of the aortic wall. Approximately 90% of syphilitic aneurysms are located in the ascending aorta or aortic arch. *Tuberculous aneurysms* (Chap. 158) typically affect the thoracic aorta and result from direct extension of infection from hilar lymph nodes or contiguous abscesses, or from bacterial seeding. Loss of aortic wall elasticity results from granulomatous destruction of the medial layer. A *mycotic aneurysm* is a rare condition that develops as a result of staphylococcal, streptococcal, *Salmonella* or other bacterial or fungal infections of the aorta, usually at an atherosclerotic plaque. These aneurysms are usually saccular. Blood cultures are often positive and reveal the nature of the infecting agent.

Vasculitides associated with aortic aneurysm include Takayasu's arteritis and giant cell arteritis, which may cause aneurysms of the aortic arch and descending thoracic aorta. Spondyloarthropathies, such as

ankylosing spondylitis, rheumatoid arthritis, psoriatic arthritis, relapsing polychondritis, and Reiter's syndrome, are associated with dilatation of the ascending aorta. Behçet's syndrome (Chap. 320) causes thoracic and abdominal aortic aneurysms. *Traumatic aneurysms* may occur after penetrating or nonpenetrating chest trauma and most commonly affect the descending thoracic aorta just beyond the site of insertion of the ligamentum arteriosum. Chronic aortic dissections are associated with weakening of the aortic wall that may lead to the development of aneurysmal dilatation.

THORACIC AORTIC ANEURYSMS

The clinical manifestations and natural history of thoracic aortic aneurysms depend on their location. Cystic medial necrosis is the most common cause of ascending aortic aneurysms, whereas atherosclerosis is the condition most frequently associated with aneurysms of the aortic arch and descending thoracic aorta. The average growth rate of thoracic aneurysms is 0.1–0.2 cm per year. Thoracic aortic aneurysms associated with Marfan syndrome or aortic dissection may expand at a greater rate. The risk of rupture is related to the size of the aneurysm and the presence of symptoms, ranging approximately from 2–3% per year for thoracic aortic aneurysms <4.0 cm in diameter to 7% per year for those >6 cm in diameter. Most thoracic aortic aneurysms are asymptomatic; however, compression or erosion of adjacent tissue by aneurysms may cause symptoms such as chest pain, shortness of breath, cough, hoarseness, or dysphagia. Aneurysmal dilatation of the ascending aorta may cause congestive heart failure as a consequence of aortic regurgitation, and marked compression of the superior vena cava may produce congestion of the head, neck, and upper extremities.

A chest x-ray may be the first test to suggest the diagnosis of a thoracic aortic aneurysm (Fig. 242-1). Findings include widening of the mediastinal shadow and displacement or compression of the trachea or left mainstem bronchus. Two-dimensional echocardiography, particularly transesophageal echocardiography, can be used to assess the proximal ascending aorta and descending thoracic aorta. Contrast-enhanced computed tomography (CT), magnetic resonance imaging (MRI), and conventional invasive aortography are sensitive and specific tests for assessment of aneurysms of the thoracic aorta and involvement of branch vessels (Fig. 242-2). In asymptomatic patients whose aneurysms are too small to justify surgery, noninvasive testing with either contrast-enhanced CT or MRI should be performed at least every 6–12 months to monitor expansion.

FIGURE 242-1 A chest x-ray of a patient with a thoracic aortic aneurysm.

FIGURE 242-2 An aortogram demonstrating a large fusiform aneurysm of the descending thoracic aorta.

℞ THORACIC AORTIC ANEURYSMS

Patients with thoracic aortic aneurysms, and particularly patients with Marfan syndrome who have evidence of aortic root dilatation, should receive long-term beta-blocker therapy. Additional medical therapy should be given, as necessary, to control hypertension. Operative repair with placement of a prosthetic graft is indicated in patients with symptomatic thoracic aortic aneurysms, and in those in whom the aortic diameter is >5.5–6 cm or has increased by >1 cm per year. In patients with Marfan syndrome or bicuspid aortic valve, thoracic aortic aneurysms >5 cm should be considered for surgery.

ABDOMINAL AORTIC ANEURYSMS

Abdominal aortic aneurysms occur more frequently in males than in females, and the incidence increases with age. Abdominal aortic aneurysms ≥4.0 cm may affect 1–2% of men older than 50 years. At least 90% of all abdominal aortic aneurysms >4.0 cm are related to atherosclerotic disease, and most of these aneurysms are below the level of the renal arteries. Prognosis is related to both the size of the aneurysm and the severity of coexisting coronary artery and cerebrovascular disease. The risk of rupture increases with the size of the aneurysm: the 5-year risk for aneurysms <5 cm is 1–2%, whereas it is 20–40% for aneurysms >5 cm in diameter. The formation of mural thrombi within aneurysms may predispose to peripheral embolization.

An abdominal aortic aneurysm commonly produces no symptoms. It is usually detected on routine examination as a palpable, pulsatile, expansile, and nontender mass, or it is an incidental finding during an abdominal x-ray or ultrasound study performed for other reasons. As abdominal aortic aneurysms expand, however, they may become painful. Some patients complain of strong pulsations in the abdomen; others experience pain in the chest, lower back, or scrotum. Aneurysmal pain is usually a harbinger of rupture and represents a medical emergency. More often, acute rupture occurs without any prior warning, and this complication is always life-threatening. Rarely, there is leakage of the aneurysm with severe pain and tenderness. Acute pain and hypotension occur with rupture of the aneurysm, which requires emergency operation.

Abdominal radiography may demonstrate the calcified outline of the aneurysm; however, about 25% of aneurysms are not calcified and cannot be visualized by plain x-ray. An abdominal ultrasound can delineate the transverse and longitudinal dimensions of an abdominal aortic aneurysm and may detect mural thrombus. Abdominal ultrasound is useful for serial documentation of aneurysm size and can be

FIGURE 242-3 A computed tomographic angiogram (CTA) depicting a fusiform abdominal aortic aneurysm that has been treated with a bifurcated stent graft.

used to screen patients at risk for developing aortic aneurysm, such as those with affected siblings, peripheral atherosclerosis, or peripheral artery aneurysms. In one large study, ultrasound screening of men age 65–74 years was associated with a risk reduction in aneurysm-related death by 42%. CT with contrast and MRI are accurate, noninvasive tests to determine the location and size of abdominal aortic aneurysms and to plan endovascular or open surgical repair (Fig. 242-3). Contrast aortography may be used for the evaluation of patients with aneurysms, but the procedure carries a small risk of complications, such as bleeding, allergic reactions, and atheroembolism. Since the presence of mural thrombi may reduce the luminal size, aortography may underestimate the diameter of an aneurysm.

℞ ABDOMINAL AORTIC ANEURYSMS

Operative repair of the aneurysm and insertion of a prosthetic graft are indicated for abdominal aortic aneurysms of any size that are expanding rapidly or are associated with symptoms. For asymptomatic aneurysms, operation is indicated if the diameter is >5.5 cm. In randomized trials of patients with abdominal aortic aneurysms <5.5 cm, there was no difference in the long-term (5- to 8-year) mortality rate between those followed with ultrasound surveillance and those undergoing elective aneurysm repair. Thus, serial noninvasive follow-up of smaller aneurysms (<5 cm) is an alternative to immediate surgery. Percutaneous placement of endovascular stent grafts (Fig. 242-3) for treatment of infrarenal abdominal aortic aneurysms is available for selected patients and is associated with lower short-term morbidity but comparable long-term mortality, compared with open surgical reconstruction.

In surgical candidates, careful preoperative cardiac and general medical evaluations (followed by appropriate therapy of complicating conditions) are essential. Preexisting coronary artery disease, congestive heart failure, pulmonary disease, diabetes, and advanced age add to the risk of surgery. β-adrenergic blockers decrease perioperative cardiovascular morbidity and mortality. With careful preoperative cardiac evaluation and postoperative care, the operative mortality rate approximates 1–2%. After acute rupture, the mortality rate of emergent operation is 45–50%. Endovascular repair with stent placement is an emerging approach but, at the current time, is associated with a mortality rate of approximately 40%.

ACUTE AORTIC SYNDROMES

The four major acute aortic syndromes include aortic rupture (discussed above), aortic dissection, intramural hematoma, and penetrating atherosclerotic ulcer. Aortic dissection is caused by a circumferential or, less frequently, transverse tear of the intima. It often occurs along the right lateral wall of the ascending aorta where the hydraulic shear stress is high. Another common site is the descending thoracic aorta just below the ligamentum arteriosum. The initiating event is either a primary intimal tear with secondary dissection into the media or a medial hemorrhage that dissects into and disrupts the intima. The pulsatile aortic flow then dissects along the elastic lamellar plates of the aorta and creates a false lumen. The dissection usually propagates distally down the descending aorta and into its major branches, but it may also propagate proximally. Distal propagation may be limited by atherosclerotic plaque. In some cases, a secondary distal intimal disruption occurs, resulting in the reentry of blood from the false to the true lumen.

There are at least two important pathologic and radiologic variants of aortic dissection: intramural hematoma without an intimal flap and penetrating atherosclerotic ulcer. Acute intramural hematoma is thought to result from rupture of the vasa vasorum with hemorrhage into the wall of the aorta. Most occur in the descending thoracic aorta. Acute intramural hematomas may progress to dissection and rupture. Penetrating atherosclerotic ulcers are caused by erosion of a plaque into the aortic media, are usually localized, and are not associated with extensive propagation. They are found primarily in the mid and distal portions of the descending thoracic aorta and are associated with extensive atherosclerotic disease. The ulcer can erode beyond the internal elastic lamina, leading to medial hematoma, and may progress to false aneurysm formation or rupture.

Several classification schemes have been developed for thoracic aortic dissections. DeBakey and colleagues initially classified aortic dissections as type I, in which an intimal tear occurs in the ascending aorta but involves the descending aorta as well; type II, in which the dissection is limited to the ascending aorta; and type III, in which the intimal tear is located in the descending aorta with distal propagation of the dissection (Fig. 242-4). Another classification (Stanford) is that of type A, in which the dissection involves the ascending aorta (proximal dissection), and type B, in which it is limited to the descending aorta (distal dissection). From a management standpoint, classification of aortic dissections and intramural hematomas into type A or B is more practical and useful, since DeBakey types I and II are managed in a similar manner.

The factors that predispose to aortic dissection include systemic hypertension, a coexisting condition in 70% of patients, and cystic medial necrosis. Aortic dissection is the major cause of morbidity and mortality in patients with Marfan syndrome (Chap. 357) and similarly may affect patients with Ehlers-Danlos syndrome. The incidence is also increased in patients with inflammatory aortitis (i.e., Takayasu's arteritis, giant cell arteritis), congenital aortic valve anomalies (e.g., bicuspid valve), coarctation of the aorta, and a history of aortic trauma. In addition, the risk of dissection is increased in otherwise normal women during the third trimester of pregnancy.

CLINICAL MANIFESTATIONS

The peak incidence of aortic dissection is in the sixth and seventh decades. Men are more affected than women by a ratio of 2:1. The presentations of aortic dissection and its variants are the consequences of intimal tear, dissecting hematoma, occlusion of involved arteries, and compression of adjacent tissues. Acute aortic dissection presents with the sudden onset of pain (Chap. 13), which is often described as very severe and tearing and is associated with diaphoresis. The pain may be localized to the front or back of the chest, often the interscapular region, and typically migrates with propagation of the dissection. Other symptoms include syncope, dyspnea, and weakness. Physical findings may include hypertension or hypotension, loss of pulses, aortic regurgitation, pulmonary edema, and neurologic findings due to carotid artery obstruction (hemiplegia, hemianesthesia) or spinal cord ischemia

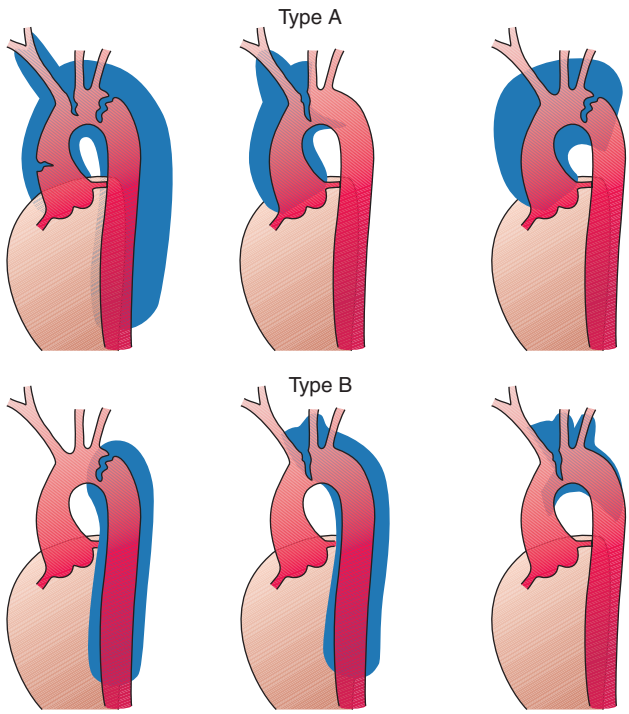

FIGURE 242-4 Classification of aortic dissections. Stanford classification: Type A dissections (*top panels*) involve the ascending aorta independent of site of tear and distal extension; type B dissections (*bottom panels*) involve transverse and/or descending aorta without involvement of the ascending aorta. DeBakey classification: Type I dissection involves ascending to descending aorta (*top left*); type II dissection is limited to ascending or transverse aorta, without descending aorta (*top center + top right*); type III dissection involves descending aorta only (*bottom left*). *[From DC Miller, in RM Doroghazi, EE Slater (eds): Aortic Dissection. New York, McGraw-Hill, 1983, with permission.]*

(paraplegia). Bowel ischemia, hematuria, and myocardial ischemia have all been observed. These clinical manifestations reflect complications resulting from the dissection occluding the major arteries. Furthermore, clinical manifestations may result from the compression of adjacent structures (e.g., superior cervical ganglia, superior vena cava, bronchus, esophagus) by the expanding dissection causing aneurysmal dilatation, and include Horner's syndrome, superior vena cava syndrome, hoarseness, dysphagia, and airway compromise. Hemopericardium and cardiac tamponade may complicate a type A lesion with retrograde dissection. Acute aortic regurgitation is an important and common (>50%) complication of proximal dissection. It is the outcome of either a circumferential tear that widens the aortic root or a disruption of the annulus by dissecting hematoma that tears a leaflet(s) or displaces it, inferior to the line of closure. Signs of aortic regurgitation include bounding pulses, a wide pulse pressure, a diastolic murmur often radiating along the right sternal border, and evidence of congestive heart failure. The clinical manifestations depend on the severity of the regurgitation.

In dissections involving the ascending aorta, the chest x-ray often reveals a widened superior mediastinum. A pleural effusion (usually left-sided) also may be present. This effusion is typically serosanguineous and not indicative of rupture unless accompanied by hypotension and falling hematocrit. In dissections of the descending thoracic aorta, a widened mediastinum may also be observed on chest x-ray. In addition, the descending aorta may appear to be wider than the ascending portion. An electrocardiogram that shows no evidence of myocardial ischemia is helpful in distinguishing aortic dissection from myocardial infarction. Rarely, the dissection involves the right or, less commonly, left coronary ostium and causes acute myocardial infarction.

The diagnosis of aortic dissection can be established by noninvasive techniques such as echocardiography, CT, or MRI. Aortography is used less commonly because of the accuracy of these noninvasive techniques. Transthoracic echocardiography can be performed simply and rapidly and has an overall sensitivity of 60–85% for aortic dissection. For diagnosing proximal ascending aortic dissections, its sensitivity exceeds 80%; it is less useful for detecting dissection of the arch and descending thoracic aorta. Transesophageal echocardiography requires greater skill and patient cooperation but is very accurate in identifying dissections of the ascending and descending thoracic aorta, but not the arch, achieving 98% sensitivity and approximately 90% specificity. Echocardiography also provides important information regarding the presence and severity of aortic regurgitation and pericardial effusion. CT and MRI are both highly accurate in identifying the intimal flap and the extent of the dissection and involvement of major arteries; each has a sensitivity and specificity >90%. They are useful in recognizing intramural hemorrhage and penetrating ulcers. MRI can also detect blood flow, which may be useful in characterizing antegrade versus retrograde dissection. The relative utility of transesophageal echocardiography, CT, and MRI depends on the availability and expertise in individual institutions as well as on the hemodynamic stability of the patient, with CT and MRI obviously less suitable for unstable patients.

Rx AORTIC DISSECTION

Medical therapy should be initiated as soon as the diagnosis is considered. The patient should be admitted to an intensive care unit for hemodynamic monitoring. Unless hypotension is present, therapy should be aimed at reducing cardiac contractility and systemic arterial pressure, and thereby shear stress. For acute dissection, unless contraindicated, β-adrenergic blockers should be administered parenterally, using intravenous propranolol, metoprolol, or the short-acting esmolol to achieve a heart rate of approximately 60 beats/min. This should be accompanied by sodium nitroprusside infusion to lower systolic blood pressure to ≤120 mmHg. Labetalol (Chap. 242), a drug with both β- and α-adrenergic blocking properties, may also be used as a parenteral agent in the acute therapy of dissection.

The calcium channel antagonists verapamil and diltiazem may be used intravenously if nitroprusside or β-adrenergic blockers cannot be employed. The addition of a parenteral angiotensin-converting enzyme (ACE) inhibitor, such as enalaprilat, to a β-adrenergic blocker also may be considered. Isolated use of direct vasodilators, such as diazoxide and hydralazine, is contraindicated because these agents can increase hydraulic shear and may propagate dissection.

Emergent or urgent surgical correction is the preferred treatment for acute ascending aortic dissections and intramural hematomas (type A) and for complicated type B dissections, including those characterized by propagation, compromise of major aortic branches, impending rupture, or continued pain. Surgery involves excision of the intimal flap, obliteration of the false lumen, and placement of an interposition graft. A composite valve-graft conduit is used if the aortic valve is disrupted. The overall in-hospital mortality rate after surgical treatment of patients with aortic dissection is reported to be 15–25%. The major causes of perioperative mortality and morbidity include myocardial infarction, paraplegia, renal failure, tamponade, hemorrhage, and sepsis. Reports of the use of endoluminal stent grafts in selected patients with type B dissection are encouraging. Other transcatheter techniques, such as fenestration of the intimal flaps and stenting of narrowed branch vessels to increase flow to compromised organs, are investigational approaches used in selected patients. For uncomplicated and stable distal dissections and intramural hematomas (type B), medical therapy is the preferred treatment. The in-hospital mortality rate of medically treated patients with type B dissection is 10–20%. Long-term therapy for patients with aortic dissection and intramural hematomas (with or without surgery) consists of the control of hypertension and reduction of cardiac contractility with the use of beta blockers plus other antihypertensive agents, such as ACE inhibitors or calcium antagonists. Patients with chronic type B dissection and intramural hematomas should be followed on an outpatient basis every 6–12 months by contrast-enhanced CT or MRI to detect propagation or expansion. Patients with Marfan syndrome are at high risk for postdissection complications. The long-term prognosis for patients with treated dissections is generally good with careful follow-up; the 10-year survival rate is approximately 60%.

AORTIC OCCLUSION

CHRONIC ATHEROSCLEROTIC OCCLUSIVE DISEASE

Atherosclerosis may affect the thoracic and abdominal aorta. Occlusive aortic disease caused by atherosclerosis is usually confined to the distal abdominal aorta below the renal arteries. Frequently the disease extends to the iliac arteries (Chap. 243). Claudication characteristically involves the buttocks, thighs, and calves and may be associated with impotence in males (Leriche syndrome). The severity of the symptoms depends on the adequacy of collaterals. With sufficient collateral blood flow, a complete occlusion of the abdominal aorta may occur without the development of ischemic symptoms. The physical findings include absence of femoral and other distal pulses bilaterally, and the detection of an audible bruit over the abdomen (usually at or below the umbilicus) and the common femoral arteries. Atrophic skin, loss of hair, and coolness of the lower extremities are usually observed. In advanced ischemia, rubor on dependency and pallor on elevation can be seen.

The diagnosis is usually established by physical examination and noninvasive testing, including leg pressure measurements, Doppler velocity analysis, pulse volume recordings, and duplex ultrasonography. The anatomy may be defined by MRI, CT, or conventional aortography, typically performed when considering revascularization. Catheter-based endovascular or operative treatment is indicated in patients with lifestyle-limiting or debilitating symptoms of claudication and in patients with critical limb ischemia.

ACUTE OCCLUSION

Acute occlusion in the distal abdominal aorta constitutes a medical emergency because it threatens the viability of the lower extremities; it usually results from an occlusive embolus that almost always originates from the heart. Rarely, acute occlusion may occur as the result of in situ thrombosis in a preexisting severely narrowed segment of the aorta.

The clinical picture is one of acute ischemia of the lower extremities. Severe rest pain, coolness, and pallor of the lower extremities and the absence of distal pulses bilaterally are the usual manifestations. Diagnosis should be established rapidly by MRI, CT, or aortography. Emergency thrombectomy or revascularization is indicated.

AORTITIS

Aortitis, a term referring to inflammatory disease of the aorta, may be caused by large vessel vasculitides such as Takayasu's arteritis and giant cell arteritis, rheumatic and HLA-B27–associated spondyloarthropathies, Behçet's syndrome, ANCA-associated vasculitides, Cogan's syndrome, and infections, such as syphilis, tuberculosis, and *Salmonella*, or may be associated with retroperitoneal fibrosis. Aortitis may result in aneurysmal dilatation and aortic regurgitation, occlusion of the aorta and its branch vessels, or acute aortic syndromes.

TAKAYASU'S ARTERITIS

This inflammatory disease often affects the ascending aorta and aortic arch, causing obstruction of the aorta and its major arteries. Takayasu's arteritis is also termed *pulseless disease* because of the frequent occlusion of the large arteries originating from the aorta. It may also involve the descending thoracic and abdominal aorta and occlude large branches such as the renal arteries. Aortic aneurysms may also occur. The pathology is a panarteritis, characterized by mononuclear cells and occasionally giant cells, with marked intimal hyperplasia, medial and adventitial thickening, and, in the chronic form, fibrotic occlusion. The disease is most prevalent in young females of Asian descent but does occur in women of other geographic and ethnic origins and also in young men. During the acute stage, fever, malaise, weight loss, and other systemic symptoms may be evident. Elevations of the erythrocyte sedimentation rate and C-reactive protein are common. The chronic stages of the disease, which is intermittently active, present with symptoms related to large artery occlusion, such as upper extremity claudication, cerebral ischemia, and syncope. Since the process is progressive and there is no definitive therapy, the prognosis is usually poor. Glucocorticoids and immunosuppressive agents have been reported to be effective in some patients during the acute phase. Surgical bypass or endovascular intervention of a critically stenotic artery may be necessary.

GIANT CELL ARTERITIS

(See also Chap. 319) This vasculitis occurs in older individuals and affects women more often than men. Primarily large and medium-sized arteries are affected. The pathology is that of focal granulomatous lesions involving the entire arterial wall; it may be associated with polymyalgia rheumatica. Obstruction of medium-sized arteries (e.g., temporal and ophthalmic arteries) and of major branches of the aorta and the development of aortitis and aortic regurgitation are important complications of the disease. High-dose glucocorticoid therapy may be effective when given early.

RHEUMATIC AORTITIS

Rheumatoid arthritis (Chap. 314), ankylosing spondylitis (Chap. 318), psoriatic arthritis (Chap. 318), Reiter's syndrome (Chap. 318), relapsing polychondritis, and inflammatory bowel disorders may all be associated with aortitis involving the ascending aorta. The inflammatory lesions usually involve the ascending aorta and may extend to the sinuses of Valsalva, the mitral valve leaflets, and adjacent myocardium. The clinical manifestations are aneurysm, aortic regurgitation, and involvement of the cardiac conduction system.

SYPHILITIC INFECTIVE AORTITIS

Infective aortitis may result from direct invasion of the aortic wall by bacterial pathogens, such as *Staphylococcus*, *Streptococcus*, and *Salmonella*, or by fungi. These bacteria cause aortitis by infecting the aorta at sites of atherosclerotic plaque. Bacterial proteases lead to degradation of collagen, and the ensuing destruction of the aortic wall leads to formation of a saccular aneurysm, referred to as a mycotic aneurysm. Mycotic aneurysms have a predilection for the suprarenal abdominal aorta. The pathologic characteristics of the aortic wall include acute and chronic inflammation, abscesses, hemorrhage, and necrosis. Mycotic aneurysms typically affect the elderly and occur in men three times more frequently than in women. Patients may present with fever, sepsis, and chest, back, or abdominal pain; there may have been a preceding diarrheal illness. Blood cultures are positive in the majority of patients. Both CT and MRI are useful to diagnose mycotic aneurysms. Treatment includes antibiotic therapy and surgical removal of the affected part of the aorta, and revascularization of the lower extremities with grafts placed in uninfected tissue.

Syphilitic aortitis is a late manifestation of luetic infection (Chap. 162) that usually affects the proximal ascending aorta, particularly the aortic root, resulting in aortic dilatation and aneurysm formation. Syphilitic aortitis may occasionally involve the aortic arch or the descending aorta. The aneurysms may be saccular or fusiform and are usually asymptomatic, but compression of and erosion into adjacent structures may result in symptoms; rupture may also occur.

The initial lesion is an obliterative endarteritis of the vasa vasorum, especially in the adventitia. This is an inflammatory response to the invasion of the adventitia by the spirochetes. Destruction of the aortic media occurs as the spirochetes spread into this layer, usually via the lymphatics accompanying the vasa vasorum. Destruction of collagen and elastic tissues leads to dilation of the aorta, scar formation, and calcification. These changes account for the characteristic radiographic appearance of linear calcification of the ascending aorta.

The disease typically presents as an incidental chest radiographic finding 15–30 years after initial infection. Symptoms may result from aortic regurgitation, narrowing of coronary ostia due to syphilitic aortitis, compression of adjacent structures (e.g., esophagus), or rupture. Diagnosis is established by a positive serologic test, i.e., rapid plasmin reagin (RPR) or fluorescent treponemal antibody. Treatment includes penicillin and surgical excision and repair.

ARTERIAL DISORDERS

PERIPHERAL ARTERIAL DISEASE

Peripheral arterial disease (PAD) is defined as a clinical disorder in which there is a stenosis or occlusion in the aorta or arteries of the limbs. Atherosclerosis is the leading cause of PAD in patients > 40 years old. Other causes include thrombosis, embolism, vasculitis, fibromuscular dysplasia, entrapment, cystic adventitial disease, and trauma. The highest prevalence of atherosclerotic PAD occurs in the sixth and seventh decades of life. As in patients with atherosclerosis of the coronary and cerebral vasculature, there is an increased risk of developing PAD in cigarette smokers and in persons with diabetes mellitus, hypercholesterolemia, hypertension, or hyperhomocysteinemia.

Pathology (See also Chap. 235) Segmental lesions causing stenosis or occlusion are usually localized to large and medium-sized vessels. The pathology of the lesions includes atherosclerotic plaques with calcium deposition, thinning of the media, patchy destruction of muscle and elastic fibers, fragmentation of the internal elastic lamina, and thrombi composed of platelets and fibrin. The primary sites of involvement are the abdominal aorta and iliac arteries (30% of symptomatic patients), the femoral and popliteal arteries (80–90% of patients), and the more distal vessels, including the tibial and peroneal arteries (40–50% of patients). Atherosclerotic lesions occur preferentially at arterial branch points, sites of increased turbulence, altered shear stress, and intimal injury. Involvement of the distal vasculature is most common in elderly individuals and patients with diabetes mellitus.

Clinical Evaluation Fewer than 50% of patients with PAD are symptomatic, although many have a slow or impaired gait. The most common *symptom* is intermittent claudication, which is defined as a pain, ache, cramp, numbness, or a sense of fatigue in the muscles; it occurs during exercise and is relieved by rest. The site of claudication is distal to the location of the occlusive lesion. For example, buttock, hip, and thigh discomfort occur in patients with aortoiliac disease, whereas calf claudication develops in patients with femoral-popliteal disease. Symptoms are far more common in the lower than in the upper extremities because of the higher incidence of obstructive lesions in the former region. In patients with severe arterial occlusive disease in whom resting blood flow cannot accommodate basal nutritional needs of the tissues, critical limb ischemia may develop. Patients will complain of rest pain or a feeling of cold or numbness in the foot and toes. Frequently, these symptoms occur at night when the legs are horizontal and improve when the legs are in a dependent position. With severe ischemia, rest pain may be persistent.

Important *physical findings* of PAD include decreased or absent pulses distal to the obstruction, the presence of bruits over the narrowed artery, and muscle atrophy. With more severe disease, hair loss, thickened nails, smooth and shiny skin, reduced skin temperature, and pallor or cyanosis are frequent physical signs. In patients with critical limb ischemia, ulcers or gangrene may occur. Elevation of the legs and repeated flexing of the calf muscles produce pallor of the soles of the feet, whereas rubor, secondary to reactive hyperemia, may develop when the legs are dependent. The time required for rubor to develop or for the veins in the foot to fill when the patient's legs are transferred from an elevated to a dependent position is related to the severity of the ischemia and the presence of collateral vessels. Patients with severe ischemia may develop peripheral edema because they keep their legs in a dependent position much of the time. Ischemic neuropathy can result in numbness and hyporeflexia.

Noninvasive Testing The history and physical examination are often sufficient to establish the diagnosis of PAD. An objective assessment of the presence and severity of disease is obtained by noninvasive techniques. Arterial pressure can be recorded noninvasively in the legs by placement of sphygmomanometric cuffs at the ankles and use of a Doppler device to auscultate or record blood flow from the dorsalis pedis and posterior tibial arteries. Normally, systolic blood pressure in the legs and arms is similar. Indeed, ankle pressure may be slightly higher than arm pressure due to pulse-wave amplification. In the presence of hemodynamically significant stenoses, the systolic blood pressure in the leg is decreased. Thus, the ratio of the ankle and brachial artery pressures (termed the *ankle:brachial index*, or ABI) is ≥1.0 in normal individuals and <1.0 in patients with peripheral arterial disease; a ratio of <0.5 is consistent with severe ischemia.

Other noninvasive tests include segmental pressure measurements, pulse volume recordings, Doppler flow velocity waveform analysis, duplex ultrasonography (which combines B-mode imaging and pulse-wave Doppler examination), transcutaneous oximetry, and stress testing (usually using a treadmill). Placement of pneumatic cuffs enables assessment of systolic pressure along the legs. The presence of pressure gradients between sequential cuffs provides evidence of the presence and location of hemodynamically significant stenoses. Also, the volume displacement in the leg is decreased with each pulse, and the Doppler velocity contour becomes progressively blunted in the presence of significant PAD. Duplex ultrasonography is used to image and detect stenotic lesions in native arteries and bypass grafts.

Treadmill testing allows the physician to assess functional limitations objectively. Decline of the ABI immediately after exercise provides further support for the diagnosis of PAD in patients with equivocal symptoms and findings on examination.

Magnetic resonance angiography (MRA), computed tomographic angiography, and conventional contrast angiography should not be used

for routine diagnostic testing but are performed prior to potential revascularization. Each test is useful in defining the anatomy to assist planning for catheter-based and surgical revascularization procedures.

Prognosis The natural history of patients with PAD is influenced primarily by the extent of coexisting coronary artery and cerebrovascular disease. Approximately one-third to one-half of patients with symptomatic PAD have evidence of coronary artery disease based on clinical presentation and electrocardiogram, and over one-half have significant coronary artery disease by coronary angiography. Patients with PAD have a 15–30% 5-year mortality rate and a two- to sixfold increased risk of death from coronary heart disease. Mortality is highest in those with the most severe PAD. The likelihood of symptomatic progression of PAD appears less than the chance of succumbing to coronary artery disease. Approximately 75–80% of nondiabetic patients who present with mild to moderate claudication remain symptomatically stable. Deterioration is likely to occur in the remainder, with approximately 1–2% of the group ultimately developing critical limb ischemia. Approximately 25–30% of patients with critical limb ischemia survive and undergo amputation within 1 year. The prognosis is worse in patients who continue to smoke cigarettes or who have diabetes mellitus.

℞ PERIPHERAL ARTERIAL DISEASE

Patients with PAD should receive therapies to reduce the risk of associated cardiovascular events, such as myocardial infarction and death, and to improve limb symptoms, prevent progression to critical limb ischemia, and preserve limb viability. Risk factor modification and antiplatelet therapy should be initiated to improve cardiovascular outcomes. The importance of discontinuing cigarette smoking cannot be overemphasized. The physician must assume a major role in this lifestyle modification. Counseling and adjunctive drug therapy with the nicotine patch, bupropion, or varenicline increase smoking cessation rates and reduce recidivism. It is important to control blood pressure in hypertensive patients. Angiotensin-converting enzyme inhibitors may reduce the risk of cardiovascular events in patients with symptomatic PAD. β-Adrenergic blockers do not worsen claudication and may be used to treat hypertension, especially in patients with coexistent coronary artery disease. Treatment of hypercholesterolemia with statins is advocated to reduce the risk of myocardial infarction, stroke and death. The National Cholesterol Education Program Adult Treatment Panel considers PAD to be a coronary heart disease equivalent and recommends treatment to reduce LDL cholesterol to <100 mg/dL. Platelet inhibitors, particularly aspirin, reduce the risk of adverse cardiovascular events in patients with peripheral atherosclerosis. Clopidogrel, a drug that inhibits platelet aggregation via its effect on adenosine diphosphate–dependent platelet-fibrinogen binding, appears to be more effective than aspirin in reducing cardiovascular morbidity and mortality in patients with PAD. There is insufficient evidence of efficacy to support the routine use of dual antiplatelet therapy with both aspirin and clopidogrel in patients with PAD. The anticoagulant warfarin is not indicated to improve outcome in patients with chronic PAD.

Therapies for intermittent claudication and critical limb ischemia include supportive measures, medications, nonoperative interventions, and surgery. Supportive measures include meticulous care of the feet, which should be kept clean and protected against excessive drying with moisturizing creams. Well-fitting and protective shoes are advised to reduce trauma. Elastic support hose should be avoided, as they reduce blood flow to the skin. In patients with critical limb ischemia, shock blocks under the head of the bed together with a canopy over the feet may improve perfusion pressure and ameliorate some of the rest pain.

Patients with claudication should be encouraged to exercise regularly and at progressively more strenuous levels. Supervised exercise training programs for 30–45 min sessions, three to five times per week for at least 12 weeks, prolong walking distance. Patients also should be advised to walk until near-maximum claudication discomfort occurs, then resting until the symptoms resolve before resuming ambulation. Pharmacologic treatment of PAD has not been as successful as the medical treatment of coronary artery disease (Chap. 237). In particular, vasodilators as a class have not proved to be beneficial. During exercise, peripheral vasodilation occurs distal to sites of significant arterial stenoses. As a result, perfusion pressure falls, often to levels less than that generated in the interstitial tissue by the exercising muscle. Drugs such as α-adrenergic blocking agents, calcium channel antagonists, papaverine, and other vasodilators have not been shown to be effective in patients with PAD.

Cilostazol, a phosphodiesterase inhibitor with vasodilator and antiplatelet properties, increases claudication distance by 40–60% and improves measures of quality of life. The mechanism of action accounting for its beneficial effects is not known. Pentoxifylline, a substituted xanthine derivative, has been reported to decrease blood viscosity and to increase red cell flexibility, thereby increasing blood flow to the microcirculation and enhancing tissue oxygenation. Although several placebo-controlled studies have found that pentoxifylline increases the duration of exercise in patients with claudication, its efficacy has not been confirmed in all clinical trials. Statins and propionyl-L-carnitine, a drug that affects skeletal muscle metabolic function, appear promising for treatment of intermittent claudication in initial clinical trials.

Several studies have suggested that long-term parenteral administration of vasodilator prostaglandins decreases pain and facilitates healing of ulcers in patients with critical limb ischemia. Clinical trials of angiogenic growth factors are proceeding. Intramuscular gene transfer of DNA encoding vascular endothelial growth factor, basic fibroblast growth factor, hepatocyte growth factor, or hypoxia-inducible factor-1α, and also administration of endothelial progenitor cells, may promote collateral blood vessel growth in patients with critical limb ischemia. Some trial results have been negative and others encouraging. The outcome of ongoing studies will further elucidate the potential role of therapeutic angiogenesis for PAD.

Revascularization Revascularization procedures, including catheter-based and surgical interventions, are usually indicated for patients with disabling, progressive, or severe symptoms of intermittent claudication despite medical therapy, and for those with critical limb ischemia. MRA, CT, or conventional contrast angiography should be performed to assess vascular anatomy in patients who are being considered for revascularization. Nonoperative interventions include percutaneous transluminal angiography (PTA), stent placement, and atherectomy (Chap. 240). PTA and stenting of the iliac artery are associated with higher success rates than PTA and stenting of the femoral and popliteal arteries. Approximately 90–95% of iliac PTAs are initially successful, and the 3-year patency rate is >75%. Patency rates may be higher if a stent is placed in the iliac artery. The initial success rates for femoral-popliteal PTA and stenting are approximately 80%, with 60% 3-year patency rates. Patency rates are influenced by the severity of pretreatment stenoses; the prognosis of occlusive lesions is worse than that of nonocclusive stenotic lesions. The role of drug-eluting stents in PAD is currently unclear.

Several operative procedures are available for treating patients with aortoiliac and femoral-popliteal artery disease. The preferred operative procedure depends on the location and extent of the obstruction(s) and general medical condition of the patient. Operative procedures for aortoiliac disease include aortobifemoral bypass, axillofemoral bypass, femoral-femoral bypass, and aortoiliac endarterectomy. The most frequently used procedure is the aortobifemoral bypass using knitted Dacron grafts. Immediate graft patency approaches 99%, and 5- and 10-year graft patency in survivors is >90% and 80%, respectively. Operative complications include myocardial infarction and stroke, infection of the graft, peripheral embolization, and sexual dysfunction from interruption of autonomic nerves in the pelvis. Operative mortality ranges from 1–3%, mostly due to ischemic heart disease.

Operative therapy for femoral-popliteal artery disease includes in situ and reverse autogenous saphenous vein bypass grafts, placement of polytetrafluoroethylene (PTFE) or other synthetic grafts, and thromboendarterectomy. Operative mortality ranges from 1–3%. The long-term patency rate depends on the type of graft used, the location of the distal anastomosis, and the patency of runoff vessels beyond the anastomosis. Patency rates of femoral-popliteal saphenous vein bypass grafts approach 90% at 1 year and 70–80% at 5 years. Five-year patency rates of infrapopliteal saphenous vein bypass grafts are 60–70%. In contrast, 5-year patency rates of infrapopliteal PTFE grafts are <30%. Lumbar sympathectomy alone or as an adjunct to aortofemoral reconstruction has fallen into disfavor.

Preoperative cardiac risk assessment may identify individuals especially likely to experience an adverse cardiac event during the perioperative period. Patients with angina, prior myocardial infarction, ventricular ectopy, heart failure, or diabetes are among those at increased risk. Noninvasive tests, such as treadmill testing (if feasible), dipyridamole or adenosine radionuclide myocardial perfusion imaging, dobutamine echocardiography, and ambulatory ischemia monitoring permit further stratification of pa-

tient risk (Chap. 240). Patients with abnormal test results require close supervision and adjunctive management with anti-ischemic medications. β-Adrenergic blockers reduce the risk of postoperative cardiovascular complications. Coronary angiography and coronary artery revascularization are not indicated in most patients undergoing peripheral vascular surgery, but cardiac catheterization should be considered in patients with unstable angina and angina refractory to medical therapy, as well as those suspected of having left main or three-vessel coronary artery disease.

FIBROMUSCULAR DYSPLASIA

This is a hyperplastic disorder affecting medium-sized and small arteries. It occurs predominantly in females and usually involves renal and carotid arteries but can affect extremity vessels, such as the iliac and subclavian arteries. The histologic classification includes intimal fibroplasia, medial dysplasia, and adventitial hyperplasia. Medial dysplasia is subdivided into medial fibroplasia, perimedial fibroplasia, and medial hyperplasia. Medial fibroplasia is the most common type and is characterized by alternating areas of thinned media and fibromuscular ridges. The internal elastic lamina is usually preserved. The iliac arteries are the limb arteries most likely to be affected by fibromuscular dysplasia. It is identified angiographically by a "string of beads" appearance caused by thickened fibromuscular ridges contiguous with thin, less-involved portions of the arterial wall. When limb vessels are involved, clinical manifestations are similar to those for atherosclerosis, including claudication and rest pain. PTA and surgical reconstruction have been beneficial in patients with debilitating symptoms or threatened limbs.

THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans (Buerger's disease) is an inflammatory occlusive vascular disorder involving small and medium-sized arteries and veins in the distal upper and lower extremities. Cerebral, visceral, and coronary vessels may be affected rarely. This disorder develops most frequently in men <40 years. The prevalence is higher in Asians and individuals of eastern European descent. While the cause of thromboangiitis obliterans is not known, there is a definite relationship to cigarette smoking in patients with this disorder.

In the initial stages of thromboangiitis obliterans, polymorphonuclear leukocytes infiltrate the walls of the small and medium-sized arteries and veins. The internal elastic lamina is preserved, and a cellular, inflammatory, thrombus develops in the vascular lumen. As the disease progresses, mononuclear cells, fibroblasts, and giant cells replace the neutrophils. Later stages are characterized by perivascular fibrosis, organized thrombus, and recanalization.

The clinical features of thromboangiitis obliterans often include a triad of claudication of the affected extremity, Raynaud's phenomenon, and migratory superficial vein thrombophlebitis. Claudication is usually confined to the calves and feet or the forearms and hands because this disorder primarily affects distal vessels. In the presence of severe digital ischemia, trophic nail changes, painful ulcerations, and gangrene may develop at the tips of the fingers or toes. The physical examination shows normal brachial and popliteal pulses but reduced or absent radial, ulnar, and/or tibial pulses. Arteriography is helpful in making the diagnosis. Smooth, tapering segmental lesions in the distal vessels are characteristic, as are collateral vessels at sites of vascular occlusion. Proximal atherosclerotic disease is usually absent. The diagnosis can be confirmed by excisional biopsy and pathologic examination of an involved vessel.

There is no specific treatment except abstention from tobacco. The prognosis is worse in individuals who continue to smoke, but results are discouraging even in those who do stop smoking. Arterial bypass of the larger vessels may be used in selected instances, as well as local debridement, depending on the symptoms and severity of ischemia. Antibiotics may be useful; anticoagulants and glucocorticoids are not helpful. If these measures fail, amputation may be required.

VASCULITIS

Other vasculitides may affect the arteries supplying the upper and lower extremities. **Takayasu's arteritis and giant cell (temporal) arteritis are discussed in Chap. 319.**

ACUTE ARTERIAL OCCLUSION

This results in the sudden cessation of blood flow to an extremity. The severity of ischemia and the viability of the extremity depend on the location and extent of the occlusion and the presence and subsequent development of collateral blood vessels. There are two principal causes of acute arterial occlusion: embolism and thrombus in situ.

The most common sources of arterial emboli are the heart, aorta, and large arteries. Cardiac disorders that cause thromboembolism include atrial fibrillation, both chronic and paroxysmal; acute myocardial infarction; ventricular aneurysm; cardiomyopathy; infectious and marantic endocarditis; thrombi associated with prosthetic heart valves; and atrial myxoma. Emboli to the distal vessels may also originate from proximal sites of atherosclerosis and aneurysms of the aorta and large vessels. Less frequently, an arterial occlusion results paradoxically from a venous thrombus that has entered the systemic circulation via a patent foramen ovale or other septal defect. Arterial emboli tend to lodge at vessel bifurcations because the vessel caliber decreases at these sites; in the lower extremities, emboli lodge most frequently in the femoral artery, followed by the iliac artery, aorta, and popliteal and tibioperoneal arteries.

Acute arterial thrombosis in situ occurs most frequently in atherosclerotic vessels at the site of an atherosclerotic plaque or aneurysm and in arterial bypass grafts. Trauma to an artery may also result in the formation of an acute arterial thrombus. Arterial occlusion may complicate arterial punctures and placement of catheters. Less-frequent causes include thoracic outlet compression syndrome, which causes subclavian artery occlusion, and entrapment of the popliteal artery by abnormal placement of the medial head of the gastrocnemius muscle. Polycythemia and hypercoagulable disorders (Chaps. 103 and 112) are also associated with acute arterial thrombosis.

Clinical Features The symptoms of an acute arterial occlusion depend on the location, duration, and severity of the obstruction. Often, severe pain, paresthesia, numbness, and coldness develop in the involved extremity within 1 h. Paralysis may occur with severe and persistent ischemia. Physical findings include loss of pulses distal to the occlusion, cyanosis or pallor, mottling, decreased skin temperature, muscle stiffening, loss of sensation, weakness, and/or absent deep tendon reflexes. If acute arterial occlusion occurs in the presence of an adequate collateral circulation, as is often the case in acute graft occlusion, the symptoms and findings may be less impressive. In this situation, the patient complains about an abrupt decrease in the distance walked before claudication occurs or of modest pain and paresthesia. Pallor and coolness are evident, but sensory and motor functions are generally preserved. The diagnosis of acute arterial occlusion is usually apparent from the clinical presentation. Arteriography is useful for confirming the diagnosis and demonstrating the location and extent of occlusion.

℞ ACUTE ARTERIAL OCCLUSION

Once the diagnosis is made, the patient should be anticoagulated with intravenous heparin to prevent propagation of the clot. In cases of severe ischemia of recent onset, and particularly when limb viability is jeopardized, immediate intervention to ensure reperfusion is indicated. Endovascular or surgical thromboembolectomy or arterial bypass procedures are used to restore blood flow to the ischemic extremity promptly, particularly when a large proximal vessel is occluded.

Intraarterial thrombolytic therapy with recombinant tissue plasminogen activator or urokinase is often effective when acute arterial occlusion is caused by a thrombus in an atherosclerotic vessel or arterial bypass graft. Thrombolytic therapy may also be indicated when the patient's overall condition contraindicates surgical intervention or when smaller distal vessels are occluded, thus preventing surgical access. Meticulous observation for hemorrhagic complications is required during intraarterial thrombolytic therapy. Another endovascular approach for thrombus removal is percutaneous mechanical thrombectomy using devices that employ hydrodynamic forces or rotating baskets to fragment and remove the clot. These may be used alone but are usually used in conjunction with pharmacologic thrombolysis.

FIGURE 243-1 Atheroembolism causing cyanotic discoloration and impending necrosis of the toes (blue toe syndrome).

If the limb is not in jeopardy, a more conservative approach that includes observation and administration of anticoagulants may be taken. Anticoagulation prevents recurrent embolism and reduces the likelihood of thrombus propagation; it can be initiated with intravenous heparin and followed by oral warfarin. Recommended dosages are the same as those used for deep vein thrombosis (see below). Emboli resulting from infective endocarditis, the presence of prosthetic heart valves, or atrial myxoma often require surgical intervention to remove the cause.

ATHEROEMBOLISM

Atheroembolism constitutes a subset of acute arterial occlusion. In this condition, multiple small deposits of fibrin, platelets, and cholesterol debris embolize from proximal atherosclerotic lesions or aneurysmal sites. Large protruding aortic atheromas are a source of emboli that may lead to stroke and renal insufficiency as well as limb ischemia. Atheroembolism may occur after intraarterial procedures. Since the emboli tend to lodge in the small vessels of the muscle and skin and may not occlude the large vessels, distal pulses usually remain palpable. Patients complain of acute pain and tenderness at the site of embolization. Digital vascular occlusion may result in ischemia and the "blue toe" syndrome; digital necrosis and gangrene may develop (Fig. 243-1). Localized areas of tenderness, pallor, and livedo reticularis (see below) occur at sites of emboli. Skin or muscle biopsy may demonstrate cholesterol crystals.

Ischemia resulting from atheroemboli is notoriously difficult to treat. Usually neither surgical revascularization procedures nor thrombolytic therapy is helpful because of the multiplicity, composition, and distal location of the emboli. Some evidence suggests that platelet inhibitors prevent atheroembolism. Surgical intervention to remove or bypass the atherosclerotic vessel or aneurysm that causes the recurrent atheroemboli may be necessary.

THORACIC OUTLET COMPRESSION SYNDROME

This is a symptom complex resulting from compression of the neurovascular bundle (artery, vein, or nerves) at the thoracic outlet as it courses through the neck and shoulder. Cervical ribs, abnormalities of the scalenus anticus muscle, proximity of the clavicle to the first rib, or abnormal insertion of the pectoralis minor muscle may compress the subclavian artery, subclavian vein (see below), and brachial plexus as these structures pass from the thorax to the arm. Depending on the structures affected, thoracic outlet compression syndrome may be divided into arterial, venous, and neurogenic forms. Patients with neurogenic thoracic outlet compression may develop shoulder and arm pain, weakness, and paresthesias. Patients with arterial compression may experience claudication, Raynaud's phenomenon, and even ischemic tissue loss and gangrene. Venous compression may cause thrombosis of the subclavian and axillary veins; this is often associated with effort and referred to as *Paget-Schroetter syndrome*.

APPROACH TO THE PATIENT: Thoracic Outlet Compression Syndrome

Examination of the patient with thoracic outlet compression syndrome is often normal unless provocative maneuvers are performed. Occasionally, distal pulses are decreased or absent and digital cyanosis and ischemia may be evident. Tenderness may be present in the supraclavicular fossa. In patients with axillo-subclavian venous thrombosis, the affected extremity typically is swollen. Dilated collateral veins may be apparent around the shoulder and upper arm.

Several maneuvers that support the diagnosis of thoracic outlet compression syndrome may be used to precipitate symptoms, cause a subclavian artery bruit, and diminish arm pulses. These include the abduction and external rotation test, in which the affected arm is abducted by 90° and the shoulder is externally rotated; the scalene maneuver (extension of the neck and rotation of the head to the side of the symptoms); the costoclavicular maneuver (posterior rotation of shoulders); and the hyperabduction maneuver (raising the arm 180°). A chest x-ray will indicate the presence of cervical ribs. Duplex ultrasonography, MRA, and contrast angiography can be performed during provocative maneuvers to demonstrate thoracic outlet compression of the subclavian artery. Duplex ultrasography, magnetic resonance venography, or contrast venography can be used to diagnose axillo-subclavian vein thrombosis. Neurophysiologic tests such as the electromyogram, nerve conduction studies, and somatosensory evoked potentials may be abnormal if the brachial plexus is involved, but the diagnosis of neurogenic thoracic outlet syndrome is not necessarily excluded if these tests are normal owing to their low sensitivity.

℞ THORACIC OUTLET COMPRESSION SYNDROME

Most patients can be managed conservatively. They should be advised to avoid the positions that cause symptoms. Many patients benefit from shoulder girdle exercises. Surgical procedures such as removal of the first rib or resection of the scalenus anticus muscle are necessary occasionally for relief of symptoms or treatment of ischemia.

ARTERIOVENOUS FISTULA

Abnormal communications between an artery and a vein, bypassing the capillary bed, may be congenital or acquired. Congenital arteriovenous fistulas are the result of persistent embryonic vessels that fail to differentiate into arteries and veins; they may be associated with birthmarks, can be located in almost any organ of the body, and frequently occur in the extremities. Acquired arteriovenous fistulas are either created to provide vascular access for hemodialysis or occur as a result of a penetrating injury such as a gunshot or knife wound or as complications of arterial catheterization or surgical dissection. An infrequent cause of arteriovenous fistula is rupture of an arterial aneurysm into a vein.

The clinical features depend on the location and size of the fistula. Frequently, a pulsatile mass is palpable, and a thrill and bruit lasting throughout systole and diastole are present over the fistula. With long-standing fistulas, clinical manifestations of chronic venous insufficiency, including peripheral edema; large, tortuous varicose veins; and stasis pigmentation become apparent because of the high venous pressure. Evidence of ischemia may occur in the distal portion of the extremity. Skin temperature is higher over the arteriovenous fistula. Large arteriovenous fistulas may result in an increased cardiac output with consequent cardiomegaly and high-output heart failure (Chap. 227).

Diagnosis The diagnosis is often evident from the physical examination. Compression of a large arteriovenous fistula may cause reflex slowing of the heart rate (Nicoladoni-Branham sign). Duplex ultrasonography may detect an arteriovenous fistula, especially that which affects the femoral artery and vein at the site of catheter access. Comput-

ed tomographic and conventional angiography can confirm the diagnosis and are useful in demonstrating the site and size of the arteriovenous fistula.

℞ ARTERIOVENOUS FISTULA

Management of arteriovenous fistulas may involve surgery, radiotherapy, or embolization. Congenital arteriovenous fistulas are often difficult to treat because the communications may be numerous and extensive, and new ones frequently develop after ligation of the most obvious ones. Many of these lesions are best treated conservatively using elastic support hose to reduce the consequences of venous hypertension. Occasionally, embolization with autologous material, such as fat or muscle, or with hemostatic agents, such as gelatin sponges or silicon spheres, is used to obliterate the fistula. Acquired arteriovenous fistulas are usually amenable to surgical treatment that involves division or excision of the fistula. Occasionally, autogenous or synthetic grafting is necessary to reestablish continuity of the artery and vein.

RAYNAUD'S PHENOMENON

Raynaud's phenomenon is characterized by episodic digital ischemia, manifested clinically by the sequential development of digital blanching, cyanosis, and rubor of the fingers or toes following cold exposure and subsequent rewarming. Emotional stress may also precipitate Raynaud's phenomenon. The color changes are usually well demarcated and are confined to the fingers or toes. Typically, one or more digits will appear white when the patient is exposed to a cold environment or touches a cold object. The blanching, or pallor, represents the ischemic phase of the phenomenon and results from vasospasm of digital arteries. During the ischemic phase, capillaries and venules dilate, and cyanosis results from the deoxygenated blood that is present in these vessels. A sensation of cold or numbness or paresthesia of the digits often accompanies the phases of pallor and cyanosis.

With rewarming, the digital vasospasm resolves, and blood flow into the dilated arterioles and capillaries increases dramatically. This "reactive hyperemia" imparts a bright red color to the digits. In addition to rubor and warmth, patients often experience a throbbing, painful sensation during the hyperemic phase. Although the triphasic color response is typical of Raynaud's phenomenon, some patients may develop only pallor and cyanosis; others may experience only cyanosis.

Pathophysiology Raynaud originally proposed that cold-induced episodic digital ischemia was secondary to exaggerated reflex sympathetic vasoconstriction. This theory is supported by the fact that α-adrenergic blocking drugs as well as sympathectomy decrease the frequency and severity of Raynaud's phenomenon in some patients. An alternative hypothesis is that the digital vascular responsiveness to cold or to normal sympathetic stimuli is enhanced. It is also possible that normal reflex sympathetic vasoconstriction is superimposed on local digital vascular disease or that there is enhanced adrenergic neuroeffector activity.

Raynaud's phenomenon is broadly separated into two categories: the idiopathic variety, termed *Raynaud's disease*, and the secondary variety, which is associated with other disease states or known causes of vasospasm (Table 243-1).

Raynaud's Disease This appellation is applied when the secondary causes of Raynaud's phenomenon have been excluded. Over 50% of patients with Raynaud's phenomenon have Raynaud's disease. Women are affected about five times more often than men, and the age of presentation is usually between 20 and 40 years. The fingers are involved more frequently than the toes. Initial episodes may involve only one or two fingertips, but subsequent attacks may involve the entire finger and may include all the fingers. The toes are affected in 40% of patients. Although vasospasm of the toes usually occurs in patients with symptoms in the fingers, it may happen alone. Rarely, the earlobes, the tip of the nose, and the penis are involved. Raynaud's phenomenon occurs frequently in patients who also have migraine headaches or variant angina. These associations suggest that there may be a common predisposing cause for the vasospasm.

TABLE 243-1 CLASSIFICATION OF RAYNAUD'S PHENOMENON

Primary or idiopathic Raynaud's phenomenon: Raynaud's disease
Secondary Raynaud's phenomenon
Collagen vascular diseases: scleroderma, systemic lupus erythematosus, rheumatoid arthritis, dermatomyositis, polymyositis
Arterial occlusive diseases: atherosclerosis of the extremities, thromboangiitis obliterans, acute arterial occlusion, thoracic outlet syndrome
Pulmonary hypertension
Neurologic disorders: intervertebral disk disease, syringomyelia, spinal cord tumors, stroke, poliomyelitis, carpal tunnel syndrome
Blood dyscrasias: cold agglutinins, cryoglobulinemia, cryofibrinogenemia, myeloproliferative disorders, Waldenström's macroglobulinemia
Trauma: vibration injury, hammer hand syndrome, electric shock, cold injury, typing, piano playing
Drugs: ergot derivatives, methysergide, β-adrenergic receptor blockers, bleomycin, vinblastine, cisplatin

Results of physical examination are often entirely normal; the radial, ulnar, and pedal pulses are normal. The fingers and toes may be cool between attacks and may perspire excessively. Thickening and tightening of the digital subcutaneous tissue (*sclerodactyly*) develop in 10% of patients. Angiography of the digits for diagnostic purposes is not indicated.

In general, patients with Raynaud's disease appear to have the milder forms of Raynaud's phenomenon. Fewer than 1% of these patients lose a part of a digit. After the diagnosis is made, the disease improves spontaneously in approximately 15% of patients and progresses in about 30%.

Secondary Causes of Raynaud's Phenomenon Raynaud's phenomenon occurs in 80–90% of patients with systemic sclerosis (scleroderma) and is the presenting symptom in 30% (Chap. 316). It may be the only symptom of scleroderma for many years. Abnormalities of the digital vessels may contribute to the development of Raynaud's phenomenon in this disorder. Ischemic fingertip ulcers may develop and progress to gangrene and autoamputation. About 20% of patients with systemic lupus erythematosus (SLE) have Raynaud's phenomenon (Chap. 313). Occasionally, persistent digital ischemia develops and may result in ulcers or gangrene. In most severe cases, the small vessels are occluded by a proliferative endarteritis. Raynaud's phenomenon occurs in about 30% of patients with dermatomyositis or polymyositis (Chap. 383). It frequently develops in patients with rheumatoid arthritis and may be related to the intimal proliferation that occurs in the digital arteries.

Atherosclerosis of the extremities is a frequent cause of Raynaud's phenomenon in men >50 years. Thromboangiitis obliterans is an uncommon cause of Raynaud's phenomenon but should be considered in young men, particularly those who are cigarette smokers. The development of cold-induced pallor in these disorders may be confined to one or two digits of the involved extremity. Occasionally, Raynaud's phenomenon may follow acute occlusion of large and medium-sized arteries by a thrombus or embolus. Embolization of atheroembolic debris may cause digital ischemia. The latter situation often involves one or two digits and should not be confused with Raynaud's phenomenon. In patients with thoracic outlet compression syndrome, Raynaud's phenomenon may result from diminished intravascular pressure, stimulation of sympathetic fibers in the brachial plexus, or a combination of both. Raynaud's phenomenon occurs in patients with primary pulmonary hypertension (Chap. 244); this is more than coincidental and may reflect a neurohumoral abnormality that affects both the pulmonary and digital circulations.

A variety of blood dyscrasias may be associated with Raynaud's phenomenon. Cold-induced precipitation of plasma proteins, hyperviscosity, and aggregation of red cells and platelets may occur in patients with cold agglutinins, cryoglobulinemia, or cryofibrinogenemia. Hyperviscosity syndromes that accompany myeloproliferative disorders and Waldenström's macroglobulinemia should also be considered in the initial evaluation of patients with Raynaud's phenomenon.

Raynaud's phenomenon occurs often in patients whose vocations require the use of vibrating hand tools, such as chain saws or jackhammers.

The frequency of Raynaud's phenomenon also seems to be increased in pianists and keyboard operators. Electric shock injury to the hands or frostbite may lead to the later development of Raynaud's phenomenon.

Several drugs have been causally implicated in Raynaud's phenomenon. These include ergot preparations; methysergide; β-adrenergic receptor antagonists; and the chemotherapeutic agents bleomycin, vinblastine, and cisplatin.

℞ RAYNAUD'S PHENOMENON

Most patients with Raynaud's phenomenon experience only mild and infrequent episodes. These patients need reassurance and should be instructed to dress warmly and avoid unnecessary cold exposure. In addition to gloves and mittens, patients should protect the trunk, head, and feet with warm clothing to prevent cold-induced reflex vasoconstriction. Tobacco use is contraindicated.

Drug treatment should be reserved for the severe cases. Dihydropyridine calcium channel antagonists, such as nifedipine, isradipine, felodipine, and amlodipine, decrease the frequency and severity of Raynaud's phenomenon. Diltiazem may be considered but is less effective. The postsynaptic α_1-adrenergic antagonist prazosin has been used with favorable responses; doxazosin and terazosin may also be effective. Other sympatholytic agents, such as methyldopa, guanethidine, and phenoxybenzamine, may be useful in some patients, as may topical glyceryl trinitrate. Digital sympathectomy is helpful in some patients who are unresponsive to medical therapy.

ACROCYANOSIS

In this condition, there is arterial vasoconstriction and secondary dilation of the capillaries and venules with resulting persistent cyanosis of the hands and, less frequently, the feet. Cyanosis may be intensified by exposure to a cold environment. Acrocyanosis may be categorized as primary or secondary to an underlying condition. In primary acrocyanosis, women are affected much more frequently than men, and the age of onset is usually <30 years. Generally, patients are asymptomatic but seek medical attention because of the discoloration. The prognosis is favorable, and pain, ulcers, and gangrene do not occur. Examination reveals normal pulses, peripheral cyanosis, and moist palms. Trophic skin changes and ulcerations do *not* occur. The disorder can be distinguished from Raynaud's phenomenon because it is persistent and not episodic, the discoloration extends proximally from the digits, and blanching does not occur. Ischemia secondary to arterial occlusive disease can usually be excluded by the presence of normal pulses. Central cyanosis and decreased arterial oxygen saturation are not present. Patients should be reassured and advised to dress warmly and avoid cold exposure. Pharmacologic intervention is not indicated.

Secondary acrocyanosis may result from hypoxemia, connective tissue diseases, atheroembolism, antiphospholipid antibodies, cold agglutinins, or cryoglobulins, and is associated with anorexia nervosa and orthostatic tachycardia syndrome. Treatment should be directed at the underlying disorder.

LIVEDO RETICULARIS

In this condition, localized areas of the extremities develop a mottled or rete (net-like) appearance of reddish to blue discoloration. The mottled appearance may be more prominent following cold exposure. There are primary and secondary forms of livedo reticularis. The primary, or idiopathic, form of this disorder may be benign or associated with ulcerations. The benign form occurs more frequently in women than in men, and the most common age of onset is in the third decade. Patients with the benign form are usually asymptomatic and seek attention for cosmetic reasons. These patients should be reassured and advised to avoid cold environments. No drug treatment is indicated. Primary livedo reticularis with ulceration is also called *atrophie blanche en plaque*. The ulcers are painful and may take months to heal. Secondary livedo reticularis can occur with atheroembolism (see above), SLE and other vasculitides, anticardiolipin antibodies, hyperviscosity, cryoglobulinemia, and Sneddon's syndrome (ischemic stroke and livedo reticularis). Rarely, skin ulcerations develop.

PERNIO (CHILBLAINS)

This is a vasculitic disorder associated with exposure to cold; acute forms have been described. Raised erythematous lesions develop on the lower part of the legs and feet in cold weather. These are associated with pruritus and a burning sensation, and they may blister and ulcerate. Pathologic examination demonstrates angiitis characterized by intimal proliferation and perivascular infiltration of mononuclear and polymorphonuclear leukocytes. Giant cells may be present in the subcutaneous tissue. Patients should avoid exposure to cold, and ulcers should be kept clean and protected with sterile dressings. Sympatholytic drugs may be effective in some patients.

ERYTHROMELALGIA

This disorder is characterized by burning pain and erythema of the extremities. The feet are involved more frequently than the hands, and males are affected more frequently than females. Erythromelalgia may occur at any age but is most common in middle age. It may be primary (also termed erythermalgia) or secondary. The most common causes of secondary erythromelalgia are myeloproliferative disorders such as polycythemia vera and essential thrombocytosis. Less-common causes include drugs, such as calcium channel blockers, bromocriptine, and pergolide; neuropathies; connective tissue diseases, such as systemic lupus erythematosus; and paraneoplastic syndromes. Patients complain of burning in the extremities that is precipitated by exposure to a warm environment and aggravated by a dependent position. The symptoms are relieved by exposing the affected area to cool air or water or by elevation. Erythromelalgia can be distinguished from ischemia secondary to peripheral arterial disorders and peripheral neuropathy because the peripheral pulses are present and the neurologic examination is normal. There is no specific treatment; aspirin may produce relief in patients with erythromelalgia secondary to myeloproliferative disease. Treatment of associated disorders in secondary erythromelalgia may be helpful.

FROSTBITE

In this condition, tissue damage results from severe environmental cold exposure or from direct contact with a very cold object. Tissue injury results from both freezing and vasoconstriction. Frostbite usually affects the distal aspects of the extremities or exposed parts of the face, such as the ears, nose, chin, and cheeks. Superficial frostbite involves the skin and subcutaneous tissue. Patients experience pain or paresthesia, and the skin appears white and waxy. After rewarming, there is cyanosis and erythema, wheal-and-flare formation, edema, and superficial blisters. Deep frostbite involves muscle, nerves, and deeper blood vessels. It may result in edema of the hand or foot, vesicles and bullae, tissue necrosis, and gangrene.

Initial treatment is rewarming, performed in an environment where reexposure to freezing conditions will not occur. Rewarming is accomplished by immersion of the affected part in a water bath at temperatures of 40°–44°C (104°–111°F). Massage, application of ice water, and extreme heat are contraindicated. The injured area should be cleansed with soap or antiseptic and sterile dressings applied. Analgesics are often required during rewarming. Antibiotics are used if there is evidence of infection. The efficacy of sympathetic blocking drugs is not established. Following recovery, the affected extremity may exhibit increased sensitivity to cold.

DISORDERS OF THE VEINS AND LYMPHATICS

VENOUS DISORDERS

Veins in the extremities can be broadly classified as either superficial or deep. In the lower extremity, the superficial venous system includes the greater and lesser saphenous veins and their tributaries. The deep veins of the leg accompany the major arteries. Perforating veins connect the superficial and deep systems at multiple locations. Bicuspid valves are present throughout the venous system to direct the flow of venous blood centrally.

Venous Thrombosis The presence of thrombus within a superficial or deep vein and the accompanying inflammatory response in the vessel

wall is termed *venous thrombosis* or *thrombophlebitis*. Initially the thrombus is composed principally of platelets and fibrin. Red cells become interspersed with fibrin, and the thrombus tends to propagate in the direction of blood flow. The inflammatory response in the vessel wall may be minimal or characterized by granulocyte infiltration, loss of endothelium, and edema.

The factors that predispose to venous thrombosis were initially described by Virchow in 1856 and include stasis, vascular damage, and hypercoagulability. Accordingly, a variety of clinical situations are associated with increased risk of venous thrombosis (Table 243-2). Venous thrombosis may occur in >50% of patients having orthopedic surgical procedures, particularly those involving the hip or knee, and in 10–40% of patients who undergo abdominal or thoracic operations. The prevalence of venous thrombosis is particularly high in patients with cancer of the pancreas, lungs, genitourinary tract, stomach, and breast. Approximately 10–20% of patients with idiopathic deep vein thrombosis have or develop clinically overt cancer; there is no consensus on whether these individuals should be subjected to intensive diagnostic workup to search for occult malignancy.

The risk of thrombosis is increased following trauma, such as fractures of the spine, pelvis, femur, and tibia. Immobilization, regardless of the underlying disease, is a major predisposing cause of venous thrombosis. This fact may account for the relatively high incidence in patients with acute myocardial infarction or congestive heart failure. The incidence of venous thrombosis is increased during pregnancy, particularly in the third trimester and in the first month postpartum, and in individuals who use oral contraceptives, postmenopausal hormone replacement therapy, or selective estrogen receptor modulators. A variety of clinical disorders that produce systemic hypercoagulability, including resistance to activated protein C (factor V Leiden); prothrombin G20210A gene mutation; antithrombin III, protein C, and protein S deficiencies; antiphospholipid syndrome; hyperhomocysteinemia; SLE; myeloproliferative diseases; dysfibrinogenemia; and disseminated intravascular coagulation, are associated with venous thrombosis. Venulitis occurring in thromboangiitis obliterans, Behçet's syndrome, and homocystinuria may also cause venous thrombosis.

Deep Venous Thrombosis See Chapter 256.

Superficial Vein Thrombosis Thrombosis of the greater or lesser saphenous veins or their tributaries—i.e., superficial vein thrombosis—does not result in pulmonary embolism. It is associated with intravenous catheters and infusions, occurs in varicose veins, and may develop in association with deep venous thrombosis (DVT). Migrating superficial vein thrombosis is often a marker for a carcinoma and may also occur in patients with vasculitides, such as thromboangiitis obliterans. The clinical features of superficial vein thrombosis are easily distinguished from those of DVT. Patients complain of pain localized to the site of the thrombus. Examination reveals a reddened, warm, and tender cord extending along a superficial vein. The surrounding area may be red and edematous.

TABLE 243-2 CONDITIONS ASSOCIATED WITH AN INCREASED RISK FOR DEVELOPMENT OF VENOUS THROMBOSIS

Surgery
Orthopedic, thoracic, abdominal, and genitourinary procedures
Neoplasms
Pancreas, lung, ovary, testes, urinary tract, breast, stomach
Trauma
Fractures of spine, pelvis, femur, or tibia; spinal cord injuries
Immobilization
Acute myocardial infarction, congestive heart failure, stroke, postoperative convalescence
Pregnancy
Estrogen
For replacement or contraception; Selective estrogen replacement modulators
Hypercoagulable states
Resistance to activated protein C; prothrombin or 20210 A gene mutation deficiencies of antithrombin III, protein C, or protein S; antiphospholipid antibodies; myeloproliferative diseases; dysfibrinogenemia; disseminated intravascular coagulation
Venulitis
Thromboangiitis obliterans, Behçet's disease, homocysteinuria
Previous deep vein thrombosis

℞ SUPERFICIAL VEIN THROMBOSIS

Treatment is primarily supportive. Initially, patients can be placed at bed rest with leg elevation and application of warm compresses. Nonsteroidal anti-inflammatory drugs may provide analgesia but may also obscure clinical evidence of thrombus propagation. If a thrombosis of the greater saphenous vein develops in the thigh and extends toward the saphenofemoral vein junction, it is reasonable to consider anticoagulant therapy to prevent extension of the thrombus into the deep system and a possible pulmonary embolism.

Varicose Veins Varicose veins are dilated, tortuous superficial veins that result from defective structure and function of the valves of the saphenous veins, from intrinsic weakness of the vein wall, from high intraluminal pressure, or, rarely, from arteriovenous fistulas. Varicose veins can be categorized as primary or secondary. Primary varicose veins originate in the superficial system and occur two to three times as frequently in women as in men. Approximately half of patients have a family history of varicose veins. Secondary varicose veins result from deep venous insufficiency and incompetent perforating veins or from deep venous occlusion causing enlargement of superficial veins that are serving as collaterals.

Patients with venous varicosities are often concerned about the cosmetic appearance of their legs. Symptoms consist of a dull ache or pressure sensation in the legs after prolonged standing; it is relieved with leg elevation. The legs feel heavy, and mild ankle edema develops occasionally. Extensive venous varicosities may cause skin ulcerations near the ankle. Superficial venous thrombosis may be a recurring problem, and, rarely, a varicosity ruptures and bleeds. Visual inspection of the legs in the dependent position usually confirms the presence of varicose veins.

Varicose veins can usually be treated with conservative measures. Symptoms often decrease when the legs are elevated periodically, when prolonged standing is avoided, and when elastic support hose are worn. External compression stockings provide a counterbalance to the hydrostatic pressure in the veins. Ablative procedures, including sclerotherapy, endovenous radiofrequency or laser ablation, and surgery may be considered to treat varicose veins in selected patients who have persistent symptoms, suffer recurrent superficial vein thrombosis, and/or develop skin ulceration. Ablative therapy may also be indicated for cosmetic reasons. Small, symptomatic varicose veins can be treated with sclerotherapy, in which a sclerosing solution is injected into the involved varicose vein and a compression bandage is applied. Percutaneous, endovenous delivery of radiofrequency or laser energy can be used to treat incompetent greater saphenous veins. Surgical therapy usually involves ligation and stripping of the greater and lesser saphenous veins.

Chronic Venous Insufficiency Chronic venous insufficiency may result from DVT and/or valvular incompetence. Following DVT, the delicate valve leaflets become thickened and contracted so that they cannot prevent retrograde flow of blood; the vein becomes rigid and thick-walled. Although most veins recanalize after an episode of thrombosis, the large proximal veins may remain occluded. Secondary incompetence develops in distal valves because high pressures distend the vein and separate the leaflets. Primary deep venous valvular dysfunction may also occur without previous thrombosis. Patients with venous insufficiency often complain of a dull ache in the leg that worsens with prolonged standing and resolves with leg elevation. Examination demonstrates increased leg circumference, edema, and superficial varicose veins. Erythema, dermatitis, and hyperpigmentation develop along the distal aspect of the leg, and skin ulceration may occur near the me-

TABLE 243-3 CAUSES OF LYMPHEDEMA

dial and lateral malleoli. Cellulitis may be a recurring problem. Patients should be advised to avoid prolonged standing or sitting; frequent leg elevation is helpful. Graduated compression stockings should be worn during the day. These efforts should be intensified if skin ulcers develop. Ulcers should be treated with applications of wet to dry dressings or occlusive hydrocolloid dressings. Commercially available compressive dressings comprising paste with zinc oxide, calamine, glycerin, and gelatin may be applied and should be changed weekly until healing occurs. Recurrent ulceration and severe edema may be treated by surgical interruption of incompetent communicating veins. Subfascial endoscopic perforator surgery (SEPS) is a minimally invasive technique to interrupt incompetent communicating veins. Rarely, surgical valvuloplasty and bypass of venous occlusions are employed.

LYMPHATIC DISORDERS

Lymphatic capillaries are blind-ended tubes formed by a single layer of endothelial cells. The absent or widely fenestrated basement membrane of lymphatic capillaries allows access to interstitial proteins and particles. Lymphatic capillaries merge to form larger vessels that contain smooth muscle and are capable of vasomotion. Small and medium-sized lymphatic vessels empty into progressively larger channels, most of which drain into the thoracic duct. The lymphatic circulation is involved in the absorption of interstitial fluid and in the response to infection.

Lymphedema Lymphedema may be categorized as primary or secondary (Table 243-3). The prevalence of primary lymphedema is approximately 1 per 10,000 individuals. Primary lymphedema may be secondary to agenesis, hypoplasia, or obstruction of the lymphatic vessels. It may be associated with Turner's syndrome, Klinefelter's syndrome, Noonan's syndrome, yellow nail syndrome, intestinal lymphangiectasia syndrome, and lymphangiomyomatosis. Women are affected more frequently than men. There are three clinical subtypes: congenital lymphedema, which appears shortly after birth; lymphedema praecox, which has its onset at the time of puberty; and lymphedema tarda, which usually begins after age 35. Familial forms of congenital lymphedema (Milroy's disease) and lymphedema praecox (Meige's disease) may be inherited in an autosomal dominant manner with variable penetrance; autosomal or sex-linked recessive forms are less common.

Secondary lymphedema is an acquired condition resulting from damage to or obstruction of previously normal lymphatic channels (Table 243-3). Recurrent episodes of bacterial lymphangitis, usually caused by streptococci, are a very common cause of lymphedema. The most common cause of secondary lymphedema worldwide is filariasis (Chap. 211). Tumors, such as prostate cancer and lymphoma, can also obstruct lymphatic vessels. Both surgery and radiation therapy for breast carcinoma may cause lymphedema of the upper extremity. Less-common causes include tuberculosis, contact dermatitis, lymphogranuloma venereum, rheumatoid arthritis, pregnancy, and self-induced or factitious lymphedema following application of tourniquets.

Lymphedema is generally a painless condition, but patients may experience a chronic dull, heavy sensation in the leg, and most often they are concerned about the appearance of the leg. Lymphedema of the lower extremity, initially involving the foot, gradually progresses up the leg so that the entire limb becomes edematous. In the early stages, the edema is soft and pits easily with pressure. In the chronic stages, the limb has a woody texture, and the tissues become indurated and fibrotic. At this point the edema may no longer be pitting. The limb loses its normal contour, and the toes appear square. Lymphedema should be distinguished from other disorders that cause unilateral leg swelling, such as DVT and chronic venous insufficiency. In the latter condition, the edema is softer, and there is often evidence of a stasis dermatitis, hyperpigmentation, and superficial venous varicosities.

The evaluation of patients with lymphedema should include diagnostic studies to clarify the cause. Abdominal and pelvic ultrasound and CT can be used to detect obstructing lesions such as neoplasms. MRI may reveal edema in the epifascial compartment and identify lymph nodes and enlarged lymphatic channels. Lymphoscintigraphy and lymphangiography are rarely indicated, but either can be used to confirm the diagnosis or to differentiate primary from secondary lymphedema. Lymphoscintigraphy involves the injection of radioactively labeled technetium-containing colloid into the distal subcutaneous tissue of the affected extremity. In lymphangiography, contrast material is injected into a distal lymphatic vessel that has been isolated and cannulated. In primary lymphedema, lymphatic channels are absent, hypoplastic, or ectatic. In secondary lymphedema, lymphatic channels are usually dilated, and it may be possible to determine the level of obstruction.

℞ LYMPHEDEMA

Patients with lymphedema of the lower extremities must be instructed to take meticulous care of their feet to prevent recurrent lymphangitis. Skin hygiene is important, and emollients can be used to prevent drying. Prophylactic antibiotics are often helpful, and fungal infection should be treated aggressively. Patients should be encouraged to participate in physical activity; frequent leg elevation can reduce the amount of edema. Physical therapy, including massage to facilitate lymphatic drainage, may be helpful. Patients can be fitted with graduated compression hose to reduce the amount of lymphedema that develops with upright posture. Occasionally, intermittent pneumatic compression devices can be applied at home to facilitate reduction of the edema. Diuretics are contraindicated and may cause depletion of intravascular volume and metabolic abnormalities. Microsurgical lymphatico-venous anastomotic procedures have been performed to rechannel lymph flow from obstructed lymphatic vessels into the venous system.

244 Pulmonary Hypertension

Stuart Rich

Pulmonary hypertension, an abnormal elevation in pulmonary artery pressure, may be the result of left heart failure, pulmonary parenchymal or vascular disease, thromboembolism, or a combination of these factors. Whether the pulmonary hypertension arises from cardiac, pulmonary, or intrinsic vascular disease, it generally is a feature of advanced disease. Because the causes of pulmonary hypertension are so diverse, it is essential that the etiology underlying the pulmonary hypertension be clearly determined before embarking on treatment.

Cor pulmonale (Chap. 227) is a term used to indicate right ventricular (RV) enlargement secondary to any underlying cardiac or pulmonary disease. Pulmonary hypertension is the most common cause of cor pulmonale. Advanced cor pulmonale is associated with the development of RV failure.

PATHOPHYSIOLOGY

The right ventricle responds to an increase in resistance within the pulmonary circulation by increasing RV systolic pressure as necessary to preserve cardiac output. Over time, chronic changes occur in the pulmonary circulation that result in progressive remodeling of the vasculature, which can sustain or promote pulmonary hypertension even if the initiating factor is removed.

The ability of the RV to adapt to increased vascular resistance is influenced by several factors, including age and the rapidity of the development of pulmonary hypertension. For example, a large acute pulmonary thromboembolism can result in RV failure and shock, whereas chronic thromboembolic disease of equal severity may result in only mild exercise intolerance. Coexisting hypoxemia can impair the ability of the ventricle to compensate. Several studies support the concept that RV failure occurs in pulmonary hypertension when the RV myocardium becomes ischemic due to excessive demands and inadequate right ventricular coronary blood flow to the RV. The onset of clinical RV failure, usually manifest by peripheral edema, is associated with a poor outcome.

DIAGNOSIS

The most common symptom attributable to pulmonary hypertension is exertional dyspnea. Other common symptoms are fatigue, angina pectoris that may represent RV ischemia, syncope, near syncope, and peripheral edema.

The physical examination typically reveals increased jugular venous pressure, a reduced carotid pulse, and a palpable RV impulse. Most patients have an increased pulmonic component of the second heart sound, a right-sided fourth heart sound, and tricuspid regurgitation (Chap. 220). Peripheral cyanosis and/or edema tend to occur in later stages of the disease.

Laboratory Findings (Fig. 244-1) The chest x-ray generally shows enlarged central pulmonary arteries. The lung fields may or may not reveal other pathology. The electrocardiogram usually shows right axis deviation and RV hypertrophy. The echocardiogram commonly demonstrates RV and right atrial enlargement, a reduction in left ventricular (LV) cavity size, and a tricuspid regurgitant jet that can be used to estimate RV systolic pressure. Pulmonary function tests are helpful in documenting underlying obstructive airways disease, whereas high-resolution chest CT is preferred to diagnose restrictive lung disease. Hypoxemia and an abnormal diffusing capacity for carbon monoxide are common features of pulmonary hypertension of many causes. A perfusion lung scan is almost always abnormal in patients with thromboembolic pulmonary hypertension (Chap. 256). However, diffuse defects of a nonsegmental nature can often be seen in long-standing pulmonary hypertension in the absence of thromboemboli. Laboratory tests should include antinuclear antibody and HIV testing. Because of the high frequency of thyroid abnormalities in patients with idiopathic pulmonary hypertension, it is recommended that the thyroid-stimulating hormone level be determined periodically.

Cardiac Catheterization This procedure is mandatory for accurate measurement of pulmonary artery pressure, cardiac output, and LV filling pressure, as well as for exclusion of an underlying cardiac shunt. Care should be taken to measure pressures only at end expiration. It is also recommended that patients with pulmonary arterial hypertension undergo drug testing with a short-acting pulmonary vasodilator at the time of cardiac catheterization to determine the extent of pulmonary vasodilator reactivity (Fig. 244-2). Inhaled nitric oxide, intravenous adenosine, and intravenous epoprostenol appear to have comparable effects in reducing pulmonary artery pressure acutely. Nitric oxide is administered via inhalation in 10–20 parts per million. Adenosine is given in doses of 50 μg/kg per min and increased every 2 min until side effects develop. Epoprostenol is given in doses of 2 ng/kg per min and increased every 30 min until side effects develop. Patients who respond can often be treated with calcium channel blockers and have a more favorable prognosis.

PULMONARY ARTERIAL HYPERTENSION

There are many causes of pulmonary arterial hypertension (PAH) (Table 244-1). Patients with PAH share a common histopathology characterized by medial hypertrophy, eccentric and concentric intimal fibrosis, recanalized thrombi appearing as fibrous webs, and plexiform lesions.

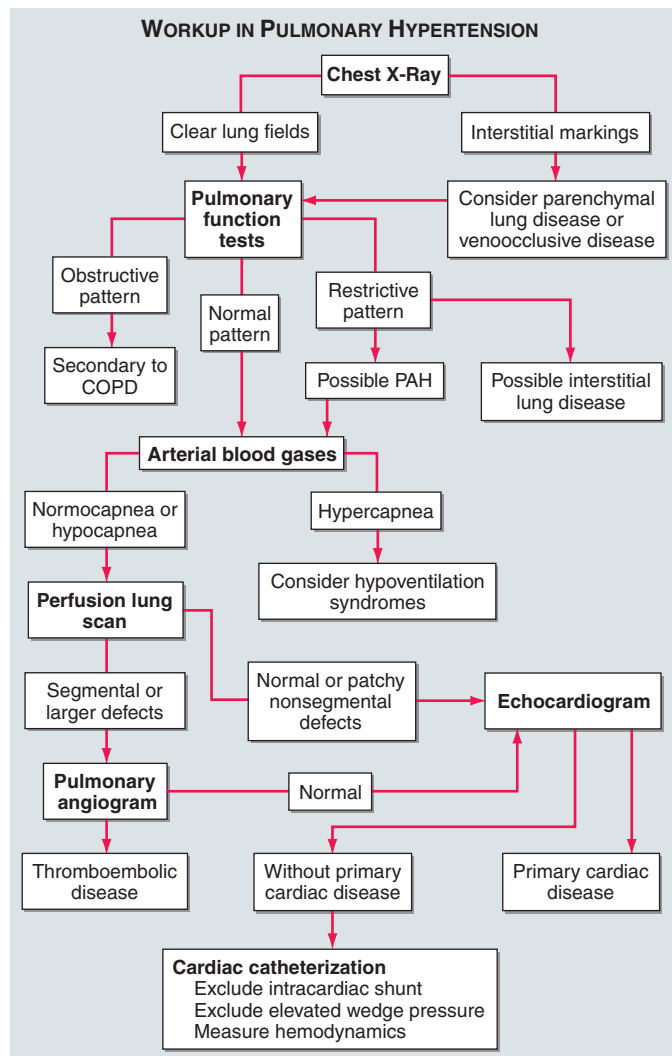

FIGURE 244-1 An algorithm for the workup of a patient with unexplained pulmonary hypertension. *(Adapted with permission from Rich.)*

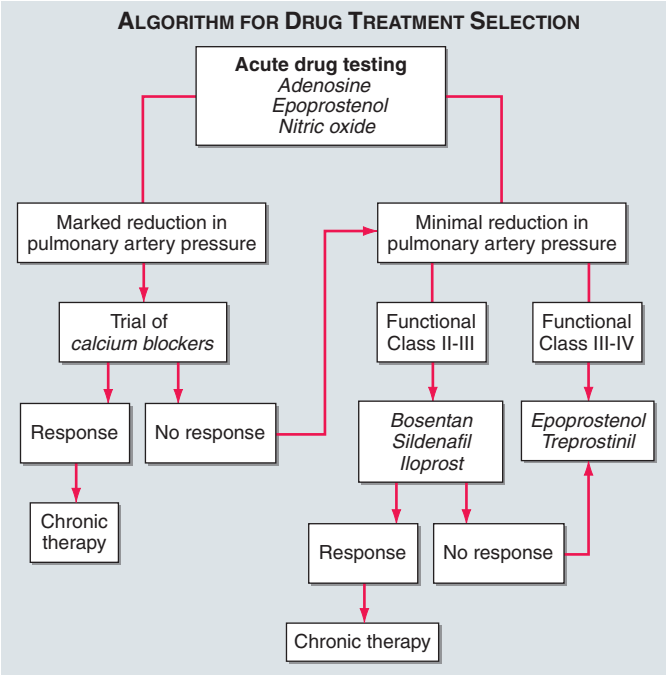

FIGURE 244-2 An algorithm for the selection of optimal drug treatment of a patient with pulmonary arterial hypertension. A marked reduction in pulmonary artery pressure from acute vasodilator testing is defined as a fall in mean pulmonary artery pressure (MPAP) ≥ 10 mmHg and a final MPAP that is <40 mmHg. *(Adapted with permission from Rich.)*

PATHOBIOLOGY

Abnormalities in molecular pathways regulating the pulmonary vascular endothelial and smooth-muscle cells have been described as underlying PAH. These include inhibition of the voltage-regulated potassium channel, mutations in the bone morphogenetic protein-2 receptor, increased serotonin uptake in the smooth-muscle cells, increased angiopoietin expression in the smooth-muscle cells, and excessive thrombin deposition related to a procoagulant state. As a result there appears to be loss of apoptosis of the smooth-muscle cells allowing their proliferation, and the emergence of apoptosis-resistant endothelial cells which can obliterate the vascular lumen.

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

Idiopathic pulmonary arterial hypertension (IPAH), formerly referred to as primary pulmonary hypertension is uncommon, with an estimated incidence of two cases per million. There is a strong female predominance, with most patients presenting in the fourth and fifth decades, although the age range is from infancy to >60 years.

Familial IPAH accounts for up to 20% of cases of IPAH and is characterized by autosomal dominant inheritance, variable age of onset, and incomplete penetrance. The clinical and pathologic features of familial and sporadic IPAH are identical. Heterozygous germline mutations that involve the gene coding the type II bone morphogenetic protein receptor (BMPR II), a member of the transforming growth factor (TGF)β superfamily, appear to account for most cases of familial IPAH. The TGF-β superfamily comprise multifunctional proteins that initiate diverse cellular responses by binding to and activating serine/threonine kinase receptors. The low gene penetrance suggests that other risk factors or abnormalities are necessary to manifest clinical disease. Germline mutations in the activin-like kinase gene and endoglin gene, which have been linked to hereditary hemorrhagic telangiectasia (HHT) have been described to coexist in some patients with familial IPAH (Fig. 244-3).

NATURAL HISTORY

The natural history of IPAH is uncertain, and because the predominant symptom is dyspnea, which can have an insidious onset, the disease is typically diagnosed late in its course. Prior to current therapies, a mean survival of 2–3 years from the time of diagnosis was reported. Functional class remains a strong predictor of survival, with patients who are in New York Heart Association (NYHA) functional class IV having a mean survival of <6 months. The cause of death is usually RV failure, which is manifest by progressive hypoxemia, tachycardia, hypotension, and edema.

PULMONARY ARTERIAL HYPERTENSION

Pulmonary arterial hypertension (PAH) refers to a variety of diseases, which includes idiopathic (I)PAH, as noted in Table 244-1. The regulatory authorities have approved several treatments for PAH (reviewed below) without making a distinction between the different types. However, physicians need to be mindful that the efficacy and side effects of these drugs might not be the same in all types of PAH (Fig. 244-4). Because the pulmonary artery pressure in PAH increases dramatically with exercise, patients should be cautioned against participating in activities that demand increased physical stress. Diuretic therapy relieves peripheral edema and may be useful in reducing RV volume overload in the presence of tricuspid regurgitation. Resting and exercise pulse oximetry should be obtained, as O_2 supplementation helps to alleviate dyspnea and RV ischemia in patients whose arterial O_2 saturation is reduced. Anticoagulant therapy is advocated for all patients with PAH based on retrospective and prospective studies demonstrating that warfarin increases survival of patients with PAH. The dose of warfarin is generally titrated to achieve an INR of 2–3 times control.

CALCIUM CHANNEL BLOCKERS Patients who have substantial reductions in pulmonary arterial pressure in response to short-acting vasodilators at the time of cardiac catheterization (a fall in mean pulmonary arterial pressure ≥10 mmHg and a final mean pressure <40 mmHg) should be treated initially with calcium channel blockers. Typically, patients require high doses (e.g., nifedipine, 240 mg/d, or amlodipine, 20 mg/d). Patients who respond favorably usually have dramatic reductions in pulmonary artery pressure and

TABLE 244-1 CLINICAL CLASSIFICATION OF PULMONARY HYPERTENSION

1. Pulmonary arterial hypertension (PAH)
- 1.1. Idiopathic (IPAH) (formerly PPH)
- 1.2. Familial (FPAH)
- 1.3. Associated with (APAH):
- 1.3.1. Collagen vascular disease
- 1.3.2. Congenital systemic-to-pulmonary shunts
- 1.3.3. Portal hypertension
- 1.3.4. HIV infection
- 1.3.5. Drugs and toxins
- 1.3.6. Other (thyroid disorders, glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy)
- 1.4. Associated with significant venous or capillary involvement
- 1.4.1. Pulmonary veno-occlusive disease (PVOD)
- 1.4.2. Pulmonary capillary hemangiomatosis (PCH)
- 1.5. Persistent pulmonary hypertension of the newborn

2. Pulmonary hypertension with left heart disease
- 2.1. Left-sided atrial or ventricular heart disease
- 2.2. Left-sided valvular heart disease

3. Pulmonary hypertension associated with lung diseases and/or hypoxemia
- 3.1. Chronic obstructive pulmonary disease
- 3.2. Interstitial lung disease
- 3.3. Sleep-disordered breathing
- 3.4. Alveolar hypoventilation disorders
- 3.5. Chronic exposure to high altitude
- 3.6. Developmental abnormalities

4. Pulmonary hypertension due to chronic thrombotic and/or embolic disease
- 4.1. Thromboembolic obstruction of proximal pulmonary arteries
- 4.2. Thromboembolic obstruction of distal pulmonary arteries
- 4.3. Nonthrombotic pulmonary embolism (tumor, parasites, foreign material)

5. Miscellaneous
- Sarcoidosis, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

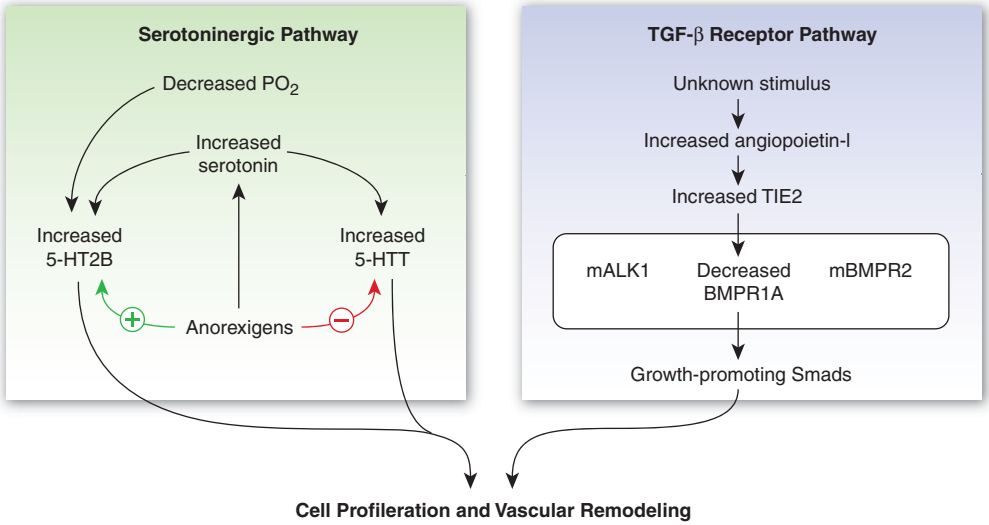

FIGURE 244-3 Mechanistic pathways promoting pulmonary arterial hypertension (PAH). External stimuli, such as hypoxia or anorexigens, can stimulate a serotoninergic pathway which, in concert with internal stimuli involving the TGF-β receptor pathway can produce PAH. 5-HT2B, serotonin receptor; 5-HTT, serotonin transporter; TGF-β, transforming growth factor β; TIE2, angiopoietein-1 receptor; BMPR1A, bone morphogenetic protein receptor 1A; mBMPR2, mutant form of bone morphogenetic protein receptor 2; mALK1, activin-receptor-like kinase. (*From Farber and Loscalzo, with permission.*)

pulmonary vascular resistance associated with improved symptoms, regression of RV hypertrophy, and improved survival now documented to exceed 20 years. However, <20% of patients respond to calcium channel blockers in the long term. These drugs should not be given to patients who are unresponsive, as they can result in hypotension, hypoxemia, tachycardia, and worsening right heart failure. These agents have not been approved for the treatment of PAH by the U.S. Food and Drug Administration.

ENDOTHELIN RECEPTOR ANTAGONISTS The nonselective endothelin receptor antagonist *bosentan* is an approved treatment of PAH for patients who are NYHA functional classes III and IV. In randomized clinical trials, bosentan improved symptoms and exercise tolerance as measured by an increase in 6-min walking distance. Therapy is initiated at 62.5 mg bid for the first month and then increased to 125 mg bid thereafter. Because of the high frequency of abnormal hepatic function tests associated with drug use, primarily an increase in transaminases, it is recommended that liver function be monitored monthly throughout the duration of use. Bosentan is also contraindicated in patients who are on cyclosporine or glyburide concurrently.

PHOSPHODIESTERASE-5 INHIBITORS *Sildenafil*, a phosphodiesterase-5 inhibitor, is approved for the treatment of PAH patients who are NYHA functional classes II and III. Phosphodiesterase-5 is responsible for the hydrolysis of cyclic GMP in pulmonary vascular smooth muscle, the mediator through which nitric oxide lowers pulmonary artery pressure and inhibits pulmonary vascular growth. Randomized clinical trials have shown that sildenafil improves symptoms and exercise tolerance in PAH. The recommended dose is 20 mg tid. The most common side effect is headache. Sildenafil should not be given to patients who are taking nitrate compounds.

PROSTACYCLINS *Iloprost*, a prostacyclin analogue, is approved via inhalation for PAH patients who are NYHA functional classes III and IV. It has been shown to improve symptoms and exercise tolerance. Therapy can be given at either 2.5 or 5 mcg per inhalation treatment. The inhaler must be given by a dedicated nebulizer. The most common side effects are flushing and cough. Because of the very short half-life (<30 min) it is recommended to administer treatments as often as every 2 h.

Epoprostenol is approved for the treatment of PAH patients who are NYHA functional class III or IV. Clinical trials have demonstrated an improve-

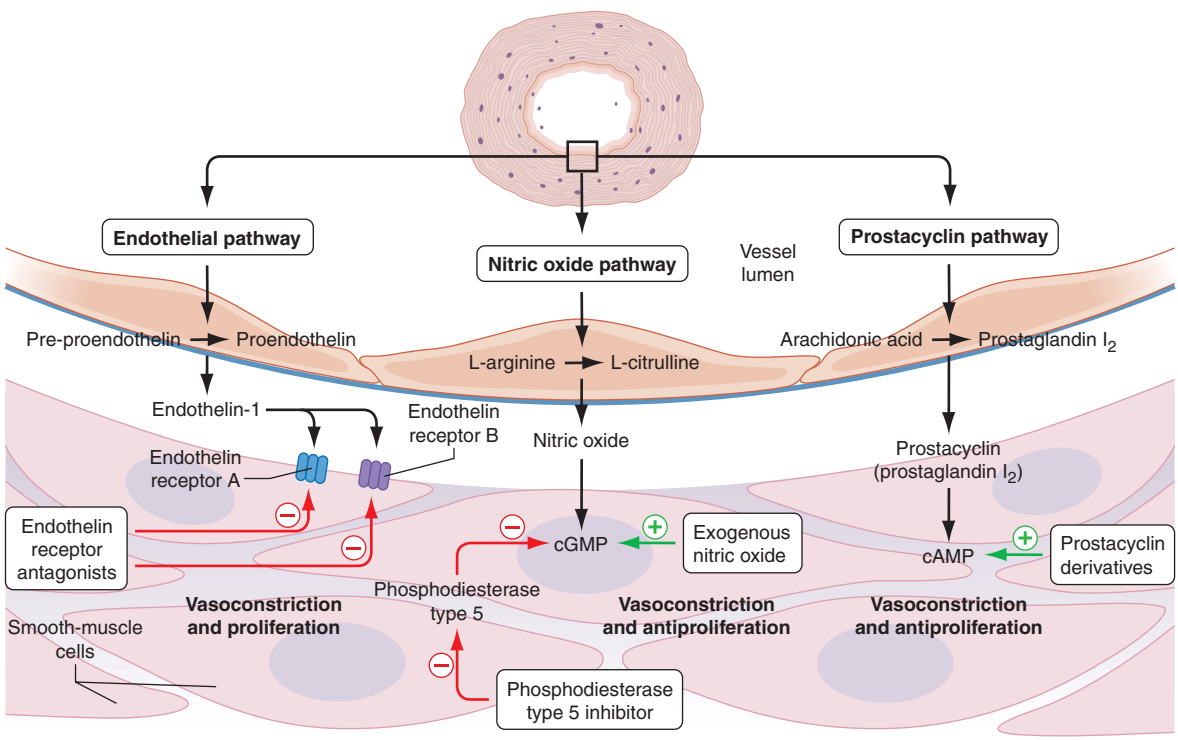

FIGURE 244-4 Current therapies target multiple growth factor pathways that appear to be involved in the pathogenesis of PAH. Whether treating multiple pathways simultaneously will yield better results is unknown. *(From Humbert et al., with permission.)*

ment in symptoms, exercise tolerance, and survival even if no acute hemodynamic response to drug challenge occurs. The drug is administered intravenously and requires placement of a permanent central venous catheter and infusion through an ambulatory infusion pump system. Side effects include flushing, jaw pain, and diarrhea, which are generally tolerated by most patients.

Treprostinil, an analogue of epoprostenol, is approved for patients with PAH who are NYHA functional classes II–IV. Treprostinil has a longer half-life than epoprostenol (4 h), is stable at room temperature, and may be given intravenously or subcutaneously through a small infusion pump that was originally developed for insulin. Clinical trials have demonstrated an improvement in symptoms and exercise capacity. The major problem with the subcutaneous administration has been local pain at the infusion site, which has caused many patients to discontinue therapy. Side effects are similar to those seen with epoprostenol.

The intravenous prostacyclins have the greatest efficacy as treatments for PAH, and are often effective in patients who have failed all other treatments. Favorable properties include vasodilation, platelet inhibition, inhibition of vascular smooth-muscle growth, and inotropic effects. It generally takes several months to titrate the dose of epoprostenol or treprostinil upwards to optimal clinical efficacy, which can be determined by symptoms, exercise testing, and catheterization. The optimal doses of these drugs have not been determined, but the typical doses of epoprostenol range from 25 to 40 ng/kg/min, and from 50 to 100 ng/kg/min for treprostinil. The major problem with intravenous therapy is infection related to the venous catheter, which requires close monitoring and diligence on behalf of the patient.

Although most clinical trials have focused on patients with advanced symptoms, it is recommended that every patient diagnosed with PAH be treated (Fig. 244-2). While no treatment has been demonstrated to be superior as first-line therapy, patients often prefer to initiate their treatment with an oral or inhaled form of therapy. In the trials using bosentan, sildenafil, and iloprost, full clinical benefit was generally manifest within the first 2 months of therapy. Patients who fail to adequately improve should have the treatment discontinued and started on a different therapy. Equally important is that delaying a more effective treatment may allow the disease to progress and become less responsive. The use of these drugs in combination has become popular, but there are no randomized clinical trials demonstrating beneficial effects in combination.

LUNG TRANSPLANTATION (See also Chap. 260) Lung transplantation is considered for patients who, while on an intravenous prostacyclin, continue to manifest right heart failure. Acceptable results have been achieved with heart-lung, bilateral lung, and single-lung transplant. The availability of donor organs often influences the choice of procedure.

CONDITIONS ASSOCIATED WITH PULMONARY HYPERTENSION

COLLAGEN VASCULAR DISEASE

All of the collagen vascular diseases may be associated with PAH. This complication occurs commonly with the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal involvement, sclerodactyly, and telangiectasia) and in scleroderma (Chap. 316), and less frequently in systemic lupus erythematosus (Chap. 313), Sjögren's syndrome (Chap. 317), dermatomyositis, polymyositis (Chap. 319), and rheumatoid arthritis (Chap. 314). It is usual for these patients to have some element of coexistent interstitial pulmonary fibrosis even though it may not be apparent on chest x-ray, CT, or pulmonary function tests. Consequently, these patients tend to have hypoxemia as an important clinical feature, along with the other classic findings of pulmonary hypertension.

Treatment of these patients is identical to that of patients with IPAH (see above) but is less effective. The treatment of the pulmonary hypertension, however, does not affect the natural history of the underlying collagen vascular disease.

CONGENITAL SYSTEMIC TO PULMONARY SHUNTS

It is common for large post-tricuspid cardiac shunts (e.g., ventricular septal defect, patent ductus arteriosus) to produce severe PAH (Chap. 229). Although less common, it may also occur in pre-tricuspid shunts (e.g., atrial septal defect, anomalous pulmonary venous drainage). In patients with uncorrected shunts, the clinical features include those associated with right-to-left shunting such as hypoxemia and peripheral cyanosis, which worsen dramatically with exertion (Chap. 35). PAH may occur years or even decades after surgical correction of these lesions, in which case there will be no associated right-to-left shunting. These patients present similarly to patients with IPAH but tend to have better long-term survival. The treatments are similar to those for IPAH.

PORTAL HYPERTENSION

Portal hypertension is associated with PAH, but the mechanism remains unknown. Patients with advanced cirrhosis can have the combined features of a high-output cardiac state in association with the features of pulmonary hypertension and RV failure. Thus, a normal cardiac output may actually reflect a marked impairment of RV function. The etiology of ascites and edema can be confusing in these patients since it can have both cardiac and hepatic causes. Patients with mild pulmonary hypertension who have a favorable response to epoprostenol have undergone successful liver transplantation with improvement of the pulmonary vascular disease.

ANOREXIGENS

A causal relationship has been established between exposure to several anorexigens, including aminorex and the fenfluramines, and the development of PAH. Often the pulmonary hypertension will not develop until years after the last exposure. While the clinical features are identical to those of IPAH, the patients appear to be less responsive to medical treatments and have a poorer prognosis.

PULMONARY VENOOCCLUSIVE DISEASE

Pulmonary venoocclusive disease is a rare and distinct pathologic entity found in <10% of patients who present with unexplained pulmonary hypertension. Histologically it is manifest by intimal proliferation and fibrosis of the intrapulmonary veins and venules, occasionally extending to the arteriolar bed. The pulmonary venous obstruction explains the increase in pulmonary capillary wedge pressure observed in patients with advanced disease. These patients may develop orthopnea that can mimic LV failure. The therapy of this condition is not established.

PULMONARY CAPILLARY HEMANGIOMATOSIS

Pulmonary capillary hemangiomatosis is a very rare form of pulmonary hypertension. Histologically it is characterized by the presence of infiltrating thin-walled blood vessels throughout the pulmonary interstitium and walls of the pulmonary arteries and veins. The presenting symptoms are usually those of IPAH but often with hemoptysis as a clinical feature. The diagnosis can be made with pulmonary angiography. The clinical course is usually one of progressive deterioration leading to death. There is no established therapy.

PULMONARY VENOUS HYPERTENSION

Pulmonary hypertension occurs as a result of increased resistance to pulmonary venous drainage. It is often associated with diastolic dysfunction of the left ventricle; diseases affecting the pericardium or mitral or aortic valves; or rare entities such as cor triatriatum, left atrial myxoma, extrinsic compression of the central pulmonary veins from fibrosing mediastinitis, and pulmonary venoocclusive disease. Pulmonary venous hypertension affects the pulmonary veins and venules, producing arterialization of the external elastic lamina, medial hypertrophy, and focal eccentric intimal fibrosis. Microcirculatory lesions include capillary congestion, focal alveolar edema, and dilatation of the interstitial lymphatics. Although these lesions are potentially reversible, regression may take years after the underlying cause is removed. In some patients pulmonary venous hypertension triggers reactive vasoconstriction in the pulmonary arterial bed and results in proliferative changes of the intima and media that can produce severe elevations in pulmonary artery pressure. Clinically it may be confusing and appear as if two separate disease processes are occurring simultaneously. The

distinction is important, however, as treatments that are effective in PAH may make patients with pulmonary venous hypertension worse.

LEFT VENTRICULAR DIASTOLIC DYSFUNCTION

Pulmonary hypertension as a result of LV diastolic failure is common but often unrecognized (Chap. 227). It can occur with or without LV systolic failure. The most common causes are hypertensive heart disease; coronary artery disease; or impaired LV compliance related to age, diabetes, obesity, and hypoxemia. Symptoms of orthopnea and paroxysmal nocturnal dyspnea are prominent. Many patients improve considerably if LV end-diastolic pressure is lowered.

MITRAL VALVE DISEASE

Mitral stenosis and mitral regurgitation represent important causes of pulmonary hypertension (Chap. 230). These patients often have reactive pulmonary vasoconstriction resulting in marked elevations in pulmonary artery pressures. An echocardiogram usually shows abnormalities such as thickened mitral valve leaflets with reduced mobility or severe mitral regurgitation documented by Doppler echocardiography (Chap. 222). At cardiac catheterization, a pressure gradient between the pulmonary capillary wedge pressure and LV end-diastolic pressure is diagnostic of mitral stenosis.

In patients with mitral stenosis, corrective surgery of the mitral valve or mitral balloon valvuloplasty predictably results in a reduction in pulmonary artery pressure and pulmonary vascular resistance. Patients with mitral regurgitation, however, may not have as dramatic a response from surgery due to persistent elevations in LV end-diastolic pressure.

PULMONARY HYPERTENSION ASSOCIATED WITH LUNG DISEASE AND HYPOXEMIA

The mechanism of hypoxic pulmonary vasoconstriction involves the inhibition of potassium currents and membrane depolarization of pulmonary vascular smooth muscle as a result of the change in membrane sulfhydryl redox status. Increased calcium entry into the vascular smooth-muscle cells mediates hypoxic pulmonary vasoconstriction. Pulmonary vascular remodeling in response to chronic hypoxia is also mediated by a reduction in nitric oxide production; an increase in endothelin 1; and increased expression of platelet-derived growth factors, vascular endothelial growth factor, and angiotensin II. Chronic hypoxia results in muscularization of the arterioles with minimal effects on the intima. When it occurs as an isolated entity, the changes produced are potentially reversible.

Although chronic hypoxia is an established cause of pulmonary hypertension, it rarely leads to an increase in the systolic pulmonary artery pressure >50 mmHg. Polycythemia in response to the hypoxemia is a characteristic finding. Hypoxia may also occur in conjunction with other causes of pulmonary hypertension associated with more extensive vascular changes. Clinically, the hypoxia tends to have an added adverse effect. Patients with chronic hypoxia who have a marked elevation in pulmonary pressure should be evaluated for other causes of the pulmonary hypertension.

CHRONIC OBSTRUCTIVE LUNG DISEASE

Chronic obstructive lung disease (COLD) is associated with mild pulmonary hypertension in the advanced stages (Chap. 254). Pulmonary hypertension has been attributed to multiple factors, including hypoxic pulmonary vasoconstriction, acidemia, hypercapnia, the mechanical effects of high lung volume on pulmonary vessels, the loss of small vessels in the vascular bed, and regions of emphysematous lung destruction.

The presence of pulmonary hypertension in patients with COLD confers a worse outcome. The only effective therapy is supplemental oxygen. Several large clinical trials have documented that continuous oxygen therapy relieves some of the pulmonary vasoconstriction, relieves chronic ischemia throughout the systemic and pulmonary vascular beds, and improves survival. Long-term oxygen therapy is indicated if the resting arterial P_{O_2} remains <55 mmHg.

INTERSTITIAL LUNG DISEASE

Pulmonary hypertension from interstitial lung disease is often associated with obliteration of the pulmonary vascular bed by lung destruction and fibrosis (Chap. 255). In addition, hypoxemia and pulmonary vasculopathy can be contributory factors. Interstitial lung disease is often associated with the collagen vascular diseases. A large number of patients have pulmonary fibrosis of unknown etiology. Patients are commonly older than 50 years and report an insidious onset of progressive dyspnea and cough for months to years. It is uncommon for the mean pulmonary artery pressure to exceed 40 mmHg. While none of the medical treatments developed for PAH have been shown to be effective in these patients, their use may worsen the hypoxemia.

SLEEP-DISORDERED BREATHING

The incidence of pulmonary hypertension in the setting of *obstructive sleep apnea*, a common condition (Chap. 259), appears to be <20% and is generally mild. Some patients, however, present with severe pulmonary hypertension in conjunction with sleep apnea, which may or may not be related. It is recommended that the sleep apnea and the PAH be treated as coexisting problems.

ALVEOLAR HYPOVENTILATION

Pulmonary hypertension can occur in patients with chronic hypoventilation and hypoxia secondary to thoracovertebral deformities. Symptoms are slowly progressive and related to hypoxemia (Chap. 258). In patients with advanced disease, intermittent positive-pressure breathing and supplemental oxygen have been used successfully.

Pulmonary hypertension secondary to hypoxemia has been reported in patients with neuromuscular disease as a result of generalized weakness of the respiratory muscles and in patients with diaphragmatic paralysis, generally a result of trauma to the phrenic nerve. Patients with nontraumatic bilateral diaphragmatic paralysis may go unrecognized until they present with either respiratory failure or pulmonary hypertension.

PULMONARY HYPERTENSION DUE TO THROMBOEMBOLIC DISEASE

ACUTE PULMONARY THROMBOEMBOLISM

See Chap. 256.

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Patients appropriately treated for acute pulmonary thromboembolism with intravenous heparin and chronic oral warfarin therapy usually do not develop chronic pulmonary hypertension. However, some patients have impaired fibrinolytic resolution of the thromboembolism, which leads to organization and incomplete recanalization and chronic obstruction of the pulmonary vascular bed. The entity of chronic thromboembolic pulmonary hypertension has been well characterized and often mimics PAH. In many patients, the initial pulmonary thromboembolism was undetected or untreated. Many of these patients have underlying thrombophilic disorders, such as the lupus anticoagulant/anticardiolipin antibody syndrome, prothrombin gene mutation, or Factor V Leiden (Chap. 111).

Diagnosis The physical examination is typical of pulmonary hypertension but may include bruits heard over areas of the lung, representing blood flow through vessels with partial occlusion. A perfusion lung scan or contrast-enhanced spiral CT scan usually reveals multiple thromboemboli. However, pulmonary angiography is necessary to determine the precise location and proximal extent of the thromboemboli, and hence the potential for operability.

Rx CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

Pulmonary thromboendarterectomy is an established surgical treatment in patients whose thrombi are accessible to surgical removal. The operative mortality is fairly high, at ~12% in experienced centers. Postoperative survi-

vors who have a good result can expect to realize an improvement in functional class and exercise tolerance. Lifelong anticoagulation using warfarin is mandatory. Thrombolytic therapy is rarely of help in patients with chronic thromboembolic pulmonary hypertension and may expose these patients to the increased risk of bleeding without potential benefit.

SICKLE CELL DISEASE

Cardiovascular system abnormalities are prominent in the clinical spectrum of sickle cell disease, including pulmonary hypertension. The etiology is multifactorial, including hemolysis, impaired nitric oxide bioavailability, hypoxemia, thromboembolism, chronic high cardiac output, and chronic liver disease. Regardless of the mechanism(s), the presence of pulmonary hypertension in patients with sickle cell disease is associated with a higher morbidity and mortality. Intensification of sickle cell disease–specific therapy appears to reduce the morbidity. The use of drugs to treat pulmonary hypertension is under clinical trials, but their efficacy remains unknown.

OTHER DISORDERS DIRECTLY AFFECTING PULMONARY VASCULATURE

SARCOIDOSIS

Sarcoidosis can produce severe pulmonary hypertension as a result of chronic severe fibrocystic lung involvement (Chap. 322), or direct cardiovascular involvement. Consequently, patients with sarcoidosis who present with progressive dyspnea and clinical features of pulmonary hypertension need a thorough evaluation. There is a subset of patients with sarcoidosis who present with severe pulmonary hypertension believed to be due to direct pulmonary vascular involvement. Many of these patients exhibit a favorable response to intravenous epoprostenol therapy.

SCHISTOSOMIASIS

Although extremely rare in North America, schistosomiasis is the most common cause of pulmonary hypertension worldwide (Chap. 212). The development of pulmonary hypertension often occurs in the setting of hepatosplenic disease and portal hypertension. Schistosome ova can embolize from the liver to the lungs, where they result in an inflammatory pulmonary vascular reaction and chronic changes. The diagnosis is confirmed by finding the parasite ova in the urine or stools of patients with symptoms, which can be difficult. The efficacy of therapies directed toward pulmonary hypertension in these patients is unknown.

HIV INFECTION

The mechanism by which HIV infection produces pulmonary hypertension remains unknown (Chap. 182). Although it is uncommon for HIV infection to result in pulmonary hypertension, the marked rise in the prevalence of HIV infection worldwide could have a significant impact on the frequency that these entities are seen in combination. The evaluation and treatments are identical to those for IPAH. Treatment of the HIV infection does not appear to affect the severity or natural history of the underlying pulmonary hypertension.

SECTION 1 DIAGNOSIS OF RESPIRATORY DISORDERS

245 Approach to the Patient with Disease of the Respiratory System

David A. Lipson, Steven E. Weinberger

Patients with disease of the respiratory system generally present because of symptoms, an abnormality on a chest radiograph, or both. These findings often lead to a set of diagnostic possibilities; the differential diagnosis is then refined on the basis of additional information gleaned from the history and physical examination, pulmonary function testing, additional imaging studies, and bronchoscopic examination. This chapter will consider the approach to the patient based on the major patterns of presentation, focusing on the history, the physical examination, and the chest radiograph. **For further discussion of pulmonary function testing, see Chap. 246, and of other diagnostic studies, see Chap. 247.**

CLINICAL PRESENTATION

History

Dyspnea (shortness of breath) and cough are nonspecific but common presenting symptoms for patients with respiratory system disease. Less common symptoms include hemoptysis (the coughing up of blood) and chest pain that often is pleuritic in nature.

DYSPNEA (See also Chap. 33) When evaluating a patient with shortness of breath, one should first determine the time course over which the symptom has become manifest. Patients who were well previously and developed *acute* shortness of breath (over a period of minutes to days) may have acute disease affecting either the upper or the intrathoracic airways (e.g., laryngeal edema or acute asthma, respectively), the pulmonary parenchyma (acute cardiogenic or noncardiogenic pulmonary edema or an acute infectious process such as a bacterial pneumonia), the pleural space (a pneumothorax), or the pulmonary vasculature (a pulmonary embolus). A *subacute* presentation (over days to weeks) can suggest an exacerbation of preexisting airways disease (asthma or chronic bronchitis), an indolent parenchymal infection (*Pneumocystis jiroveci* pneumonia in a patient with AIDS, mycobacterial or fungal pneumonia), a noninfectious inflammatory process that proceeds at a relatively slow pace (Wegener's granulomatosis, eosinophilic pneumonia, cryptogenic organizing pneumonia, and many others), neuromuscular disease (Guillain-Barré syndrome, myasthenia gravis), pleural disease (pleural effusion from a variety of possible causes), or chronic cardiac disease (congestive heart failure). A *chronic* presentation (over months to years) often indicates chronic obstructive lung disease, chronic interstitial lung disease, or chronic cardiac disease. Chronic diseases of airways (not only chronic obstructive lung disease but also asthma) are characterized by exacerbations and remissions. Patients often have periods when they are severely limited by shortness of breath, but these may be interspersed with periods in which symptoms are minimal or absent. In contrast, many of the diseases of the pulmonary parenchyma are characterized by slow but inexorable progression. Chronic respiratory symptoms may also be multifactorial in nature, as patients with chronic obstructive pulmonary disease may also have concomitant heart disease.

OTHER RESPIRATORY SYMPTOMS *Cough* (Chap. 34) may indicate the presence of lung disease, but cough per se is not useful for the differential diagnosis. The presence of sputum accompanying the cough often suggests airway disease and may be seen in asthma, chronic bronchitis, or bronchiectasis.

Hemoptysis (Chap. 34) can originate from disease of the airways, the pulmonary parenchyma, or the vasculature. Diseases of the airways can be inflammatory (acute or chronic bronchitis, bronchiectasis, or cystic fibrosis) or neoplastic (bronchogenic carcinoma or bronchial carcinoid tumors). Parenchymal diseases causing hemoptysis may be either localized (pneumonia, lung abscess, tuberculosis, or infection with *Aspergillus*) or diffuse (Goodpasture's syndrome, idiopathic pulmonary hemosiderosis). Vascular diseases potentially associated with hemoptysis include pulmonary thromboembolic disease and pulmonary arteriovenous malformations.

Chest pain (Chap. 13) caused by diseases of the respiratory system usually originates from involvement of the parietal pleura. As a result, the pain is accentuated by respiratory motion and is often referred to as pleuritic. Common examples include primary pleural disorders, such as neoplasm or inflammatory disorders involving the pleura, or pulmonary parenchymal disorders that extend to the pleural surface, such as pneumonia or pulmonary infarction.

ADDITIONAL HISTORIC INFORMATION Information about risk factors for lung disease should be explicitly explored to ensure a complete basis of historic data. A history of current and past smoking, especially of cigarettes, should be sought from all patients. The smoking history should include the number of years of smoking, the intensity (i.e., number of packs per day), and, if the patient no longer smokes, the interval since smoking cessation. The risk of lung cancer falls progressively in the decade following discontinuation of smoking, and loss of lung function above the expected age-related decline ceases with the discontinuation of smoking. Even though chronic obstructive lung disease and neoplasia are the two most important respiratory complications of smoking, other respiratory disorders (e.g., spontaneous pneumothorax, respiratory bronchiolitis–interstitial lung disease, pulmonary Langerhans cell histiocytosis, and pulmonary hemorrhage with Goodpasture's syndrome) are also associated with smoking. A history of significant secondhand (passive) exposure to smoke, whether in the home or at the workplace, should also be sought as it may be a risk factor for neoplasia or an exacerbating factor for airways disease.

The patient may have been exposed to other inhaled agents associated with lung disease, which act either via direct toxicity or through immune mechanisms (Chaps. 249 and 250). Such exposures can be either occupational or avocational, indicating the importance of detailed occupational and personal histories, the latter stressing exposures related to hobbies or the home environment. Important agents include the inorganic dusts associated with pneumoconiosis (especially asbestos and silica dusts) and organic antigens associated with hypersensitivity pneumonitis (especially antigens from molds and animal proteins). Asthma, which is more common in women than men, is often exacerbated by exposure to environmental allergens (dust mites, pet dander, or cockroach allergens in the home or allergens in the outdoor environment such as pollen and ragweed) or may be caused by occupational exposures (diisocyanates). Exposure to particular infectious agents can be suggested by contacts with individuals with known respiratory infections (especially tuberculosis) or by residence in an area with endemic pathogens (histoplasmosis, coccidioidomycosis, blastomycosis).

A history of coexisting nonrespiratory disease or of risk factors for or previous treatment of such diseases should be sought, as they may

predispose a patient to both infectious and noninfectious respiratory system complications. Common examples include systemic rheumatic diseases that are associated with pleural or parenchymal lung disease (Chap. 314), metastatic neoplastic disease in the lung, or impaired host defense mechanisms and secondary infection, which occur in the case of immunoglobulin deficiency or with hematologic and lymph node malignancies. Risk factors for AIDS should be sought, as the lungs are not only the most common site of AIDS-defining infection but can also be involved by noninfectious complications of AIDS (Chap. 182). Treatment of nonrespiratory disease can be associated with respiratory complications, either because of effects on host defense mechanisms (immunosuppressive agents, cancer chemotherapy) with resulting infection or because of direct effects on the pulmonary parenchyma (cancer chemotherapy, radiation therapy, or treatment with other agents, such as amiodarone) or on the airways (beta-blocking agents causing airflow obstruction, angiotensin-converting enzyme inhibitors causing cough) (Chap. 249).

Family history is important for evaluating diseases that have a genetic component. These include disorders such as cystic fibrosis, α_1-antitrypsin deficiency, pulmonary hypertension, pulmonary fibrosis, and asthma.

Physical Examination The general principles of inspection, palpation, percussion, and auscultation apply to the examination of the respiratory system. However, the physical examination should be directed not only toward ascertaining abnormalities of the lungs and thorax but also toward recognizing other findings that may reflect underlying lung disease.

On *inspection*, the rate and pattern of breathing as well as the depth and symmetry of lung expansion are observed. Breathing that is unusually rapid, labored, or associated with the use of accessory muscles of respiration generally indicates either augmented respiratory demands or an increased work of breathing. Asymmetric expansion of the chest is usually due to an asymmetric process affecting the lungs, such as endobronchial obstruction of a large airway, unilateral parenchymal or pleural disease, or unilateral phrenic nerve paralysis. Visible abnormalities of the thoracic cage include kyphoscoliosis and ankylosing spondylitis, either of which can alter compliance of the thorax, increase the work of breathing, and cause dyspnea.

On *palpation*, the symmetry of lung expansion can be assessed, generally confirming the findings observed by inspection. Vibration produced by spoken sounds is transmitted to the chest wall and is assessed by the presence or absence and symmetry of tactile fremitus. Transmission of vibration is decreased or absent if pleural liquid is interposed between the lung and the chest wall or if an endobronchial obstruction alters sound transmission. In contrast, transmitted vibration may increase over an area of underlying pulmonary consolidation. Palpation may also reveal focal tenderness, as seen with costochondritis or rib fracture.

The relative resonance or dullness of the tissue underlying the chest wall is assessed by *percussion*. The normal sound of underlying air-containing lung is resonant. In contrast, consolidated lung or a pleural effusion sounds dull, while emphysema or air in the pleural space results in a hyperresonant percussion note.

On *auscultation* of the lungs, the examiner listens for both the quality and intensity of the breath sounds and for the presence of extra, or adventitious, sounds. Normal breath sounds heard through the stethoscope at the periphery of the lung are described as *vesicular breath sounds*, in which inspiration is louder and longer than expiration. If sound transmission is impaired by endobronchial obstruction or by air or liquid in the pleural space, breath sounds are diminished in intensity or absent. When sound transmission is improved through consolidated lung, the resulting *bronchial breath sounds* have a more tubular quality and a more pronounced expiratory phase. Sound transmission can also be assessed by listening to spoken or whispered sounds; when these are transmitted through consolidated lung, *bronchophony* and *whispered pectoriloquy*, respectively, are present. The sound of a spoken E becomes more like an A, although with a nasal or bleating quality, a finding that is termed *egophony*.

The primary adventitious (abnormal) sounds that can be heard include crackles (rales), wheezes, and rhonchi. *Crackles* are the discontinuous, typically inspiratory sound created when alveoli and small airways open and close with respiration. They are often associated with interstitial lung disease, microatelectasis, or filling of alveoli by liquid. *Wheezes*, which are generally more prominent during expiration than inspiration, reflect the oscillation of airway walls that occurs when there is airflow limitation, as may be produced by bronchospasm, airway edema or collapse, or intraluminal obstruction by neoplasm or secretions. *Rhonchi* is the term applied to the sounds created when there is free liquid or mucus in the airway lumen; the viscous interaction between the free liquid and the moving air creates a low-pitched vibratory sound. Other adventitious sounds include pleural friction rubs and stridor. The gritty sound of a *pleural friction rub* indicates inflamed pleural surfaces rubbing against each other, often during both inspiratory and expiratory phases of the respiratory cycle. *Stridor*, which occurs primarily during inspiration, represents flow through a narrowed upper airway, as occurs in an infant with croup.

A summary of the patterns of physical findings on pulmonary examination in common types of respiratory system disease is shown in Table 245-1.

A meticulous *general physical examination* is mandatory in patients with disorders of the respiratory system. Enlarged lymph nodes in the cervical and supraclavicular regions should be sought. Disturbances of mentation or even coma can occur in patients with acute carbon dioxide retention and hypoxemia. Telltale stains on the fingers point to heavy cigarette smoking; infected teeth and gums may occur in patients with aspiration pneumonitis and lung abscess.

Clubbing of the digits can be found in lung cancer, interstitial lung disease, and chronic infections in the thorax, such as bronchiectasis, lung abscess, and empyema. Clubbing can also be seen with congenital heart disease associated with right-to-left shunting and with a variety of chronic inflammatory or infectious diseases, such as inflammatory bowel disease and endocarditis. A number of systemic diseases, such as systemic lupus erythematosus, scleroderma, and rheumatoid arthritis,

TABLE 245-1 TYPICAL CHEST EXAMINATION FINDINGS IN SELECTED CLINICAL CONDITIONS

Condition	Percussion	Fremitus	Breath Sounds	Voice Transmission	Adventitious Sounds
Normal	Resonant	Normal	Vesicular (at lung bases)	Normal	Absent
Consolidation or atelectasis (with patent airway)	Dull	Increased	Bronchial	Bronchophony, whispered pectoriloquy, egophony	Crackles
Consolidation or atelectasis (with blocked airway)	Dull	Decreased	Decreased	Decreased	Absent
Asthma	Resonant	Normal	Vesicular	Normal	Wheezing
Interstitial lung disease	Resonant	Normal	Vesicular	Normal	Crackles
Emphysema	Hyperresonant	Decreased	Decreased	Decreased	Absent or wheezing
Pneumothorax	Hyperresonant	Decreased	Decreased	Decreased	Absent
Pleural effusion	Dull	Decreased	Decreased[a]	Decreased[a]	Absent or pleural friction rub

[a]May be altered by collapse of underlying lung, which will increase transmission of sound.

may be associated with pulmonary complications, even though their primary clinical manifestations and physical findings are not primarily related to the lungs. Conversely, other diseases that most commonly affect the respiratory system, such as sarcoidosis, can have findings on physical examination not related to the respiratory system, including ocular findings (uveitis, conjunctival granulomas) and skin findings (erythema nodosum, cutaneous granulomas).

CHEST RADIOGRAPHY

Chest radiography is often the initial diagnostic study performed to evaluate patients with respiratory symptoms, but it can also provide the initial evidence of disease in patients who are free of symptoms. Perhaps the most common example of the latter situation is the finding of one or more nodules or masses when the radiograph is performed for a reason other than evaluation of respiratory symptoms.

A number of diagnostic possibilities are often suggested by the radiographic pattern (**Chap. e24**). A localized region of opacification involving the pulmonary parenchyma can be described as a nodule (usually <3 cm in diameter), a mass (usually ≥3 cm in diameter), or an infiltrate. Diffuse disease with increased opacification is usually characterized as having an alveolar, an interstitial, or a nodular pattern. In contrast, increased radiolucency can be localized, as seen with a cyst or bulla, or generalized, as occurs with emphysema. The chest radiograph is also particularly useful for the detection of pleural disease, especially if manifested by the presence of air or liquid in the pleural space. An abnormal appearance of the hila and/or the mediastinum can suggest a mass or enlargement of lymph nodes.

A summary of representative diagnoses suggested by these common radiographic patterns is presented in **Table 245-2**, and an atlas of chest radiographs and other chest images can be found in **Chap. e24**.

Additional Diagnostic Evaluation Further information for clarification of radiographic abnormalities is frequently obtained with CT scanning of the chest (see Figs. 247-1, 247-2; 255-1, 255-2; 262-3). This technique is more sensitive than plain radiography in detecting subtle abnormalities and can suggest specific diagnoses based on the pattern of abnormality. **For further discussion of the use of other imaging studies, including MRI, scintigraphic studies, ultrasound, and angiography, see Chap. 247.**

Alteration in the function of the lungs as a result of respiratory system disease is assessed objectively by pulmonary function tests, and effects on gas exchange are evaluated by measurement of arterial blood gases or by oximetry (Chap. 246). As part of pulmonary function testing, quantitation of forced expiratory flow assesses the presence of obstructive physiology, which is consistent with diseases affecting the structure or function of the airways, such as asthma and chronic obstructive lung disease. Measurement of lung volumes assesses the presence of restrictive disorders seen with diseases of the pulmonary parenchyma or respiratory pump and with space-occupying processes within the pleura. Bronchoscopy is useful in some settings for visualizing abnormalities of the airways and for obtaining a variety of samples from either the airway or the pulmonary parenchyma (Chap. 247).

TABLE 245-2 MAJOR RESPIRATORY DIAGNOSES WITH COMMON CHEST RADIOGRAPHIC PATTERNS

Solitary circumscribed density—nodule (<3 cm) or mass (≥3 cm)
Primary or metastatic neoplasm
Localized infection (bacterial abscess, mycobacterial or fungal infection)
Wegener's granulomatosis (one or several nodules)
Rheumatoid nodule (one or several nodules)
Vascular malformation
Bronchogenic cyst
Localized opacification (infiltrate)
Pneumonia (bacterial, atypical, mycobacterial, or fungal infection)
Neoplasm
Radiation pneumonitis
Bronchiolitis obliterans with organizing pneumonia
Bronchocentric granulomatosis
Pulmonary infarction
Diffuse interstitial disease
Idiopathic pulmonary fibrosis
Pulmonary fibrosis with systemic rheumatic disease
Sarcoidosis
Drug-induced lung disease
Pneumoconiosis
Hypersensitivity pneumonitis
Infection (*Pneumocystis*, viral pneumonia)
Langerhans cell histiocytosis
Diffuse alveolar disease
Cardiogenic pulmonary edema
Acute respiratory distress syndrome
Diffuse alveolar hemorrhage
Infection (*Pneumocystis*, viral or bacterial pneumonia)
Sarcoidosis
Diffuse nodular disease
Metastatic neoplasm
Hematogenous spread of infection (bacterial, mycobacterial, fungal)
Pneumoconiosis
Langerhans cell histiocytosis

INTEGRATION OF THE PRESENTING CLINICAL PATTERN AND DIAGNOSTIC STUDIES

Patients with respiratory symptoms but a normal chest radiograph often have diseases affecting the airways, such as asthma or chronic obstructive pulmonary disease. However, the latter diagnosis is also commonly associated with radiographic abnormalities, such as diaphragmatic flattening, an increase in the retrosternal air space, and attenuation of vascular markings. Other disorders of the respiratory system for which the chest radiograph is normal include disorders of the respiratory pump (either the chest wall or the neuromuscular apparatus controlling the chest wall) or pulmonary circulation and occasionally interstitial lung disease. Chest examination and pulmonary function tests are generally helpful in sorting out these diagnostic possibilities. Obstructive diseases associated with a normal or relatively normal chest radiograph are often characterized by findings on physical examination and pulmonary function testing that are typical for these conditions. Similarly, diseases of the respiratory pump or interstitial diseases may also be suggested by findings on physical examination or by particular patterns of restrictive disease seen on pulmonary function testing.

When respiratory symptoms are accompanied by radiographic abnormalities, diseases of the pulmonary parenchyma or the pleura are usually present. Either diffuse or localized parenchymal lung disease is generally visualized well on the radiograph, and both air and liquid in the pleural space (pneumothorax and pleural effusion, respectively) are usually readily detected by radiography.

Radiographic findings in the absence of respiratory symptoms often indicate localized disease affecting the airways or the pulmonary parenchyma. One or more nodules or masses can suggest intrathoracic malignancy, but they can also be the manifestation of a current or previous infectious process. Multiple nodules affecting only one lobe suggest an infectious etiology rather than malignancy, as metastatic disease would not have a predilection for only one discrete area of the lung. Patients with diffuse parenchymal lung disease on radiographic examination may be free of symptoms, as is sometimes the case with pulmonary sarcoidosis.

246 Disturbances of Respiratory Function

Steven E. Weinberger, Ilene M. Rosen

The respiratory system includes the lungs, the central nervous system (CNS), the chest wall (with the diaphragm and intercostal muscles), and the pulmonary circulation. The CNS controls the activity of the muscles of the chest wall, which constitute the pump of the respiratory system. Because these components of the respiratory system act in concert to achieve gas exchange, malfunction of an individual component or alteration of the relationships among components can lead to disturbances in function. In this chapter we consider three major aspects of disturbed respiratory function: (1) disturbances in ventilatory function, (2) disturbances in the pulmonary circulation, and (3) disturbances in gas exchange. **For further discussion of disorders relating to CNS control of ventilation, see Chap. 258.**

DISTURBANCES IN VENTILATORY FUNCTION

Ventilation is the process whereby the lungs replenish the gas in the alveoli. Measurements of ventilatory function in common diagnostic use consist of quantification of the gas volume contained in the lungs under certain circumstances and the rate at which gas can be expelled from the lungs. The two measurements of lung volume commonly used for respiratory diagnosis are (1) total lung capacity (TLC), the volume of gas contained in the lungs after a maximal inspiration; and (2) residual volume (RV), the volume of gas remaining in the lungs at the end of a maximal expiration. The volume of gas that is exhaled from the lungs in going from TLC to RV is the *vital capacity* (VC) **(Fig. 246-1)**.

Common clinical measurements of airflow are obtained from maneuvers in which the subject inspires to TLC and then forcibly exhales to RV. Three measurements are commonly made from a recording of forced exhaled volume versus time—i.e., a *spirogram*: (1) the volume of gas exhaled during the first second of expiration [forced expiratory volume (FEV) in 1 s, or FEV_1], (2) the total volume exhaled [forced vital capacity (FVC)], and (3) the average expiratory flow rate during the middle 50% of the VC [forced expiratory flow (FEF) between 25 and 75% of the VC, or $FEF_{25–75\%}$, also called the maximal midexpiratory flow rate (MMFR)] **(Fig. 246-2)**.

PHYSIOLOGIC FEATURES

The lungs are elastic structures, containing collagen and elastic fibers that resist expansion. For normal lungs to contain air, they must be distended either by a positive internal pressure—i.e., by a pressure in the airways and alveolar spaces—or by a negative external pressure—i.e., by a pressure outside the lung. The relationship between the volume of gas contained in the lungs and the distending pressure (the *transpulmonary pressure*, or P_{TP}, defined as alveolar pressure minus pleural pressure) is described by the pressure-volume curve of the lungs **(Fig. 246-3*A*)**.

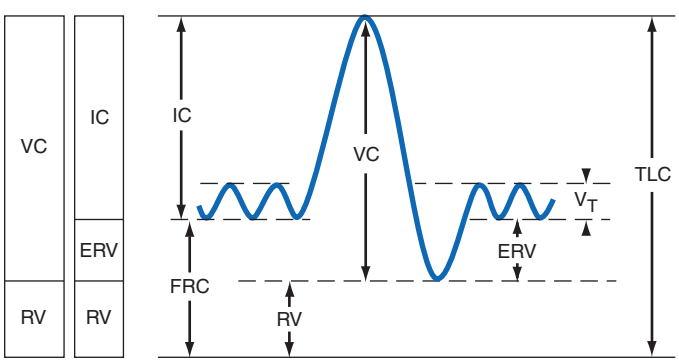

FIGURE 246-1 Lung volumes, shown by block diagrams (*left*) and by a spirographic tracing (*right*). TLC, total lung capacity; VC, vital capacity; RV, residual volume; IC, inspiratory capacity; ERV, expiratory reserve volume; FRC, functional residual capacity; V_T, tidal volume. *(From Weinberger, with permission.)*

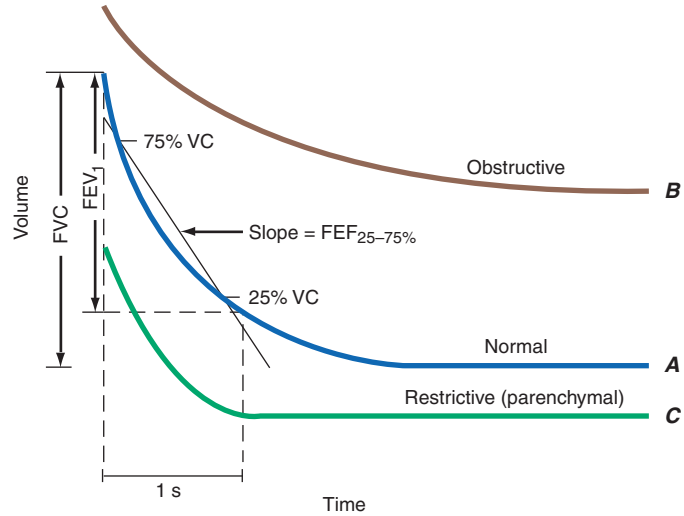

FIGURE 246-2 Spirographic tracings of forced expiration, comparing a normal tracing ***(A)*** and tracings in obstructive ***(B)*** and parenchymal restrictive ***(C)*** disease. Calculations of FVC, FEV_1, and $FEF_{25–75\%}$ are shown only for the normal tracing. Since there is no measure of absolute starting volume with spirometry, the curves are artificially positioned to show the relative starting lung volumes in the different conditions.

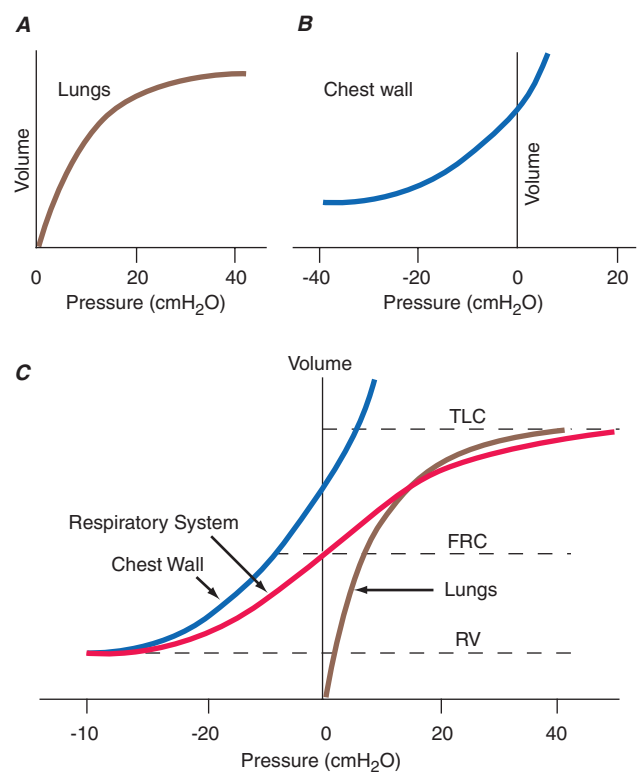

FIGURE 246-3 Pressure-volume curves. *A.* Pressure-volume curve of the lungs. ***B.*** Pressure-volume curve of the chest wall. ***C.*** Pressure-volume curve of the respiratory system, showing the superimposed component curves of the lungs and the chest wall. RV, residual volume; FRC, functional residual capacity; TLC, total lung capacity. *(From Weinberger, with permission.)*

The chest wall is also an elastic structure, with properties similar to those of an expandable and compressible spring. The relationship between the volume enclosed by the chest wall and the distending pressure for the chest wall is described by the pressure-volume curve of the chest wall (Fig. 246-3*B*). For the chest wall to assume a volume different from its resting volume, the internal or external pressures acting on it must be altered.

At functional residual capacity (FRC), defined as the volume of gas in the lungs at the end of a normal exhalation, the tendency of the lungs to contract is opposed by the equal and opposite tendency of the chest wall to expand (Fig. 246-3*C*). For the lungs and the chest wall to achieve a volume other than this resting volume (FRC), either the pressures acting on them must be changed passively—e.g., by a mechanical ventilator that delivers positive pressure to the airways and alveoli—or the respiratory muscles must actively oppose the tendency of the lungs and the chest wall to return to FRC. During inhalation to volumes above FRC, the inspiratory muscles actively overcome the tendency of the respiratory system to decrease volume back to FRC. During active exhalation to volumes below FRC, expiratory muscle activity must overcome the tendency of the respiratory system to increase volume back to FRC.

At TLC, the maximal force applied by the inspiratory muscles to expand the lungs is opposed mainly by the inward recoil of the lungs. As a consequence, the major determinants of TLC are the stiffness of the lungs and inspiratory muscle strength. If the lungs become stiffer—i.e., less compliant and with increased inward recoil—TLC is decreased. If the lungs become less stiff (more compliant and with decreased inward recoil), TLC is increased. If the inspiratory muscles are significantly weakened, they are less able to overcome the inward elastic recoil of the lungs, and TLC is lowered.

At RV, the force exerted by the expiratory muscles to decrease lung volume further is balanced by the outward recoil of the chest wall, which becomes extremely stiff at low lung volumes. Two factors influence the volume of gas contained in the lungs at RV. The first is the ability of the subject to exert a prolonged expiratory effort, which is related to muscle strength and the ability to overcome sensory stimuli from the chest wall. The second is the ability of the lungs to empty to a small volume. In normal lungs, as P_{TP} is lowered, lung volume decreases. In lungs with diseased airways, as P_{TP} is lowered, flow limitation or airway closure may limit the amount of gas that can be expired. Consequently, either weak expiratory muscles or intrinsic airways disease can result in an elevation in measured RV.

Dynamic measurements of ventilatory function are made by having the subject inhale to TLC and then perform a forced expiration to RV. If a subject performs a series of such expiratory maneuvers using increasing muscular intensity, expiratory flow rates will increase until a certain level of effort is reached. Beyond this level, additional effort at any given lung volume will not increase the forced expiratory flow rate; this phenomenon is known as the *effort independence* of FEF. The physiologic mechanisms determining the flow rates during this effort-independent phase of FEF are the elastic recoil of the lung, the airflow resistance of the airways between the alveolar zone and the physical site of flow limitation, and the airway wall compliance up to the site of flow limitation. Physical processes that decrease elastic recoil, increase airflow resistance, or increase airway wall compliance decrease the flow rate that can be achieved at any given lung volume. Conversely, processes that increase elastic recoil, decrease resistance, or stiffen airway walls increase the flow rate that can be achieved at any given lung volume.

MEASUREMENT OF VENTILATORY FUNCTION

Ventilatory function is measured under static conditions for determination of lung volumes and under dynamic conditions for determination of FEF. VC, expiratory reserve volume (ERV), and inspiratory capacity (IC) (Fig. 246-1) are measured by having the patient breathe into and out of a spirometer, a device capable of measuring expired or inspired gas volume while plotting volume as a function of time. Other volumes—specifically, RV, FRC, and TLC—cannot be measured in this way because they include the volume of gas present in the lungs even after a maximal expiration. Two techniques are commonly used to measure these volumes: helium dilution and body plethysmography. In the helium dilution method, the subject repeatedly breathes in and out from a reservoir with a known volume of gas containing a trace amount of helium. The helium is diluted by the gas previously present in the lungs and very little is absorbed into the pulmonary circulation. From knowledge of the reservoir volume and the initial and final helium concentrations, the volume of gas present in the lungs can be calculated. The helium dilution method may underestimate the volume of gas in the lungs if there are slowly communicating airspaces, such as bullae. In this situation, lung volumes can be measured more accurately with a body plethysmograph, a sealed box in which the patient sits while panting against a closed mouthpiece. Because there is no airflow into or out of the plethysmograph, the pressure changes in the thorax during panting cause compression and rarefaction of gas in the lungs and simultaneous rarefaction and compression of gas in the plethysmograph. By measuring the pressure changes in the plethysmograph and at the mouthpiece, the volume of gas in the thorax can be calculated using Boyle's law.

Lung volumes and measurements made during forced expiration are interpreted by comparing the values measured with the values expected given the age, height, sex, and race of the patient (Appendix, Table 14). Because there is some variability among normal individuals, values between 80 and 120% of the predicted value have traditionally been considered normal. Increasingly, calculated percentiles are used in determining normality. Specifically, values of individual measurements falling below the fifth percentile are considered to be below normal.

Obstructive lung disease is determined by a decreased FEV_1/VC ratio, where VC is defined as the largest of the FVC, SVC (slow vital capacity) or IVC (inspiratory vital capacity). Although a ratio <0.7 is typically considered abnormal, the normal value does vary with age. Historically, the FVC was the standard denominator for this ratio, and for most individuals the FVC, SVC, and IVC are very similar. However, in individuals with airways obstruction the SVC or IVC may be larger than the FVC. The $FEF_{25–75\%}$ is often considered a more sensitive measurement of early airflow obstruction, particularly in small airways. However, this measurement is less specific and must be interpreted cautiously in patients with abnormally small lungs (low TLC and VC). These patients exhale less air during forced expiration, and the $FEF_{25–75\%}$ may appear abnormal relative to the usual predicted value, even though it is normal relative to the size of the patient's lungs.

It is also a common practice to plot expiratory flow rates against lung volume (rather than against time); the close linkage of flow rates to lung volumes produces a typical *flow-volume curve* (Fig. 246-4). In addition, the spirometric values mentioned above can be calculated from the flow-volume curve. Commonly, flow rates during a maximal inspiratory effort performed as rapidly as possible are plotted as well, making the flow-volume curve into a *flow-volume loop*. At TLC, before expiratory flow starts, the flow rate is zero; once forced expiration has begun, a high peak flow rate is rapidly achieved. As expiration continues and lung volume approaches RV, the flow rate falls progressively, in a nearly linear fashion as a function of lung volume for a person with normal lung function. During maximal inspiration from RV to TLC, inspiratory flow is most rapid at the midpoint of inspiration, so the inspiratory portion of the loop is U-shaped or saddle-shaped. The flow rates achieved during maximal expiration can be analyzed quantitatively by comparing the flow rates at specified lung volumes with the predicted values, or qualitatively by analyzing the shape of the descending limb of the expiratory curve.

Assessing the strength of respiratory muscles is an additional part of the overall evaluation of some patients with respiratory dysfunction. When a patient exhales completely to RV and then tries to inspire maximally against an occluded airway, the pressure that can be generated is called the *maximal inspiratory pressure* (MIP). On the other hand, when a patient inhales to TLC and then tries to expire maximally against an occluded airway, the pressure generated is called the *maximal expiratory pressure* (MEP). In the proper clinical setting, these

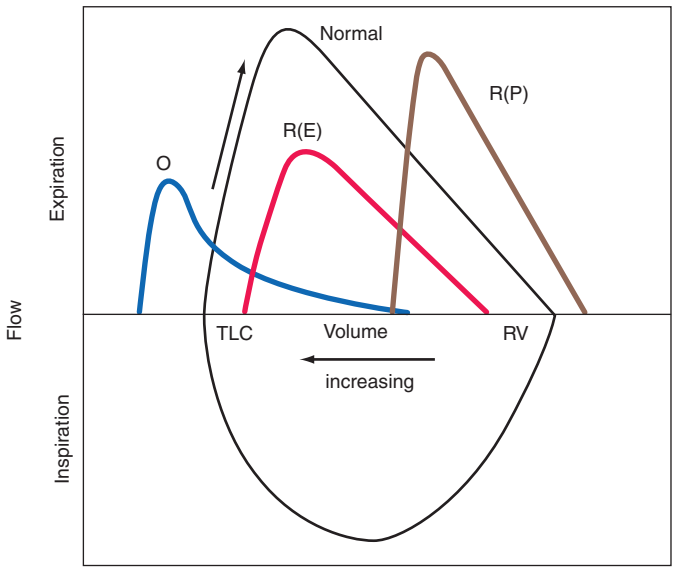

FIGURE 246-4 Flow-volume curves in different conditions: O, obstructive disease; R(P), parenchymal restrictive disease; R(E), extraparenchymal restrictive disease with limitation in inspiration and expiration. Forced expiration is plotted in all conditions; forced inspiration is shown only for the normal curve. TLC, total lung capacity; RV, residual volume. By convention, lung volume increases to the left on the abscissa. The arrow alongside the normal curve indicates the direction of expiration from TLC to RV.

studies may provide useful information regarding the cause of abnormal lung volumes and the possibility that respiratory muscle weakness may be causally related to the lung volume abnormalities.

PATTERNS OF ABNORMAL FUNCTION

The two major patterns of abnormal ventilatory function, as measured by static lung volumes and spirometry, are restrictive and obstructive patterns. In the *obstructive pattern*, the hallmark is a decrease in expiratory flow rates. With fully established disease, the ratio FEV_1/VC is decreased, as is the $FEF_{25–75\%}$ (Fig. 246-2, line *B*). The expiratory portion of the flow-volume loop demonstrates decreased flow rates for any given lung volume. Nonuniform emptying of airways is reflected by a coved (scooped) configuration of the descending part of the expiratory curve (Fig. 246-4). With early obstructive disease, which originates in the small airways, FEV_1/VC may be normal; the only abnormalities noted on routine testing of pulmonary function may be a depression in $FEF_{25–75\%}$ and an abnormal, i.e., coved, configuration in the terminal portion of the forced expiratory flow-volume curve.

In *obstructive* disease, the TLC is normal or increased. When helium equilibration tests are used to measure lung volumes, the measured volume may be less than the actual volume if helium was not well distributed to all regions of the lung. Residual volume is elevated as a result of airway closure during expiration, and the ratio RV/TLC is increased. VC is frequently decreased in obstructive disease because of the striking elevations in RV with only minor changes in TLC.

TABLE 246-1 ALTERATIONS IN VENTILATORY FUNCTION

	TLC	RV	VC	FEV_1/VC	MIP
Obstructive	N to ↑	↑	↓ or N	↓	N
Restrictive					
Pulmonary parenchymal	↓	↓	↓	N to ↑	N
Extraparenchymal					
Neuromuscular weakness	↓	Variable[a]	↓	Variable[a]	↓
Chest wall deformity	↓	Variable[b]	↓	N	N

[a]Depends upon expiratory muscle strength.
[b]Depends upon specific chest wall disorder.

The hallmark of a *restrictive pattern* is a decrease in lung volumes, primarily TLC and VC. Disorders resulting in a restrictive pattern can be broadly divided into two subgroups, depending on the location of the pathology: pulmonary parenchymal and extraparenchymal. In pulmonary parenchymal disease, RV is also generally decreased, and FEF rates are preserved. In fact, when FEV_1 is considered as a percentage of the FVC, the flow rates are often supranormal, i.e., disproportionately high relative to the size of the lungs (Fig. 246-2, line *C*). The flow-volume curve may graphically demonstrate this disproportionate relationship between flow rates and lung volumes, since the expiratory portion of the curve appears relatively tall (preserved flow rates) but narrow (decreased lung volumes), as shown in Fig. 246-4.

With extraparenchymal disease, dysfunction can be due to neuromuscular disease with associated respiratory muscle weakness or to disorders of the chest wall or pleura (Table 246-1). In the extraparenchymal diseases, TLC is decreased due to inspiratory muscle weakness, a stiff chest wall, or a space-occupying process within the pleura. If inspiratory muscle weakness is the cause of this pattern, then RV is often not significantly affected, expiratory flow rates are preserved, and MIP is decreased. Alternatively, if the restrictive pattern is due to a deformed chest wall that is abnormally rigid at volumes below FRC, the ability to expire to a normal RV is also limited. Consequently, RV is often elevated, unlike the pattern observed in the other restrictive subcategories.

CLINICAL CORRELATIONS

Table 246-1 summarizes the typical patterns of altered ventilatory function as indicated by pulmonary function testing. This information can then be useful in diagnosis, as outlined in Table 246-2.

DISTURBANCES IN THE PULMONARY CIRCULATION

PHYSIOLOGIC FEATURES

The pulmonary vasculature must handle the entire output of the right ventricle, ~5 L/min in a normal adult at rest. The comparatively thin-walled vessels of the pulmonary arterial system provide relatively little resistance to flow and are capable of handling this large volume of blood at perfusion pressures that are low compared with those of the systemic circulation. The normal mean pulmonary artery pressure is 15 mmHg, as compared to ~95 mmHg for the normal mean aortic pressure. Regional blood flow in the lung is dependent on vascular geometry and on hydrostatic forces. In an upright person, perfusion is least at the apex of the lung and greatest at the base. When cardiac output increases, as occurs during exercise, the pulmonary vasculature is capable of recruiting previously unperfused vessels and distending underperfused vessels, thus responding to the increase in flow with a decrease in pulmonary vascular resistance. In consequence, the increase in mean pulmonary arterial pressure (PAP), even with a three- to fourfold increase in cardiac output, is small.

METHODS OF MEASUREMENT

Assessment of circulatory function in the pulmonary vasculature depends on measuring pulmonary vascular pressures and cardiac output. Clinically, these measurements are commonly made in intensive care units capable of invasive monitoring and in cardiac catheterization laboratories. With a flow-directed pulmonary arterial (Swan-Ganz) catheter, PAP and pulmonary capillary wedge pressure can be measured directly, and cardiac output can be obtained by the thermodilution method. Pulmonary vascular resistance (PVR) can then be calculated according to the equation

$$PVR = 80(PAP - PCW)/CO$$

where PVR = pulmonary vascular resistance (dyn · s/cm^5); PAP = mean pulmonary arterial pressure (mmHg); PCW = pulmonary capillary wedge pressure (mmHg); and CO = cardiac output (L/min).

The normal value for pulmonary vascular resistance is ~50–150 dyn · s/cm^5.

TABLE 246-2 COMMON RESPIRATORY DISEASES BY DIAGNOSTIC CATEGORIES

Obstructive
- Asthma
- Chronic obstructive lung disease (chronic bronchitis, emphysema)
- Bronchiectasis
- Cystic fibrosis
- Bronchiolitis

Restrictive—Parenchymal
- Sarcoidosis
- Idiopathic pulmonary fibrosis
- Pneumoconiosis
- Drug- or radiation-induced interstitial lung disease

Restrictive—Extraparenchymal
- Neuromuscular
  - Diaphragmatic weakness/paralysis
  - Myasthenia gravis
  - Guillain-Barré syndrome
  - Muscular dystrophies
  - Cervical spine injury
- Chest wall
  - Kyphoscoliosis
  - Obesity
  - Ankylosing spondylitis

MECHANISMS OF ABNORMAL FUNCTION (See also Chap. 244)

PVR may increase by a variety of mechanisms. Pulmonary arterial and arteriolar vasoconstriction is a prominent response to alveolar hypoxia. PVR also increases if intraluminal thrombi or proliferation of smooth muscle in vessel walls diminishes the luminal cross-sectional area. If small pulmonary vessels are destroyed, either by scarring or by loss of alveolar walls (as in chronic obstructive lung disease), the total cross-sectional area of the pulmonary vascular bed diminishes, and PVR increases. When PVR is elevated, either PAP rises to maintain normal cardiac output or cardiac output falls if PAP does not increase.

CLINICAL CORRELATIONS

Disturbances in the function of the pulmonary vasculature as a result of primary cardiac disease, either congenital heart disease or conditions that elevate left atrial pressure, such as mitral stenosis, are beyond the scope of this chapter and are discussed in Chaps. 229 and 230, respectively. Instead, the focus will be on the pulmonary vasculature as its function is affected by diseases primarily involving the respiratory system, including the pulmonary vessels themselves.

All diseases of the respiratory system causing hypoxemia are potentially capable of increasing PVR, since alveolar hypoxia is a very potent stimulus for pulmonary vasoconstriction. The more prolonged and intense the hypoxic stimulus, the more likely it is that a significant increase in PVR producing pulmonary hypertension will result. In practice, patients with hypoxemia caused by chronic obstructive lung disease, interstitial lung disease, chest wall disease, and the obesity hypoventilation–sleep apnea syndrome are particularly prone to developing pulmonary hypertension. If there are additional structural changes in the pulmonary vasculature secondary to the underlying process, these will increase the likelihood of developing pulmonary hypertension.

With diseases directly affecting the pulmonary vessels, a decrease in the cross-sectional area of the pulmonary vascular bed is primarily responsible for increased PVR, while hypoxemia generally plays a lesser role. In the case of recurrent pulmonary emboli, parts of the pulmonary arterial system are occluded by intraluminal thrombi originating in the systemic venous system. With primary pulmonary hypertension (Chap. 244) or with pulmonary vascular disease secondary to scleroderma, the small pulmonary arteries and arterioles are affected by a generalized obliterative process that narrows and occludes these vessels. PVR increases, and significant pulmonary hypertension often results.

DISTURBANCES IN GAS EXCHANGE

PHYSIOLOGIC FEATURES

The primary functions of the respiratory system are to remove the appropriate amount of CO_2 from blood entering the pulmonary circulation and to provide adequate O_2 to blood leaving the pulmonary circulation. For these functions to be carried out properly, there must be adequate provision of fresh air to the alveoli for delivery of O_2 and removal of CO_2 (ventilation), adequate circulation of blood through the pulmonary vasculature (perfusion), adequate movement of gas between alveoli and pulmonary capillaries (diffusion), and appropriate contact between alveolar gas and pulmonary capillary blood (ventilation-perfusion matching).

A normal individual at rest inspires ~12–16 times per minute, each breath having a tidal volume of ~500 mL. A portion (~30%) of the fresh air inspired with each breath does not reach the alveoli but remains in the conducting airways of the lung. This component of each breath, which is not generally available for gas exchange, is called the *anatomic dead space* component. The remaining 70% reaches the alveolar zone, mixes rapidly with the gas already there, and can participate in gas exchange. In this example, the total ventilation each minute is ~7 L, composed of 2 L/min of dead space ventilation and 5 L/min of alveolar ventilation. In certain diseases, some alveoli are ventilated but not perfused, so that some ventilation in addition to the anatomic dead space component is wasted. If total dead space ventilation is increased but total minute ventilation is unchanged, then alveolar ventilation must fall correspondingly.

Gas exchange is dependent on alveolar ventilation rather than total minute ventilation, as outlined below. The partial pressure of CO_2 in arterial blood (Pa_{CO_2}) is directly proportional to the amount of CO_2 produced per minute ($\dot{V}_{CO_2}$) and inversely proportional to alveolar ventilation ($\dot{V}_A$), according to the relationship

$$Pa_{CO_2} = 0.863 \times \dot{V}_{CO_2}/\dot{V}_A$$

where $\dot{V}_{CO_2}$ is expressed in mL/min, $\dot{V}_A$ in L/min, and Pa_{CO_2} in mmHg. At fixed $\dot{V}_{CO_2}$, when alveolar ventilation increases, Pa_{CO_2} falls, and when alveolar ventilation decreases, Pa_{CO_2} rises. Maintaining a normal level of O_2 in the alveoli (and consequently in arterial blood) also depends on provision of adequate alveolar ventilation to replenish alveolar O_2. This principle will become more apparent from consideration of the alveolar gas equation below.

Diffusion of O_2 and CO_2 Both O_2 and CO_2 diffuse readily down their respective concentration gradients through the alveolar wall and pulmonary capillary endothelium. Under normal circumstances, this process is rapid, and equilibration of both gases is complete within one-third of the transit time of erythrocytes through the pulmonary capillary bed. Even in disease states in which diffusion of gases is impaired, the impairment is unlikely to be severe enough to prevent equilibration of CO_2 and O_2. Consequently, a diffusion abnormality rarely results in arterial hypoxemia at rest. If erythrocyte transit time in the pulmonary circulation is shortened, as occurs with exercise, and diffusion is impaired, then diffusion limitation may contribute to hypoxemia. Exercise testing can often demonstrate such physiologically significant abnormalities due to impaired diffusion. Even though diffusion limitation rarely makes a clinically significant contribution to resting hypoxemia, clinical measurements of what is known as *diffusing capacity* (see below) can be a useful measure of the integrity of the alveolar-capillary membrane.

Ventilation-Perfusion Matching In addition to the absolute levels of alveolar ventilation and perfusion, gas exchange depends critically on the proper matching of ventilation and perfusion. The spectrum of possible ventilation-perfusion ($\dot{V}/\dot{Q}$) ratios in an alveolar-capillary unit ranges from zero, in which ventilation is totally absent and the unit behaves as a shunt, to infinity, in which perfusion is totally absent and the unit behaves as dead space. The P_{O_2} and P_{CO_2} of blood leaving each alveolar-capillary unit depend on the gas tension (of blood and

air) entering that unit and on the particular $\dot{V}/\dot{Q}$ ratio of the unit. At one extreme, when an alveolar-capillary unit has a $\dot{V}/\dot{Q}$ ratio of 0 and behaves as a shunt, blood leaving the unit has the composition of mixed venous blood entering the pulmonary capillaries, i.e., $P\bar{v}_{O_2} \approx 40$ mmHg and $P\bar{v}_{CO_2} \approx 46$ mmHg. At the other extreme, when an alveolar-capillary unit has a high $\dot{V}/\dot{Q}$ ratio, it behaves almost like dead space, and the small amount of blood leaving the unit has partial pressures of O_2 and CO_2 ($P_{O_2} \approx 150$ mmHg, $P_{CO_2} \approx 0$ mmHg while breathing room air) approaching the composition of inspired gas.

In the ideal situation, all alveolar-capillary units have equal matching of ventilation and perfusion, i.e., a ratio of ~1 when each is expressed in L/min. However, even in the normal individual, some $\dot{V}/\dot{Q}$ mismatching is present, since there is normally an increasing gradient of blood flow from the apices to the bases of the lungs. There is a similar gradient of ventilation from the apices to the bases, but it is less marked than the perfusion gradient. As a result, ventilation-perfusion ratios are higher at the lung apices than at the lung bases. Therefore, blood coming from the apices has a higher P_{O_2} and lower P_{CO_2} than blood coming from the bases. The net P_{O_2} and P_{CO_2} of the blood mixture coming from all areas of the lung is a flow-weighted average of the individual components, which reflects both the relative amount of blood from each unit and the O_2 and CO_2 *content* of the blood coming from each unit. Because of the sigmoid shape of the oxyhemoglobin dissociation curve (see Fig. 99-2), it is important to distinguish between the partial pressure and the content of O_2 in blood. Hemoglobin is almost fully (~90%) saturated at a P_{O_2} of 60 mmHg, and little additional O_2 is carried by hemoglobin even with a substantial elevation of P_{O_2} >60 mmHg. On the other hand, significant O_2 desaturation of hemoglobin occurs once P_{O_2} falls to <60 mmHg and onto the steep descending limb of the curve. As a result, blood coming from regions of the lung with a high $\dot{V}/\dot{Q}$ ratio and a high P_{O_2} has only a small elevation in O_2 content and cannot compensate for blood coming from regions with a low $\dot{V}/\dot{Q}$ ratio and a low P_{O_2}, which has a significantly decreased O_2 content. Although $\dot{V}/\dot{Q}$ mismatching can influence P_{CO_2}, this effect is less marked and is often overcome by an increase in overall minute ventilation.

MEASUREMENT OF GAS EXCHANGE

Arterial Blood Gases The most commonly used measures of gas exchange are the partial pressures of O_2 and CO_2 in arterial blood, i.e., Pa_{O_2} and Pa_{CO_2}, respectively. These partial pressures do not measure directly the quantity of O_2 and CO_2 in blood but rather the driving pressure for the gas in blood. The actual quantity or content of a gas in blood also depends on the solubility of the gas in plasma and the ability of any component of blood to react with or bind the gas of interest. Since hemoglobin is capable of binding large amounts of O_2, oxygenated hemoglobin is the primary form in which O_2 is transported in blood. The actual content of O_2 in blood therefore depends both on the hemoglobin concentration and on the Pa_{O_2}. The Pa_{O_2} determines what percentage of hemoglobin is saturated with O_2, based on the position on the oxyhemoglobin dissociation curve. Oxygen content in normal blood (at 37°C, pH 7.4) can be determined by adding the amount of O_2 dissolved in plasma to the amount bound to hemoglobin, according to the equation

$$O_2 \text{ content} = 1.34 \times [\text{hemoglobin}] \times \text{saturation} + 0.0031 \times P_{O_2}$$

since each gram of hemoglobin is capable of carrying 1.34 mL O_2 when fully saturated, and the amount of O_2 that can be dissolved in plasma is proportional to the P_{O_2}, with 0.0031 mL O_2 dissolved per deciliter of blood per mmHg P_{O_2}. In arterial blood, the amount of O_2 transported dissolved in plasma (~0.3 mL O_2 per deciliter of blood) is trivial compared with the amount bound to hemoglobin (~20 mL O_2 per deciliter of blood).

Most commonly, P_{O_2} is the measurement used to assess the effect of respiratory disease on the oxygenation of arterial blood. Direct measurement of O_2 saturation in arterial blood by oximetry is also important in selected clinical conditions. For example, in patients with carbon monoxide intoxication, carbon monoxide preferentially displaces O_2 from hemoglobin, essentially making a portion of hemoglobin unavailable for binding to O_2. In this circumstance, carbon monoxide saturation is high and O_2 saturation is low, even though the driving pressure for O_2 to bind to hemoglobin, reflected by P_{O_2}, is normal. Measurement of O_2 saturation is also important for the determination of O_2 content when mixed venous blood is sampled from a pulmonary arterial catheter to calculate cardiac output by the Fick technique. In mixed venous blood, the P_{O_2} is normally ~40 mmHg, but small changes in P_{O_2} may reflect relatively large changes in O_2 saturation.

A useful calculation in the assessment of oxygenation is the alveolar-arterial O_2 difference ($P_{A_{O_2}} - Pa_{O_2}$), commonly called the *alveolar-arterial O_2 gradient* (or A – a gradient). This calculation takes into account the fact that alveolar and, hence, arterial P_{O_2} can be expected to change depending on the level of alveolar ventilation, reflected by the arterial P_{CO_2}. When a patient hyperventilates and has a low P_{CO_2} in arterial blood and alveolar gas, alveolar and arterial P_{O_2} will rise; conversely, hypoventilation and a high P_{CO_2} are accompanied by a decrease in alveolar and arterial P_{O_2}. These changes in arterial P_{O_2} are independent of abnormalities in O_2 transfer at the alveolar-capillary level and reflect only the dependence of alveolar P_{O_2} on the level of alveolar ventilation.

In order to determine the alveolar-arterial O_2 difference, the alveolar P_{O_2} ($P_{A_{O_2}}$) must first be calculated. The equation most commonly used for this purpose, a simplified form of the alveolar gas equation, is

$$P_{A_{O_2}} = FI_{O_2} \times (P_B - P_{H_2O}) - Pa_{CO_2}/R$$

where FI_{O_2} = fractional concentration of inspired O_2 (0.21 when breathing room air); P_B = barometric pressure (~760 mmHg at sea level); P_{H_2O} = water vapor pressure (47 mmHg when air is fully saturated at 37°C); and R = respiratory quotient (the ratio of CO_2 production to O_2 consumption, usually assumed to be 0.8). If the preceding values are substituted into the equation for the patient breathing air at sea level, the equation becomes

$$P_{A_{O_2}} = 150 - 1.25 \times Pa_{CO_2}$$

The alveolar-arterial O_2 difference can then be calculated by subtracting measured Pa_{O_2} from calculated $P_{A_{O_2}}$. In a healthy young person breathing room air, the $P_{A_{O_2}} - Pa_{O_2}$ is normally <15 mmHg; this value increases with age and may be as high as 30 mmHg in elderly patients.

The adequacy of CO_2 elimination is measured by the partial pressure of CO_2 in arterial blood, i.e., Pa_{CO_2}. A more complete understanding of the mechanisms and chronicity of abnormal levels of P_{CO_2} also requires measurement of pH and/or bicarbonate (HCO_3^-), since P_{CO_2} and the patient's acid-base status are so closely intertwined (Chap. 48).

Pulse Oximetry Because measurement of Pa_{O_2} requires arterial puncture, it is not ideal either for office use or for routine or frequent measurement in the inpatient setting. Additionally, because it provides intermittent rather than continuous data about the patient's oxygenation, it is not ideal for close monitoring of unstable patients. Pulse oximetry, an alternative method for assessing oxygenation, is readily available in many clinical settings. Using a probe usually clipped over a patient's finger, the pulse oximeter calculates oxygen saturation (rather than Pa_{O_2}) based on measurements of absorption of two wavelengths of light by hemoglobin in pulsatile, cutaneous arterial blood. Because of differential absorption of the two wavelengths of light by oxygenated and nonoxygenated hemoglobin, the percentage of hemoglobin that is saturated with oxygen, i.e., the Sa_{O_2}, can be calculated and displayed instantaneously.

Although the pulse oximeter is widely used in the noninvasive assessment and monitoring of oxygenation, there are several issues and potential problems concerning its use. First, the clinician must be aware of the relationship between oxygen saturation and tension as shown by the oxyhemoglobin dissociation curve (see Fig. 99-2). Because the curve becomes relatively flat above an arterial P_{O_2} of 60

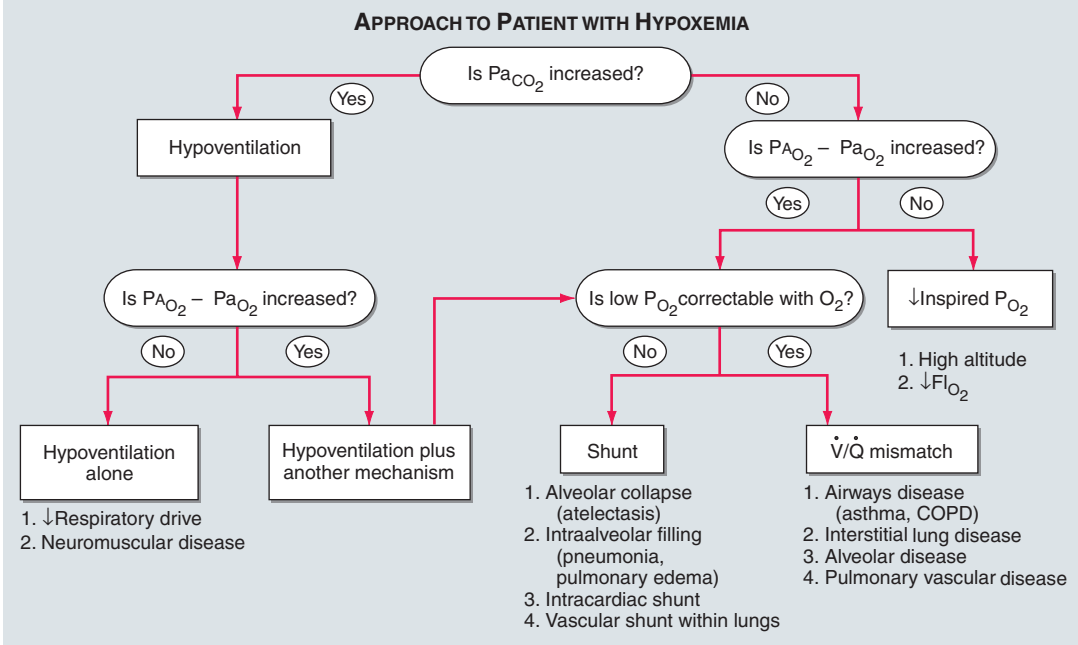

FIGURE 246-5 Flow diagram outlining the diagnostic approach to the patient with hypoxemia (Pa_{O_2} < 80 mmHg). $PA_{O_2} - Pa_{O_2}$ is usually <15 mmHg for subjects ≤30 years old and increases by ~3 mmHg per decade after age 30. COPD, chronic obstructive pulmonary disease.

mmHg (corresponding to Sa_{O_2} = 90%), the oximeter is relatively insensitive to changes in Pa_{O_2} above this level. In addition, the position of the curve and therefore the specific relationship between Pa_{O_2} and Sa_{O_2} may change depending on factors such as temperature, pH, and the erythrocyte concentration of 2,3-diphosphoglycerate. Second, when cutaneous perfusion is decreased, e.g., owing to low cardiac output or the use of vasoconstrictors, the signal from the oximeter may be less reliable or even unobtainable. Third, other forms of hemoglobin, such as carboxyhemoglobin and methemoglobin, are not distinguishable from oxyhemoglobin when only two wavelengths of light are used. The Sa_{O_2} values reported by the pulse oximeter are not reliable in the presence of significant amounts of either of these forms of hemoglobin. In contrast, the device used to measure oxygen saturation in samples of arterial blood, called the CO-oximeter, uses at least four wavelengths of light and is capable of distinguishing oxyhemoglobin, deoxygenated hemoglobin, carboxyhemoglobin, and methemoglobin. Finally, the clinician must remember that the often-used goal of $Sa_{O_2} \geq$ 90% does not indicate anything about CO_2 elimination and therefore does not ensure a clinically acceptable P_{CO_2}.

Diffusing Capacity The ability of gas to diffuse across the alveolar-capillary membrane is ordinarily assessed by the diffusing capacity of the lung for carbon monoxide (D_{LCO}). In this test, a small concentration of carbon monoxide (0.3%) is inhaled, usually in a single breath that is held for ~10 s. During the breath hold, the carbon monoxide is diluted by the gas already present in the alveoli and is also taken up by hemoglobin as the erythrocytes course through the pulmonary capillary system. The concentration of carbon monoxide is then measured in the gas exhaled after the breath hold, and D_{LCO} is calculated as the quantity of carbon monoxide absorbed per minute per mmHg pressure gradient from the alveoli to the pulmonary capillaries. The value obtained for D_{LCO} depends on the alveolar-capillary surface area available for gas exchange and on the pulmonary capillary blood volume. In addition, the thickness of the alveolar-capillary membrane, the degree of V̇/Q̇ mismatching, and the patient's hemoglobin level will affect the measurement. Because of this effect of hemoglobin levels on D_{LCO}, the measured D_{LCO} is frequently corrected to take the patient's hemoglobin level into account. The value for D_{LCO}, ideally corrected for hemoglobin, can then be compared with a predicted value, based either on age, height, and gender or on the alveolar volume (V_A) at which the value was obtained. Alternatively, the D_{LCO} can be divided by V_A and the resulting value for D_{LCO}/V_A compared with a predicted value.

APPROACH TO THE PATIENT: Disturbance of Respiratory Function

ARTERIAL BLOOD GASES Hypoxemia is a common manifestation of a variety of diseases affecting the lungs or other parts of the respiratory system. The broad clinical problem of hypoxemia is often best characterized according to the underlying mechanism. The four basic, and not mutually exclusive, mechanisms of hypoxemia are (1) a decrease in inspired P_{O_2}, (2) hypoventilation, (3) shunting, and (4) V̇/Q̇ mismatching. A fifth potential mechanism of hypoxemia, due to decreased diffusion, occurs only under selected clinical circumstances and is not usually included among the general categories of hypoxemia. Determining the underlying mechanism for hypoxemia depends on measurement of the Pa_{CO_2}, calculation of $PA_{O_2} - Pa_{O_2}$, and knowledge of the response to supplemental O_2. A flowchart summarizing the approach to the hypoxemic patient is given in Fig. 246-5. See also Chap. 35.

A decrease in the inspired P_{O_2} and hypoventilation both cause hypoxemia by lowering PA_{O_2} and therefore Pa_{O_2}. In each case, gas exchange at the alveolar-capillary level occurs normally, and $PA_{O_2} - Pa_{O_2}$ is not elevated. Hypoxemia due to decreased inspired P_{O_2} can be diagnosed from knowledge of the clinical situation. Inspired P_{O_2} is lowered either because the patient is at a high altitude, where barometric pressure is low, or, much less commonly, because the patient is breathing a gas mixture containing <21% O_2. The hallmark of hypoventilation as a cause of hypoxemia is an elevation in Pa_{CO_2}. This is associated with an increase in PA_{CO_2} and a fall in PA_{O_2}. When hypoxemia is due purely to a low inspired P_{O_2} or to alveolar hypoventilation, $PA_{O_2} - Pa_{O_2}$ is normal. If $PA_{O_2} - Pa_{O_2}$ and Pa_{CO_2} are both elevated, then an additional mechanism, such as V̇/Q̇ mismatching or shunting, is contributing to hypoxemia.

Shunting is a cause of hypoxemia when desaturated blood effectively bypasses oxygenation at the alveolar-capillary level. This situation occurs either because a structural problem allows desaturated blood to bypass the normal site of gas exchange or because perfused alveoli are not ventilated. Shunting is associated with an elevation in the $PA_{O_2} - Pa_{O_2}$ value. When shunting is an important

contributing factor to hypoxemia, the lowered Pa_{O_2} is relatively refractory to improvement by supplemental O_2.

Finally, the largest clinical category of hypoxemia is $\dot{V}/\dot{Q}$ mismatching. With $\dot{V}/\dot{Q}$ mismatching, regions with low $\dot{V}/\dot{Q}$ ratios contribute blood with a low P_{O_2} and a low O_2 content. Corresponding regions with high $\dot{V}/\dot{Q}$ ratios contribute blood with a high P_{O_2}. However, because blood is already almost fully saturated at a normal P_{O_2}, elevation of the P_{O_2} to a high value does not significantly increase O_2 saturation or content and therefore cannot compensate for the reduction of O_2 saturation and content in blood coming from regions with a low $\dot{V}/\dot{Q}$ ratio. When $\dot{V}/\dot{Q}$ mismatch is the primary cause of hypoxemia, $P_{A_{O_2}} - Pa_{O_2}$ is elevated, and P_{CO_2} generally is normal. Supplemental O_2 corrects the hypoxemia by raising the P_{O_2} in blood coming from regions with a low $\dot{V}/\dot{Q}$ ratio; this response distinguishes hypoxemia due to $\dot{V}/\dot{Q}$ mismatching from that due to true shunt.

The essential mechanism underlying all cases of hypercapnia is alveolar ventilation that is inadequate for the amount of CO_2 produced. It is conceptually useful to characterize CO_2 retention further, based on a more detailed examination of the potential contributing factors. These include (1) increased CO_2 production; (2) decreased ventilatory drive ("won't breathe"); (3) malfunction of the respiratory pump or increased airways resistance, which makes it more difficult to sustain adequate ventilation ("can't breathe"); and (4) inefficiency of gas exchange (increased dead space or $\dot{V}/\dot{Q}$ mismatch) necessitating a compensatory increase in overall minute ventilation. In practice, more than one of these mechanisms is commonly responsible for hypercapnia, since increased minute ventilation is capable of compensating for increased CO_2 production and for inefficiencies of gas exchange.

DIFFUSING CAPACITY Although abnormalities in diffusion are rarely responsible for hypoxemia, clinical measurement of diffusing capacity is frequently used to assess the functional integrity of the alveolar-capillary membrane, which includes the pulmonary capillary bed. Diseases that affect solely the airways generally do not lower $D_{L_{CO}}$, whereas diseases that affect the alveolar walls or the pulmonary capillary bed will have an effect on $D_{L_{CO}}$. Even though $D_{L_{CO}}$ is a useful marker for assessing whether disease affecting the alveolar-capillary bed is present, an abnormal $D_{L_{CO}}$ does not necessarily imply that diffusion limitation is responsible for hypoxemia in a particular patient.

CLINICAL CORRELATIONS

Useful clinical correlations can be made with the mechanisms underlying hypoxemia (Fig. 246-5). A lowered inspired P_{O_2} contributes to hypoxemia if either the patient is at high altitude or the concentration of inspired O_2 is <21%. The latter problem occurs if a patient receiving anesthesia or ventilatory support is inadvertently given a gas mixture to breathe containing <21% O_2 or if O_2 is consumed from the ambient gas, as can occur during smoke inhalation from a fire. The primary feature of hypoventilation as a cause of hypoxemia is an elevation in arterial P_{CO_2}. **For further discussion of the clinical correlations with hypoventilation, see Chap. 258.**

Shunting as a cause of hypoxemia can reflect transfer of blood from the right to the left side of the heart without passage through the pulmonary circulation, as occurs with an intracardiac shunt. This problem is most common in the setting of cyanotic congenital heart disease, when an interatrial or interventricular septal defect is associated with pulmonary hypertension so that shunting is in the right-to-left rather than the left-to-right direction. Shunting of blood through the pulmonary parenchyma is most frequently due to disease causing absence of ventilation to perfused alveoli. This can occur if the alveoli are atelectatic or if they are filled with fluid, as in pulmonary edema (both cardiogenic and noncardiogenic), or with extensive intraalveolar exudation of fluid due to pneumonia. Less commonly, vascular anomalies with arteriovenous shunting in the lung can cause hypoxemia. These anomalies can be hereditary, as found with hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber syndrome), or acquired, as in pulmonary vascular malformations secondary to hepatic cirrhosis, which are similar to the commonly recognized cutaneous vascular malformations ("spider hemangiomas").

Ventilation-perfusion mismatch is the most common cause of hypoxemia clinically. Most of the processes affecting either the airways or the pulmonary parenchyma are distributed unevenly throughout the lungs and do not necessarily affect ventilation and perfusion equally. Some areas of lung may have good perfusion and poor ventilation, whereas others may have poor perfusion and relatively good ventilation. Important examples of airways diseases in which $\dot{V}/\dot{Q}$ mismatch causes hypoxemia are asthma and chronic obstructive lung disease. Parenchymal lung diseases causing $\dot{V}/\dot{Q}$ mismatch and hypoxemia include interstitial lung disease and pneumonia.

Clinically important alterations in CO_2 elimination range from excessive ventilation and hypocapnia to inadequate CO_2 elimination and hypercapnia. **For further discussion of these clinical problems, see Chap. 258.**

Diffusing Capacity Measurement of $D_{L_{CO}}$ may be useful for assessing disease affecting the alveolar-capillary bed or the pulmonary vasculature. In practice, three main categories of disease are associated with lowered $D_{L_{CO}}$: interstitial lung disease, emphysema, and pulmonary vascular disease. With interstitial lung disease, scarring of alveolar-capillary units diminishes the area of the alveolar-capillary bed as well as pulmonary blood volume. With emphysema, alveolar walls are destroyed, so the surface area of the alveolar-capillary bed is again diminished. In patients with disease causing a decrease in the cross-sectional area and volume of the pulmonary vascular bed, such as recurrent pulmonary emboli or primary pulmonary hypertension, $D_{L_{CO}}$ is commonly diminished.

Diffusing capacity may be elevated if pulmonary blood volume is increased, as may be seen in congestive heart failure. However, once interstitial and alveolar edema ensues, the net $D_{L_{CO}}$ depends on the opposing influences of increased pulmonary capillary blood volume elevating $D_{L_{CO}}$ and pulmonary edema decreasing it. Finding an elevated $D_{L_{CO}}$ may be useful in the diagnosis of alveolar hemorrhage, as in Goodpasture's syndrome. Hemoglobin contained in erythrocytes in the alveolar lumen is capable of binding carbon monoxide, so the exhaled carbon monoxide concentration is diminished and the measured $D_{L_{CO}}$ is increased.

ACKNOWLEDGMENT

We acknowledge the contribution of Dr. Jeffrey M. Drazen to this chapter in previous editions.

247 Diagnostic Procedures in Respiratory Disease

Scott Manaker, Steven E. Weinberger

The diagnostic modalities available for assessing the patient with suspected or known respiratory system disease include imaging studies and techniques for acquiring biologic specimens, some of which involve direct visualization of part of the respiratory system. **Methods to characterize the functional changes developing as a result of disease, including pulmonary function tests and measurements of gas exchange, are discussed in Chap. 246.**

IMAGING STUDIES

Routine Radiography Routine chest radiography, generally including both posteroanterior and lateral views, is an integral part of the diagnostic evaluation of diseases involving the pulmonary parenchyma, the pleura, and, to a lesser extent, the airways and the mediastinum (see **Chap. e24**). Lateral decubitus views are often useful for determining whether pleural abnormalities represent freely flowing fluid, whereas apical lordotic views can often visualize disease at the lung apices better than the standard posteroanterior view. Portable equipment, which is often used for acutely ill patients who either cannot be transported to a radiology suite or cannot stand for posteroanterior and lateral views, generally yields a single radiograph taken in the anteroposterior direction. Common radiographic patterns and their clinical correlates are reviewed in **Chap. e24**.

Computed Tomography CT offers several advantages over routine chest radiography (**Figs. 247-1** and **247-2**; see also Figs. 255-3, 255-4, and 262-4). First, the use of cross-sectional images allows distinction between densities that would be superimposed on plain radiographs. Second, CT is far better than routine radiographic studies at characterizing tissue density, distinguishing subtle density differences between adjacent structures, and providing accurate size assessment of lesions. As a result, CT is particularly valuable in assessing hilar and mediastinal disease (which is often poorly characterized by plain radiography), in identifying and characterizing disease adjacent to the chest wall or spine (including pleural disease), and in identifying areas of fat density or calcification in pulmonary nodules (Fig. 247-1). Its utility in the assessment of mediastinal disease has made CT an important tool in the staging of lung cancer (Chap. 85), as an assessment of tumor involvement of mediastinal lymph nodes is critical to proper staging. With the additional use of contrast material, CT also makes it possible to distinguish vascular from nonvascular structures, which is particularly important in distinguishing lymph nodes and masses from vascular structures primarily in the mediastinum.

FIGURE 247-1 CT scan demonstrating a mediastinal mass of heterogeneous density (*arrow*). CT is superior to plain radiography for the detection of abnormal mediastinal densities and the distinction of masses from adjacent vascular structures.

FIGURE 247-2 High-resolution CT scan from a patient with idiopathic pulmonary fibrosis. There are scattered reticular densities (arrows point to examples) that are especially prominent at the periphery of the lungs. This particular cross-section is from the base of the lungs, where the findings in idiopathic pulmonary fibrosis tend to be most marked.

Helical CT scanning allows the collection of continuous data over a larger volume of lung during a single breath-holding maneuver than is possible with conventional CT. With CT angiography, in which IV contrast is administered and images are acquired rapidly by helical scanning, pulmonary emboli can be detected in segmental and larger pulmonary arteries. With high-resolution CT (HRCT), the thickness of individual cross-sectional images is ~1–2 mm, rather than the usual 7–10 mm, and the images are reconstructed using high-spatial-resolution algorithms. The visible detail on HRCT scans allows better recognition of subtle parenchymal and airway disease, such as bronchiectasis, emphysema, and diffuse parenchymal disease (Fig. 247-2). Certain characteristic patterns have now been recognized for many of the interstitial lung diseases, such as lymphangitic carcinoma, idiopathic pulmonary fibrosis, sarcoidosis, and eosinophilic granuloma; however, it is not yet clear in what settings these patterns obviate the need for obtaining lung tissue.

Recent advances in computer processing of helical scanning data have provided the opportunity to display images in views and planes other than the traditional cross-sectional view, including sophisticated three-dimensional reconstructions, to produce images (called *virtual bronchoscopy*) mimicking direct visualization through a bronchoscope.

Magnetic Resonance Imaging The role of MR imaging in the evaluation of respiratory system disease is less well defined than that of CT. Because MR generally provides a less detailed view of the pulmonary parenchyma as well as poorer spatial resolution, its usefulness in the evaluation of parenchymal lung disease is limited at present. However, MR images can be reconstructed in sagittal and coronal as well as transverse planes, so that the technique is well suited for imaging abnormalities near the lung apex, the spine, and the thoracoabdominal junction. MR images depend on tissue characteristics other than density, unlike CT scanning. Therefore, in selected circumstances, MR images can better suggest the nature of abnormal tissue than can density-determined CT images. Finally, MR is particularly well-suited to evaluate intrathoracic cardiovascular pathology and to distinguish vascular from nonvascular structures without the need for contrast. Flowing blood does not produce a signal on MR imaging, so vessels appear as hollow tubular

structures. This feature can be useful in determining whether abnormal hilar or mediastinal densities are vascular in origin and in defining aortic lesions, such as aneurysms or dissection. In addition, gadolinium can be used as an intravascular contrast agent for MR angiography.

Scintigraphic Imaging Radioactive isotopes, administered by either IV or inhaled routes, allow the lungs to be imaged with a gamma camera. In the past, scintigraphic imaging in the form of ventilation-perfusion lung scanning was commonly performed for evaluation of pulmonary embolism. However, with advances in CT scanning, scintigraphic imaging has largely been replaced by CT angiography in patients with suspected pulmonary embolism. When injected intravenously, albumin macroaggregates labeled with technetium 99m become lodged in pulmonary capillaries; therefore, the distribution of the trapped radioisotope follows the distribution of blood flow. When inhaled, radiolabeled xenon gas can be used to demonstrate the distribution of ventilation. For example, pulmonary thromboembolism usually produces one or more regions of ventilation-perfusion mismatch, i.e., regions in which there is a defect in perfusion that follows the distribution of a vessel and that is not accompanied by a corresponding defect in ventilation (Chap. 256). Another common use of such radioisotope scans is in a patient with impaired lung function who is being considered for lung resection. The distribution of the isotope(s) can be used to assess the regional distribution of blood flow and ventilation, allowing the physician to estimate the level of postoperative lung function.

Positron Emission Tomographic Scanning Positron emission tomographic (PET) scanning is increasingly being used to identify malignant lesions in the lung based on their increased uptake and metabolism of glucose. The technique involves injection of a radiolabeled glucose analogue, [^{18}F]-fluoro-2-deoxyglucose (FDG), which is taken up by metabolically active malignant cells. However, FDG is trapped within the cell following phosphorylation, and the unstable fluorine 18 decays by emission of positrons, which can be detected by a specialized PET camera or by a gamma camera that has been adapted for imaging of positron-emitting nuclides. This technique has been used in the evaluation of solitary pulmonary nodules and as an aid to staging lung cancer through identification of mediastinal lymph node involvement by malignancy.

Pulmonary Angiography The pulmonary arterial system can be visualized by pulmonary angiography, in which radiopaque contrast medium is injected through a catheter previously placed in the pulmonary artery. When performed in cases of pulmonary embolism, pulmonary angiography demonstrates the consequences of an intravascular thrombus—either a defect in the lumen of a vessel (a "filling defect") or an abrupt termination ("cutoff") of the vessel. Other, less common indications for pulmonary angiography include visualization of a suspected pulmonary arteriovenous malformation and assessment of pulmonary arterial invasion by a neoplasm. However, with advances in CT scanning, traditional pulmonary angiography has largely been replaced by CT angiography. The latter allows rapid acquisition of images with a less invasive procedure, since the radiocontrast material is injected intravenously rather than into a pulmonary artery.

Ultrasound Because ultrasound energy is rapidly dissipated in air, ultrasound imaging is not useful for evaluation of the pulmonary parenchyma. However, ultrasound is helpful in the detection and localization of pleural abnormalities and is often used as a guide to placement of a needle for sampling of pleural liquid (i.e., for thoracentesis). Endobronchial ultrasound, in which the ultrasound probe is passed through a bronchoscope, is emerging as a valuable adjunct to bronchoscopy, allowing identification and localization of pathology adjacent to airway walls or within the mediastinum.

TECHNIQUES FOR OBTAINING BIOLOGIC SPECIMENS

Collection of Sputum Sputum can be collected either by spontaneous expectoration or after inhalation of an irritating aerosol, such as hypertonic saline. The latter method, called *sputum induction*, is commonly used to obtain sputum for diagnostic studies, either because sputum is not spontaneously being produced or because of an expected higher yield of certain types of findings. Knowledge of the appearance and quality of the sputum specimen obtained is especially important when one is interested in Gram's staining and culture. Because sputum consists mainly of secretions from the tracheobronchial tree rather than the upper airway, the finding of alveolar macrophages and other inflammatory cells is consistent with a lower respiratory tract origin of the sample, whereas the presence of squamous epithelial cells in a "sputum" sample indicates contamination by secretions from the upper airways.

In addition to processing for routine bacterial pathogens by Gram's staining and culture, sputum can be processed for a variety of other pathogens, including staining and culture for mycobacteria or fungi, culture for viruses, and staining for *Pneumocystis jiroveci*. In the specific case of sputum obtained for evaluation of *P. jiroveci* pneumonia in a patient infected with HIV, for example, sputum should be collected by induction rather than spontaneous expectoration, and an immunofluorescent stain should be used to detect the organisms. Cytologic staining of sputum for malignant cells, using the traditional Papanicolaou method, allows noninvasive evaluation for suspected lung cancer. Traditional stains and cultures are now also being supplemented in some cases by immunologic techniques and by molecular biologic methods, including the use of polymerase chain reaction amplification and DNA probes.

Percutaneous Needle Aspiration A needle can be inserted through the chest wall into a pulmonary lesion to aspirate material for analysis by cytologic or microbiologic techniques. The procedure is usually carried out under CT guidance to assist positioning of the needle and assure localization in the lesion. The low potential risk of this procedure (intrapulmonary bleeding or creation of a pneumothorax with collapse of the underlying lung) in experienced hands is usually acceptable owing to the information obtained. However, a limitation of the technique is sampling error due to the small size of the tissue sample. Thus, findings other than a specific cytologic or microbiologic diagnosis are of limited clinical value.

Thoracentesis Sampling of pleural liquid by thoracentesis is commonly performed for diagnostic purposes or, in the case of a large effusion, for palliation of dyspnea. Diagnostic sampling, either by blind needle aspiration or after localization by ultrasound, allows the collection of liquid for microbiologic and cytologic studies. Analysis of the fluid obtained for its cellular composition and chemical constituents, including glucose, protein, and lactate dehydrogenase, allows the effusion to be classified as either exudative or transudative (Chap. 257).

Bronchoscopy Bronchoscopy is the process of direct visualization of the tracheobronchial tree. Although bronchoscopy is now performed almost exclusively with flexible fiberoptic instruments, rigid bronchoscopy, generally performed in an operating room on a patient under general anesthesia, still has a role in selected circumstances, primarily because of a larger suction channel and the fact that the patient can be ventilated through the bronchoscope channel. These situations include the retrieval of a foreign body and the suctioning of a massive hemorrhage, for which the small suction channel of the bronchoscope may be insufficient.

FLEXIBLE FIBEROPTIC BRONCHOSCOPY This outpatient procedure is usually performed in an awake but sedated patient. The bronchoscope is passed through either the mouth or the nose, between the vocal cords, and into the trachea. The ability to flex the scope makes it possible to visualize virtually all airways to the level of subsegmental bronchi. The bronchoscopist is able to identify endobronchial pathology, including tumors, granulomas, bronchitis, foreign bodies, and sites of bleeding. Samples from airway lesions can be taken by several methods, including washing, brushing, and biopsy. Washing involves instillation of

sterile saline through a channel of the bronchoscope and onto the surface of a lesion. A portion of the liquid is collected by suctioning through the bronchoscope, and the recovered material can be analyzed for cells (cytology) or organisms (by standard stains and cultures). Brushing or biopsy of the surface of the lesion, using a small brush or biopsy forceps at the end of a long cable inserted through a channel of the bronchoscope, allows recovery of cellular material or tissue for analysis by standard cytologic and histopathologic methods.

The bronchoscope can be used to sample material not only from the regions that can be directly visualized (i.e., the airways) but also from the more distal pulmonary parenchyma. With the bronchoscope wedged into a subsegmental airway, aliquots of sterile saline can be instilled through the scope, allowing sampling of cells and organisms even from alveolar spaces. This procedure, called *bronchoalveolar lavage*, has been particularly useful for the recovery of organisms such as *P. jiroveci* in patients with HIV infection.

Brushing and biopsy of the distal lung parenchyma can also be performed with the same instruments that are used for endobronchial sampling. These instruments can be passed through the scope into small airways, where they penetrate the airway wall, allowing biopsy of peribronchial alveolar tissue. This procedure, called *transbronchial biopsy*, is used when there is either relatively diffuse disease or a localized lesion of adequate size. With the aid of fluoroscopic imaging, the bronchoscopist is able to determine not only whether and when the instrument is in the area of abnormality, but also the proximity of the instrument to the pleural surface. If the forceps are too close to the pleural surface, there is a risk of violating the visceral pleura and creating a pneumothorax; the other potential complication of transbronchial biopsy is pulmonary hemorrhage. The incidence of these complications is less than several percent.

Another procedure involves use of a hollow-bore needle passed through the bronchoscope for sampling of tissue adjacent to the trachea or a large bronchus. The needle is passed through the airway wall, and cellular material can be aspirated from mass lesions or enlarged lymph nodes, generally in a search for malignant cells. This procedure can facilitate the staging of lung cancer by identifying mediastinal lymph node involvement and in some cases obviates the need for a more invasive procedure. Other promising new techniques that are not yet widely available include fluorescence bronchoscopy (to detect early endobronchial malignancy) and endobronchial ultrasound (to better identify and localize peribronchial and mediastinal pathology).

The bronchoscope may provide the opportunity for treatment as well as diagnosis. For example, an aspirated foreign body may be retrieved with an instrument passed through the scope, and bleeding may be controlled with a balloon catheter similarly introduced. Newer interventional techniques performed through a bronchoscope include methods for achieving and maintaining patency of airways that are partially or completely occluded, especially by tumors. These techniques include laser therapy, cryotherapy, argon plasma coagulation, electrocautery, and stent placement.

Video-Assisted Thoracic Surgery Advances in video technology have allowed the development of thoracoscopy, or video-assisted thoracic surgery (VATS), for the diagnosis and management of pleural as well as parenchymal lung disease. This procedure involves the passage of a rigid scope with a distal lens through a trocar inserted into the pleura. A high-quality image is shown on a monitor screen, allowing the operator to manipulate instruments passed into the pleural space through separate small intercostal incisions. With these instruments, the operator can biopsy lesions of the pleura under direct vision. In addition, this procedure is now used commonly to biopsy peripheral lung tissue or to remove peripheral nodules, for both diagnostic and therapeutic purposes. This much less invasive procedure has largely supplanted the traditional "open lung biopsy" performed by thoracotomy.

Thoracotomy Although frequently replaced by VATS, thoracotomy remains an option for the diagnostic sampling of lung tissue. It provides the largest amount of material, and it can be used to biopsy and/or excise lesions that are too deep or too close to vital structures for removal by VATS. The choice between VATS and thoracotomy needs to be made on a case-by-case basis.

Mediastinoscopy and Mediastinotomy Tissue biopsy is often critical for the diagnosis of mediastinal masses or enlarged mediastinal lymph nodes. Although CT and PET scanning are useful for determining the size and nature of mediastinal lymph nodes as part of the staging of lung cancer, confirmation that enlarged lymph nodes are actually involved with tumor generally requires biopsy and histopathologic examination. The two major procedures used to obtain specimens from masses or nodes in the mediastinum are mediastinoscopy (via a suprasternal approach) and mediastinotomy (via a parasternal approach). Both procedures are performed under general anesthesia by a qualified surgeon. In the case of suprasternal mediastinoscopy, a rigid mediastinoscope is inserted at the suprasternal notch and passed into the mediastinum along a pathway just anterior to the trachea. Tissue can be obtained with biopsy forceps passed through the scope, sampling masses or nodes that are in a paratracheal or pretracheal position. Left paratracheal and aortopulmonary lymph nodes are not accessible by this route and thus are commonly sampled by parasternal mediastinotomy (the Chamberlain procedure). This approach involves either a right or left parasternal incision and dissection directly down to a mass or node that requires biopsy.

248 Asthma

Peter J. Barnes

Asthma is a syndrome characterized by airflow obstruction that varies markedly, both spontaneously and with treatment. Asthmatics harbor a special type of inflammation in the airways that makes them more responsive than nonasthmatics to a wide range of triggers, leading to excessive narrowing with consequent reduced airflow and symptomatic wheezing and dyspnea. Narrowing of the airways is usually reversible, but in some patients with chronic asthma there may be an element of irreversible airflow obstruction. The increasing global prevalence of asthma, the large burden it now imposes on patients, and the high health care costs have led to extensive research into its mechanisms and treatment.

PREVALENCE

Asthma is one of the most common chronic diseases globally and currently affects ~300 million people. The prevalence of asthma has risen in affluent countries over the last 30 years but now appears to have stabilized, with ~10–12% of adults and 15% of children affected by the disease. In developing countries where the prevalence of asthma had been much lower, there is a rising incidence that appears to be associated with increased urbanization. The prevalence of atopy and other allergic diseases has also increased over the same time, suggesting that the reasons for the increase are likely to be systemic rather than confined to the lungs. This epidemiologic observation suggests that there is a maximum number of individuals in the community who are liable to be affected by asthma, likely by genetic predisposition. Most patients with asthma in affluent countries are atopic, with allergic sensitization to the house dust mite *Dermatophagoides pteronyssinus* and other environmental allergens.

Asthma is both common and frequently complicated by the effects of smoking on the lungs; hence, it is difficult to be certain about the natural history of the disease in adults. Asthma can present at any age with a peak age of 3 years. In childhood, twice as many males as females are asthmatic, but by adulthood the sex ratio has equalized. The commonly held belief that children "grow out of their asthma" is justified to some extent. Long-term studies that have followed children until they reach the age of 40 years suggest that many with asthma become asymptomatic during adolescence but that asthma returns in some during adult life, particularly in children with persistent symptoms and severe asthma. Adults with asthma, including those with onset during adulthood rarely become permanently asymptomatic. The severity of asthma does not vary significantly within a given patient; those with mild asthma rarely progress to more severe disease, whereas those with severe asthma usually have severe disease at the onset.

Deaths from asthma are uncommon and have been steadily declining in many affluent countries over the last decade. A rise in asthma mortality seen in several countries during the 1960s was associated with increased use of short-acting β_2-adrenergic agonists (as rescue therapy), but there is now compelling evidence that the more widespread use of inhaled corticosteroids (ICSs) in patients with persistent asthma is responsible for the decrease in mortality in recent years. Major risk factors for asthma deaths are poorly controlled disease with frequent use of bronchodilator inhalers, lack of corticosteroid therapy, and previous admissions to the hospital with near-fatal asthma.

It has proved difficult to agree on a definition of asthma, but there is good agreement on the description of the clinical syndrome and disease pathology. Until the etiologic mechanisms of the disease are better understood, it will be difficult to provide an accurate definition.

ETIOLOGY

Asthma is a heterogeneous disease with interplay between genetic and environmental factors. Several risk factors have been implicated (Table 248-1).

ATOPY

Atopy is the major risk factor for asthma, and nonatopic individuals have a very low risk of developing asthma. Patients with asthma commonly suffer from other atopic diseases, particularly allergic rhinitis, which may be found in over 80% of asthmatic patients, and atopic dermatitis (eczema). Atopy may be found in 40–50% of the population in affluent countries, with only a proportion of atopic individuals becoming asthmatic. This observation suggests that some other environmental or genetic factor(s) predispose to the development of asthma in atopic individuals. The allergens that lead to sensitization are usually proteins that have protease activity, and the commonest allergens are derived from house dust mites, cat and dog fur, cockroaches, grass and tree pollens, and rodents (in laboratory workers). Atopy is due to the genetically determined production of specific IgE antibody, with many patients showing a family history of allergic diseases.

INTRINSIC ASTHMA

A minority of asthmatic patients (approximately 10%) have negative skin test to common inhalant allergens and normal serum concentrations of IgE. These patients, with nonatopic or intrinsic asthma, usually show later onset of disease (adult-onset asthma), commonly have concomitant nasal polyps, and may be aspirin-sensitive. They usually have more severe, persistent asthma. Little is understood about mechanism, but the immunopathology in bronchial biopsies and sputum appears to be identical to that found in atopic asthma. There is recent evidence for increased local production of IgE in the airways, suggesting that there may be common IgE mediated mechanisms.

INFECTIONS

Although viral infections are common as triggers of asthma exacerbations, it is uncertain whether they play a role in etiology. There is some association between respiratory syncytial virus infection in infancy and the development of asthma, but the specific pathogenesis is difficult to elucidate, as this infection is very common in children. More recently, atypical bacteria such as *Mycoplasma* and *Chlamydia* have been implicated in the mechanism of severe asthma, but thus far evidence of a true association is not very convincing.

TABLE 248-1 RISK FACTORS AND TRIGGERS INVOLVED IN ASTHMA

Endogenous Factors	Environmental Factors
Genetic predisposition	Indoor allergens
Atopy	Outdoor allergens
Airway hyperresponsiveness	Occupational sensitizers
Gender	Passive smoking
Ethnicity?	Respiratory infections
	Obesity?
	Early viral infections?
Triggers	
Allergens	
Upper respiratory tract viral infections	
Exercise and hyperventilation	
Cold air	
Sulfur dioxide	
Drugs (β blockers, aspirin)	
Stress	
Irritants (household sprays, paint fumes)	

GENETIC CONSIDERATIONS The familial association of asthma and a high degree of concordance for asthma in identical twins indicate a genetic predisposition to the disease; however, whether or not the genes predisposing to asthma are similar or in addition to those predisposing of atopy is not yet clear. It now seems likely that different genes may also contribute to asthma specifically, and there is increasing evidence that the severity of asthma is also genetically determined. Genetic screens with classical linkage analysis and single nucleotide polymorphisms of various candidate genes indicate that asthma is polygenic, with each gene identified having a small effect that is often not replicated in different populations. This observation suggests that the interaction of many genes is important, and these may differ in different populations. The most consistent findings have been associations with polymorphisms of genes on chromosome 5q, including the T helper 2 (T_H2) cells interleukin (IL) 4, IL-5, IL-9, and IL-13, which are associated with atopy. There is increasing evidence for a complex interaction between genetic polymorphisms and environmental factors that will require very large population studies to unravel. Novel genes that have been associated with asthma, including ADAM-33, DPP-10, and GPRA, have also been identified by positional cloning, but their function in disease pathogenesis is thus far obscure. Genetic polymorphisms may also be important in determining the response to asthma therapy. For example, the Arg-Gly-16 variant in the β_2-receptor is associated with reduced response to β_2-agonists, and repeats of an Sp1 recognition sequence in the promoter region of 5-lipoxygenase may affect the response to antileukotrienes.

ENVIRONMENTAL FACTORS

It is likely that environmental factors in early life determine which atopic individuals become asthmatic. The increasing prevalence of asthma, particularly in developing countries, over the last few decades also indicates the importance of environmental mechanisms interacting with a genetic predisposition.

Hygiene Hypothesis The observation that allergic sensitization and asthma were less common in children with older siblings first suggested that lower levels of infection may be a factor in affluent societies that increase the risks of asthma. This "hygiene hypothesis" proposes that lack of infections in early childhood preserves the T_H2 cell bias at birth, whereas exposure to infections and endotoxin results in a shift toward a predominant protective T_H1 response. Children brought up on farms who are exposed to a high level of endotoxin are less likely to develop allergic sensitization than children raised on dairy farms. Intestinal parasite infection may also be associated with a reduced risk of asthma. While there is considerable epidemiologic support for the hygiene hypothesis, it cannot account for the parallel increase in T_H1-driven diseases, such as diabetes mellitus, over the same period.

Diet The role of dietary factors is controversial. Observational studies have shown that diets low in antioxidants, such as vitamin C and vitamin A, magnesium, selenium, and omega-3 polyunsaturated fats (fish oil), or high in sodium and omega-6 polyunsaturates are associated with an increased risk of asthma. However, interventional studies have not supported an important role for these dietary factors. Obesity is also an independent risk factor for asthma, particularly in women, but the mechanisms are thus far unknown.

Air Pollution There is no doubt that air pollutants, such as sulfur dioxide, ozone, and diesel particulates, may trigger asthma symptoms, but the role of different air pollutants in the etiology of the disease is much less certain. Most evidence argues against an important role for air pollution as asthma is no more prevalent in cities with a high ambient level of traffic pollution than in rural areas with low levels of pollution. Asthma had a much lower prevalence in East Germany compared to West Germany despite a much higher level of air pollution, but since reunification these differences have decreased as eastern Germany has become more affluent. Indoor air pollution may be more important with exposure to nitrogen oxides from cooking stoves and exposure to passive cigarette smoke. There is some evidence that maternal smoking is a risk factor for asthma, but it is difficult to dissociate this from an increased risk of respiratory infections.

Allergens Inhaled allergens are common triggers of asthma symptoms and have also been implicated in allergic sensitization. Exposure to house dust mites in early childhood is a risk factor for allergic sensitization and asthma, but rigorous allergen avoidance has not shown any evidence for a reduced risk of developing asthma. The increase in house dust mites in centrally heated, poorly ventilated homes with fitted carpets has been implicated in the increasing prevalence of asthma in affluent countries. Domestic pets, particularly cats, have also been associated with allergic sensitization, but early exposure to cats in the home may be protective through the induction of tolerance.

Occupational Exposure Occupational asthma is relatively common and may affect up to 10% of young adults. Over 200 sensitizing agents have been identified. Chemicals, such as toluene diisocyanate and trimellitic anhydride, may lead to sensitization independent of atopy. Individuals may also be exposed to allergens in the workplace, such as small animal allergens in laboratory workers and fungal amylase in wheat flour in bakers.

OTHER FACTORS

Several other factors have been implicated in the etiology of asthma, including lower maternal age, duration of breast-feeding, prematurity and low birth weight, and inactivity, but are unlikely to contribute to the recent global increase in asthma prevalence. There is also an association with acetaminophen (paracetamol) consumption, which remains unexplained.

PATHOGENESIS

Asthma is associated with a specific chronic inflammation of the mucosa of the lower airways. One of the main aims of treatment is to reduce this inflammation.

PATHOLOGY

The pathology of asthma has been revealed through examining the lungs at autopsy in patients who have died of asthma and from bronchial biopsies in patients with usually mild asthma. The airway mucosa is infiltrated with activated eosinophils and T lymphocytes, and there is activation of mucosal mast cells. The degree of inflammation is poorly related to disease severity and may be found in atopic patients without asthma symptoms. The inflammation is reduced by treatment with ICSs. A characteristic finding is thickening of the basement membrane due to subepithelial collagen deposition. This feature is also found in patients with eosinophilic bronchitis presenting as cough who do not have asthma; it is therefore likely to be a marker of eosinophilic inflammation in the airway, as eosinophils release fibrogenic factors. The epithelium is often shed or friable, with reduced attachments to the airway wall and increased numbers of epithelial cells in the lumen. The airway wall itself may be thickened and edematous, particularly in fatal asthma. Another common finding in fatal asthma is occlusion of the airway lumen by a mucous plug, which is composed of mucus glycoproteins secreted from goblet cells and plasma proteins from leaky bronchial vessels (Fig. 248-1). There is also vasodilatation and increased numbers of blood vessels (angiogenesis). Direct observation by bronchoscopy indicates that the airways may be narrowed, reddened, and edematous. The pathology of asthma is remarkably uniform in different types of asthma, including atopic, nonatopic, occupational, aspirin-sensitive, and pediatric asthma. These pathologic changes are found in all airways but do not extend to the lung parenchyma; small airway inflammation is found particularly in patients with severe asthma. The involvement of airways may be patchy, and this is consistent with bronchographic findings of uneven narrowing of the airways.

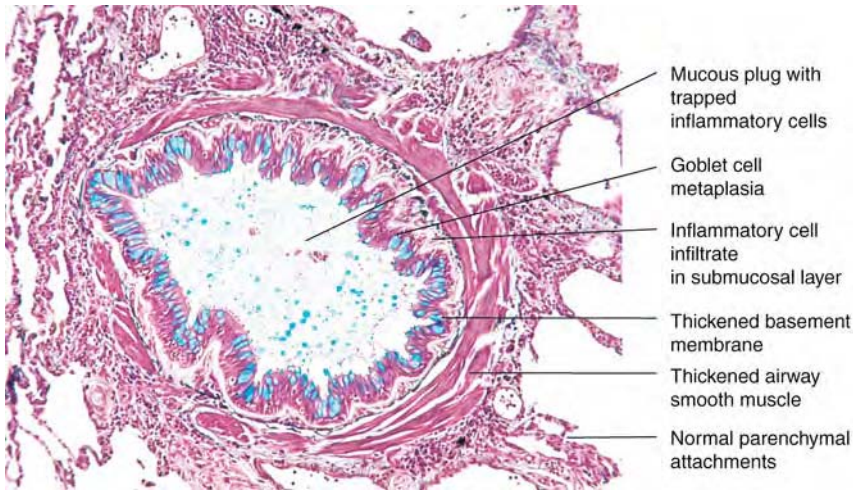

FIGURE 248-1 Histopathology of a small airway in fatal asthma. The lumen is occluded with a mucous plug, there is goblet cell metaplasia, and the airway wall is thickened, with an increase in basement membrane thickness and airway smooth muscle. *(Courtesy of Dr. J. Hogg, University of British Colombia; with permission.)*

INFLAMMATION

There is inflammation in the respiratory mucosa from trachea to terminal bronchioles, but with a predominance in the bronchi (cartilaginous airways). Considerable research has identified the major cellular components of inflammation, but it is still uncertain how inflammatory cells interact and how inflammation translates into the symptoms of asthma (Fig. 248-2). There is good evidence that the specific pattern of airway inflammation in asthma is associated with airway hyperresponsiveness (AHR), the physiologic abnormality of asthma that is correlated with variable airflow obstruction. The pattern of inflammation in asthma is characteristic of allergic diseases, with similar inflammatory cells seen in the nasal mucosa in rhinitis. However, an indistinguishable pattern of inflammation is found in intrinsic asthma, although this may reflect local rather than systemic IgE production. Although most attention has focused on the acute inflammatory changes seen in asthma, this is a chronic condition, with inflammation persisting over many years in most patients. The mechanisms involved in persistence of inflammation in asthma are still poorly understood. Superimposed on this chronic inflammatory state are acute inflammatory episodes, which correspond to exacerbations of asthma. Many inflammatory cells are known to be involved in asthma, with no predominant key cell (Fig. 248-3).

Mast Cells Mast cells are important in initiating the acute bronchoconstrictor responses to allergens and several other indirectly acting stimuli, such as exercise and hyperventilation (via osmolality or thermal changes), as well as fog. In biopsies from asthmatic patients, mast cells are localized to the airway smooth muscle layer; they are not found in normal subjects or in patients with eosinophilic cough. Mast cells are activated by allergens through an IgE-dependent mechanism, and binding of specific IgE to mast cells renders them more sensitive to activation. The importance of IgE in the pathophysiology of asthma has been highlighted by clinical studies with humanized anti-IgE antibodies, which inhibit IgE-mediated effects, reduce asthma symptoms, and prevent exacerbations. There are, however, uncertainties about the role of mast cells in more chronic allergic inflammatory events. Mast cells release several bronchoconstrictor mediators, including histamine and cysteinyl-leukotrienes, but also several cytokines, chemokines, growth factors, and neurotrophins.

Macrophages and Dendritic Cells Macrophages, which are derived from blood monocytes, may traffic into the airways in asthma and may be activated by allergens via low-affinity IgE receptors ($Fc_{\varepsilon}RII$). Macrophages have the capacity to initiate a type of inflammatory response via the release of a certain pattern of cytokines, but these cells also release anti-inflammatory mediators, such as IL-10, and thus their role in asthma is uncertain. Dendritic cells are specialized macrophage-like cells in the airway epithelium, which are the major antigen-presenting cells. Dendritic cells take up allergens, process them to peptides, and migrate to local lymph nodes where they present the allergenic peptides to uncommitted T-lymphocytes to program the production of allergen-specific T cells. Immature dendritic cells in the respiratory tract promote T_H2 cell differentiation and require cytokines, such as IL-12 and TNF-α, to promote the normally preponderant T_H1 response.

Eosinophils Eosinophil infiltration is a characteristic feature of asthmatic airways. Allergen inhalation results in a marked increase in activated eosinophils in the airways at the time of the late reaction. Eosinophils are linked to the development of airway hyperresponsiveness through the release of basic proteins and oxygen-derived free radicals. Eosinophil recruitment involves adhesion of eosinophils to vascular endothelial cells in the airway circulation due to interaction between adhesion molecules, migration into the submucosa under the direction of chemokines, and their subsequent activation and prolonged survival. Blocking antibodies to IL-5 cause a profound and prolonged reduction in circulating and sputum eosinophils, but they are not associated with reduced AHR or asthma symptoms, thus questioning the pivotal role of eosinophils in asthma. Furthermore, eosinophilic inflammation is also found in patients with chronic cough who do not have any clinical features of asthma or AHR. Increasing evidence suggests that eosinophils may be more important in release of growth factors involved in airway remodeling than in AHR.

Neutrophils Increased numbers of activated neutrophils are found in sputum and airways of some patients with severe asthma and during exacerbations, although there is a proportion of patients even with mild or moderate asthma that have a predominance of neutrophils. The role of neutrophils in asthma, which are resistant to the anti-inflammatory effects of corticosteroids, is currently unknown.

T Lymphocytes T lymphocytes play a very important role in coordinating the inflammatory response in asthma through the release of specific patterns of cytokines, resulting in the recruitment and survival of eosinophils and in the maintenance of a mast cell population in the airways. The naïve immune system and the immune system of asthmatics are skewed to express the T_H2 phenotype, whereas in normal airways T_H1 cells predominate. T_H2 cells, through the release of IL-5, are associated with eosinophilic inflammation and, through the release of IL-4 and IL-

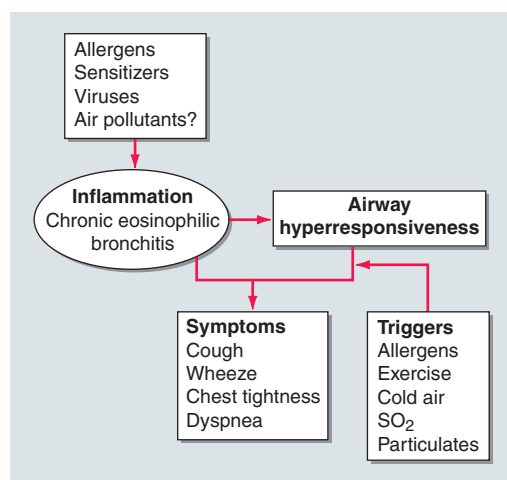

FIGURE 248-2 Inflammation in the airways of asthmatic patients leads to airway hyperresponsiveness and symptoms.

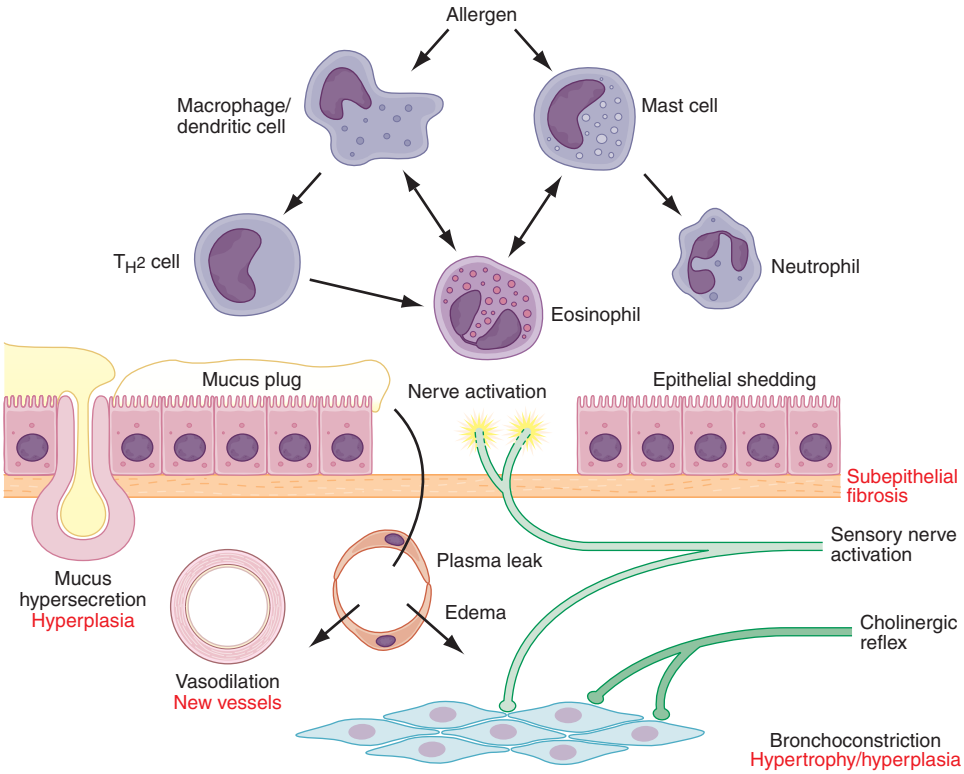

FIGURE 248-3 The pathophysiology of asthma is complex, with participation of several interacting inflammatory cells, resulting in acute and chronic inflammatory effects on the airway.

13, are associated with increased IgE formation. Recently, bronchial biopsies have demonstrated a preponderance of natural killer CD4+ T lymphocytes, which express high levels of IL-4. Regulatory T cells play an important role in determining the expression of other T cells, and there is evidence for a reduction in a certain subset of regulatory T cells (CD4+CD25+) in asthma, which is associated with increased T_H2 cells.

Structural Cells Structural cells of the airways, including epithelial cells, fibroblasts and airway smooth-muscle cells, are also an important source of inflammatory mediators, such as cytokines and lipid mediators, in asthma. Indeed, because structural cells far outnumber inflammatory cells, they may become the major source of mediators driving chronic inflammation in asthmatic airways. In addition, epithelial cells may have a key role in translating inhaled environmental signals into an airway inflammatory response, and are probably a major target cell for ICSs.

INFLAMMATORY MEDIATORS

Many different mediators have been implicated in asthma, and they may have a variety of effects on the airways that could account for the pathologic features of asthma (Fig. 248-4). Mediators such as histamine, prostaglandins, and cysteinyl-leukotrienes contract airway smooth muscle, increase microvascular leakage, increase airway mucus secretion, and attract other inflammatory cells. Because each mediator has many effects, the role of individual mediators in the pathophysiology of asthma is not yet clear. Although the multiplicity of mediators makes it unlikely that preventing the synthesis or action of a single mediator will have a major impact in clinical asthma, recent clinical studies with antileukotrienes suggest that cysteinyl-leukotrienes have a clinically important effect.

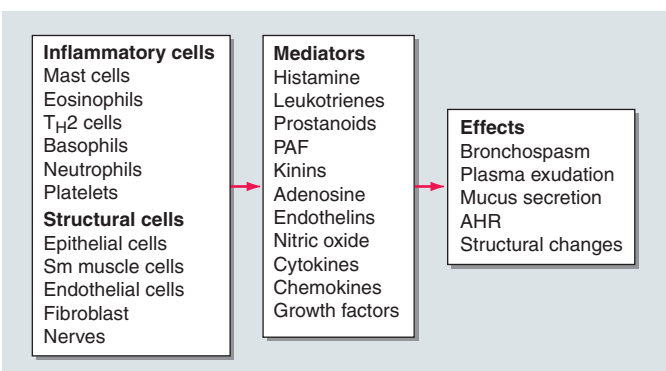

FIGURE 248-4 Many cells and mediators are involved in asthma and lead to several effects on the airways.

Cytokines Multiple cytokines regulate the chronic inflammation of asthma. The T_H2 cytokines IL-4, IL-5, and IL-13 mediate allergic inflammation, whereas proinflammatory cytokines, such as tumor necrosis factor α (TNF-α) and IL-1β, amplify the inflammatory response and play a role in more severe disease. Thymic stromal lymphopoietin is an upstream cytokine released from epithelial cells of asthmatics that orchestrates the release of chemokines, which selectively attract T_H2 cells. Some cytokines, such as IL-10 and IL-12, are anti-inflammatory and may be deficient in asthma.

Chemokines Chemokines are involved in attracting inflammatory cells from the bronchial circulation into the airways. Eotaxin (CCL11) is selectively attractant to eosinophils via CCR3 and is expressed by epithelial cells of asthmatics, whereas CCL17 (TARC) and CCL22 (MDC) from epithelial cells attract T_H2 cells via CCR4 (Fig. 248-5).

Oxidative Stress There is increased oxidative stress in asthma as activated inflammatory cells, such as macrophages and eosinophils, produce reactive oxygen species. Evidence for increased oxidative stress in asthma is provided by the increased concentrations of 8-isoprostane (a product of oxidized arachidonic acid) in exhaled breath condensates

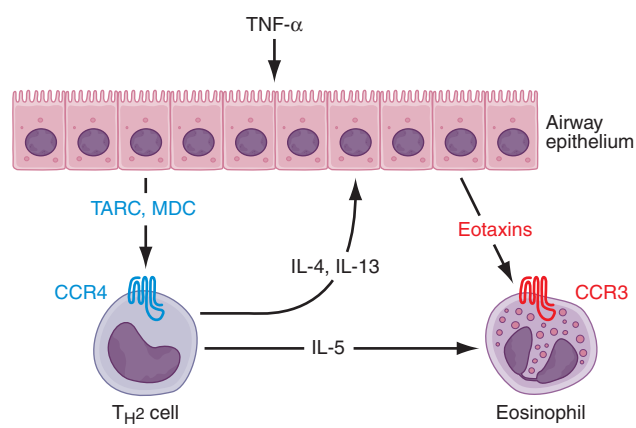

FIGURE 248-5 Chemokines in asthma. Tumor necrosis factor α (TNF-α) and other triggers of airway epithelial cells release thymus and activation-regulated chemokine (TARC, CCL17) and macrophage-derived chemokine (MDC, CCL22) from epithelial cells, which attract T_H2 cells via activation of their CCR4 receptors. These promote eosinophilic inflammation directly through the release of interleukin 5 (IL-5) and indirectly via the release of IL-4 and IL-13, which induce eotaxin (CCL11) formation in airway epithelial cells.

and increased ethane (a product of lipid peroxidation) in the expired air of asthmatic patients. Increased oxidative stress is related to disease severity, may amplify the inflammatory response, and may reduce responsiveness to corticosteroids.

Nitric Oxide Nitric oxide (NO) is produced by several cells in the airway by NO synthases, particularly airway epithelial cells and macrophages. The level of NO in the expired air of patients with asthma is higher than normal and is related to the eosinophilic inflammation. Increased NO may contribute to the bronchial vasodilation observed in asthma. Exhaled NO is increasingly used in the diagnosis and monitoring of asthmatic inflammation, although it is not used routinely in clinical practice.

Transcription Factors Proinflammatory transcription factors, such as nuclear factor κB (NFκB) and activator protein 1 (AP-1), are activated in asthmatic airways and orchestrate the expression of multiple inflammatory genes. More-specific transcription factors that are involved include nuclear factor of activated T cells and GATA-3, which regulate the expression of T_H2 cytokines in T cells.

EFFECTS OF INFLAMMATION

The chronic inflammatory response has several effects on the target cells of the airways, resulting in the characteristic pathophysiologic changes associated with asthma. Asthma may be regarded as a disease with continuous inflammation and repair proceeding simultaneously. Important advances continue to be made in our understanding of these changes, but despite these new insights, the relationship between chronic inflammatory processes and asthma symptoms is often not clear.

Airway Epithelium Airway epithelial shedding may be important in contributing to AHR and may explain how several mechanisms, such as ozone exposure, virus infections, chemical sensitizers, and allergen exposure, can lead to its development, as all of these stimuli may lead to epithelial disruption. Epithelial damage may contribute to AHR in a number of ways, including loss of its barrier function to allow penetration of allergens; loss of enzymes (such as neutral endopeptidase) that normally degrade inflammatory mediators; loss of a relaxant factor (so called epithelial-derived relaxant factor); and exposure of sensory nerves, which may lead to reflex neural effects on the airway.

Fibrosis In all asthmatic patients, the basement membrane is apparently thickened due to subepithelial fibrosis with deposition of types III and V collagen below the true basement membrane, and it is associated with eosinophil infiltration, presumably through the release of profibrotic mediators, such as transforming growth factor β. Mechanical manipulations can alter the phenotype of airway epithelial cells in a profibrotic fashion. In more severe patients, there is also fibrosis within the airway wall, which may contribute to irreversible narrowing of the airways.

Airway Smooth Muscle There is still debate about the role of abnormalities in airway smooth muscle is asthmatic airways. In vitro airway smooth muscle from asthmatic patients usually shows no increased responsiveness to constrictors. Reduced responsiveness to β-agonists has also been reported in post-mortem or surgically removed bronchi from asthmatics, although the number of β-receptors is not reduced, suggesting that β-receptors have been uncoupled. These abnormalities of airway smooth muscle may be secondary to the chronic inflammatory process. Inflammatory mediators may modulate the ion channels that serve to regulate the resting membrane potential of airway smooth-muscle cells, thus altering the level of excitability of these cells. In asthmatic airways there is also a characteristic hypertrophy and hyperplasia of airway smooth muscle, which is presumably the result of stimulation of airway smooth-muscle cells by various growth factors, such as platelet-derived growth factor or endothelin 1, released from inflammatory or epithelial cells.

Vascular Responses There is increased airway mucosal blood flow in asthma. The bronchial circulation may play an important role in regulating airway caliber, since an increase in the vascular volume may contribute to airway narrowing. Increased airway blood flow may be important in removing inflammatory mediators from the airway and may play a role in the development of exercise-induced asthma. There is an increase in the number of blood vessels in asthmatic airways as a result of angiogenesis in response to growth factors, particularly vascular-endothelial growth factor. Microvascular leakage from postcapillary venules in response to inflammatory mediators is observed in asthma, resulting in airway edema and plasma exudation into the airway lumen.

Mucus Hypersecretion Increased mucus secretion contributes to the viscid mucus plugs that occlude asthmatic airways, particularly in fatal asthma. There is evidence for hyperplasia of submucosal glands that are confined to large airways and of increased numbers of epithelial goblet cells. IL-4 and IL-13 induce mucus hypersecretion in experimental models of asthma.

Neural Effects Various defects in autonomic neural control may contribute to AHR in asthma, but these are likely to be secondary to the disease, rather than primary defects. Cholinergic pathways, through the release of acetylcholine acting on muscarinic receptors, cause bronchoconstriction and may be activated reflexly in asthma. Inflammatory mediators may activate sensory nerves, resulting in reflex cholinergic bronchoconstriction or release of inflammatory neuropeptides. Inflammatory products may also sensitize sensory nerve endings in the airway epithelium, such that the nerves become hyperalgesic. Neurotrophins, which may be released from various cell types in peripheral tissues, may cause proliferation and sensitization of airway sensory nerves. Airway nerves may also release neurotransmitters, such as substance P, which have inflammatory effects.

AIRWAY REMODELING

Several changes in the structure of the airway are characteristically found in asthma, and these may lead to irreversible narrowing of the airways. Population studies have shown a greater decline in lung function over time than in normal subjects; however, most patients with asthma preserve normal or near-normal lung function throughout life if appropriately treated. This observation suggests that the accelerated decline in lung function occurs in a smaller proportion of asthmatics, and these are usually patients with more severe disease. There is debate about whether the early use of ICSs may reduce the decline in lung function. The characteristic structural changes are increased airway smooth muscle, fibrosis, angiogenesis, and mucus hyperplasia.

ASTHMA TRIGGERS

Several stimuli trigger airway narrowing, wheezing, and dyspnea in asthmatic patients. While the previous view held that these should be avoided, it is now seen as evidence for poor control and an indicator of the need to increase controller therapy.

ALLERGENS

Inhaled allergens are able to activate mast cells with bound IgE directly leading to the immediate release of bronchoconstrictor mediators, resulting in the early response reversed by bronchodilators. Often, experimental allergen challenge is followed by a late response when there is airway edema and an acute inflammatory response with increased eosinophils and neutrophils that is not very reversible with bronchodilators. The most common allergen to trigger asthma is *Dermatophagoides* sp., and environmental exposure leads to low-grade chronic symptoms that are perennial. Perennial allergens are derived from cats and other domestic pets, as well as cockroaches. Other allergens, including grass pollen, ragweed, tree pollen, and fungal spores, are seasonal. Pollens usually cause allergic rhinitis rather than asthma, but in thunderstorms the pollen grains are disrupted, and the particles that

may be released can trigger severe asthma exacerbations (thunderstorm asthma).

VIRUS INFECTIONS

Upper respiratory tract virus infections, such as rhinovirus, respiratory syncytial virus, and coronavirus, are the commonest triggers of acute severe exacerbations. The mechanism whereby these viruses cause exacerbations is poorly understood, but there is an increase in airway inflammation with increased numbers of eosinophils and neutrophils. There is evidence for reduced production of type I interferons by epithelial cells from asthmatic patients, resulting in increased susceptibility to these viral infections and a greater inflammatory response.

PHARMACOLOGIC AGENTS

Several drugs may trigger asthma. β-adrenergic blockers commonly worsen asthma, and their use may be fatal. The mechanisms are not clear but are mediated through increased cholinergic bronchoconstriction. All beta blockers need to be avoided, and even selective β_2 blocker or topical application (e.g., timolol eye drops) may be dangerous. Angiotensin-converting enzyme inhibitors are theoretically detrimental as they inhibit breakdown of kinins, which are bronchoconstrictors; however, they rarely worsen asthma and the characteristic cough is no more frequent in asthmatics than nonasthmatics. Aspirin may worsen asthma in some patients (aspirin-sensitive asthma is discussed below under "Special Considerations").

EXERCISE

Exercise is a common trigger of asthma, particularly in children. The mechanism is linked to hyperventilation, which results in increased osmolality in airway lining fluids and triggers mast cell mediator release, resulting in bronchoconstriction. Exercise-induced asthma (EIA) typically begins after exercise has ended and recovers spontaneously within about 30 min. EIA is worse in cold, dry climates than in hot, humid conditions. It is therefore more common in sports such as cross-country running in cold weather, overland skiing, and ice hockey than in swimming. It may be prevented by prior administration of β_2-agonists and antileukotrienes, but is best prevented by regular treatment with inhaled glucocorticoids, which reduce the population of surface mast cells required for this response.

PHYSICAL FACTORS

Cold air and hyperventilation may trigger asthma through the same mechanisms as exercise. Laughter may also be a trigger. Many patients report worsening of asthma in hot weather and when the weather changes. Some asthmatics become worse when exposed to strong smells or perfumes, but the mechanism of this response is uncertain.

FOOD

There is little evidence that allergic reactions to food lead to increased asthma symptoms, despite the belief of many patients that their symptoms are triggered by particular food constituents. Exclusion diets are usually unsuccessful at reducing the frequency of episodes. Some foods, such as shellfish and nuts, may induce anaphylactic reactions that may include wheezing. Patients with aspirin-induced asthma may benefit from a salicylate-free diet, but these are difficult to maintain. Certain food additives may trigger asthma. Metabisulfite, which is used as a food preservative, may trigger asthma through the release of sulfur dioxide gas in the stomach. Tartrazine, a food yellow-coloring agent, was believed to be a trigger for asthma, but there is little convincing evidence for this.

AIR POLLUTION

Increased ambient levels of sulfur dioxide, ozone, and nitrogen oxides are associated with increased asthma symptoms.

OCCUPATIONAL FACTORS

Several substances found in the workplace may act as sensitizing agents, as discussed above, but may also act as triggers of asthma symptoms. Occupational asthma is characteristically associated with symptoms at work with relief on weekends and holidays. If removed from exposure within the first 6 months of symptoms there is usually complete recovery. More persistent symptoms lead to irreversible airway changes, and therefore early detection and avoidance are important.

HORMONAL FACTORS

Some women show premenstrual worsening of asthma, which can occasionally be very severe. The mechanisms are not completely understood but are related to a fall in progesterone and in severe cases may be improved by treatment with high doses of progesterone or gonadotropin-releasing factors. Thyrotoxicosis and hypothyroidism can both worsen asthma, although the mechanisms are uncertain.

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux is common in asthmatic patients as it is increased by bronchodilators. While acid reflux might trigger reflex bronchoconstriction, it rarely causes asthma symptoms, and anti-reflux therapy fails to reduce asthma symptoms in most patients.

STRESS

Many asthmatics report worsening of symptoms with stress. There is no doubt that psychological factors can induce bronchoconstriction through cholinergic reflex pathways. Paradoxically, very severe stress, such as bereavement, usually does not worsen, and may even improve, asthma symptoms.

PATHOPHYSIOLOGY

Limitation of airflow is due mainly to bronchoconstriction, but airway edema, vascular congestion, and luminal occlusion with exudate may also contribute. This results in a reduction in forced expiratory volume in 1 s (FEV_1), FEV_1/forced vital capacity (FVC) ratio, and peak expiratory flow (PEF), as well as an increase in airway resistance. Early closure of peripheral airway results in lung hyperinflation (air trapping), and increased residual volume, particularly during acute exacerbations. In more severe asthma, reduced ventilation and increased pulmonary blood flow result in mismatching of ventilation and perfusion and in bronchial hyperemia. Ventilatory failure is very uncommon, even in patients with severe asthma, and arterial Pa_{CO_2} tends to be low due to increased ventilation.

AIRWAY HYPERRESPONSIVENESS

AHR is the characteristic physiologic abnormality of asthma, and describes the excessive bronchoconstrictor response to multiple inhaled triggers that would have no effect on normal airways. The increase in AHR is linked to the frequency of asthma symptoms; thus, an important aim of therapy is to reduce AHR. Increased bronchoconstrictor responsiveness is seen with *direct* bronchoconstrictors, such as histamine and methacholine, which contract airway smooth muscle, but it is characteristically also seen with many *indirect* stimuli, which release bronchoconstrictors from mast cells or activate sensory neural reflexes. Most of the triggers for asthma symptoms appear to act indirectly, including allergens, exercise, hyperventilation, fog (via mast cell activation), irritant dusts, and sulfur dioxide (via cholinergic reflex).

CLINICAL FEATURES AND DIAGNOSIS

The characteristic symptoms of asthma are wheezing, dyspnea, and coughing which are variable, both spontaneously and with therapy. Symptoms may be worse at night, and patients typically awake in the early morning hours. Patients may report difficulty in filling their lungs with air. There is increased mucus production in some patients, with typically tenacious mucus that is difficult to expectorate. There may be increased ventilation and use of accessory muscles of ventilation. Prodromal symptoms may precede an attack, with itching under the chin, discomfort between the scapulae, or inexplicable fear (impending doom).

Typical physical signs are inspiratory, and to a great extent expiratory, rhonchi throughout the chest, and there may be hyperinflation. Some patients, particularly children, may present with a predominant nonproductive cough (cough-variant asthma). There may be no abnormal physical findings when asthma is under control.

DIAGNOSIS

The diagnosis of asthma is usually apparent from the symptoms of variable and intermittent airways obstruction, but is usually confirmed by objective measurements of lung function.

Lung Function Tests Simple spirometry confirms airflow limitation with a reduced FEV_1, FEV_1/FVC ratio, and PEF. Reversibility is demonstrated by a >12% or 200 mL increase in FEV_1 15 min after an inhaled short-acting β_2-agonist or, in some patients, by a 2- to 4-week trial of oral glucocorticoids (prednisone or prednisolone 30–40 mg daily). Measurements of PEF twice daily may confirm the diurnal variations in airflow obstruction. Flow-volume loops show reduced peak flow and reduced maximum expiratory flow. Further lung function tests are rarely necessary, but whole body plethysmography shows increased airway resistance and may show increased total lung capacity and residual volume. Gas diffusion is usually normal but there may be a small increase in gas transfer in some patients.

Airway Responsiveness The increased AHR is normally measured by methacholine or histamine challenge with calculation of the provocative concentration that reduces FEV_1 by 20% (PC_{20}). This is rarely useful in clinical practice, but can be used in the differential diagnosis of chronic cough and when the diagnosis is in doubt in the setting of normal pulmonary function tests. Occasionally exercise testing is done to demonstrate the post-exercise bronchoconstriction if there is a predominant history of EIA. Allergen challenge is rarely necessary, and should only be undertaken by a specialist if specific occupational agents are to be identified.

Hematologic Tests Blood tests are not usually helpful. Total serum IgE and specific IgE to inhaled allergens (RAST) may be measured in some patients.

Imaging Chest roentgenography is usually normal but may show hyperinflated lungs in more severe patients. In exacerbations, there may be evidence of a pneumothorax. Lung shadowing usually indicates pneumonia or eosinophilic infiltrates in patients with bronchopulmonary aspergillosis. High-resolution CT may show areas of bronchiectasis in patients with severe asthma, and there may be thickening of the bronchial walls, but these changes are not diagnostic of asthma.

Skin Tests Skin prick tests to common inhalant allergens are positive in allergic asthma and negative in intrinsic asthma, but are not helpful in diagnosis. Positive skin responses may be useful in persuading patients to undertake allergen avoidance measures.

DIFFERENTIAL DIAGNOSIS

It is usually not difficult to differentiate asthma from other conditions that cause wheezing and dyspnea. Upper airway obstruction by a tumor or laryngeal edema can mimic severe asthma, but patients typically present with stridor localized to large airways. The diagnosis is confirmed by a flow-volume loop, which shows a reduction in inspiratory as well as expiratory flow, and bronchoscopy to demonstrate the site of upper airway narrowing. Persistent wheezing in a specific area of the chest may indicate endobronchial obstruction with a foreign body. Left ventricular failure may mimic the wheezing of asthma but basilar crackles are present in contrast to asthma.

Eosinophilic pneumonias and systemic vasculitis, including Churg-Strauss syndrome and polyarteritis nodosa, may be associated with wheezing. Chronic obstructive pulmonary disease (COPD) is usually easy to differentiate from asthma as symptoms show less variability, never completely remit, and show much less (or no) reversibility to bronchodilators. Approximately 10% of COPD patients have features of asthma, with increased sputum eosinophils and a response to oral corticosteroids; these patients probably have both diseases concomitantly.

TABLE 248-2 AIMS OF ASTHMA THERAPY

Minimal (ideally no) chronic symptoms, including nocturnal
Minimal (infrequent) exacerbations
No emergency visits
Minimal (ideally no) use of as-required β_2-agonist
No limitations on activities, including exercise
PEF circadian variation <20%
(Near) normal PEF
Minimal (or no) adverse effects from medicine

Note: PEF, peak expiratory flow.

℞ ASTHMA

The treatment of asthma is straightforward and the majority of patients are now managed by internists with effective and safe therapies. There are several aims of therapy **(Table 248-2)**. Most emphasis has been placed on drug therapy, but several nonpharmacologic approaches have also been used. The main drugs for asthma can be divided into *bronchodilators*, which give rapid relief of symptoms mainly through relaxation of airway smooth muscle, and *controllers*, which inhibit the underlying inflammatory process.

BRONCHODILATOR THERAPIES Bronchodilators act primarily on airway smooth muscle to reverse the bronchoconstriction of asthma. This gives rapid relief of symptoms but has little or no effect on the underlying inflammatory process. Thus, bronchodilators are not sufficient to control asthma in patients with persistent symptoms. There are three classes of bronchodilator in current use: β_2-adrenergic agonists, anticholinergics, and theophylline; of these, β_2-agonists are by far the most effective.

β_2-Agonists β_2-Agonists activate β_2-adrenergic receptors, which are widely expressed in the airways. β_2-Receptors are coupled through a stimulatory G protein to adenylyl cyclase, resulting in increased intracellular cyclic AMP, which relaxes smooth-muscle cells and inhibits certain inflammatory cells.

Mode of Action The primary action of β_2-agonists is to relax airway smooth-muscle cells of all airways, where they act as functional antagonists, reversing and preventing contraction of airway smooth-muscle cells by all known bronchoconstrictors. This generalized action is likely to account for their great efficacy as bronchodilators in asthma. There are also additional non-bronchodilator effects that may be clinically useful, including inhibition of mast cell mediator release, reduction in plasma exudation, and inhibition of sensory nerve activation **(Table 248-3)**. Inflammatory cells express small numbers of β_2-receptors, but these are rapidly downregulated with β_2-agonist activation so that, in contrast to corticosteroids, there are no effects on inflammatory cells in the airways and there is no reduction in AHR.

Clinical Use β_2-Agonists are usually given by inhalation to reduce side effects. Short-acting β_2-agonists (SABAs), such as albuterol and terbutaline, have a duration of action of 3–6 hours. They have a rapid onset of bronchodilation and are therefore used as needed for symptom relief. Increased use of SABAs indicates that asthma is not controlled. They are also useful in preventing EIA if taken prior to exercise. SABAs are used in high doses by nebulizer or via a metered dose inhaler with a spacer. Long-acting β_2-agonists (LABAs) include salmeterol and formoterol, both of which have a duration of action over 12 hours and are given twice daily. LABAs have replaced the regular use of SABAs, but LABAs should not be given in the

TABLE 248-3 EFFECTS OF β-ADRENERGIC AGONISTS ON AIRWAYS

Relaxation of airway smooth muscle (proximal and distal airways)

Inhibition of plasma exudation and airway edema
Increased mucociliary clearance
Increased mucus secretion
Decreased cough
No effect on chronic inflammation

absence of ICS therapy as they do not control the underlying inflammation. They do, however, improve asthma control and reduce exacerbations when added to ICS, which allows asthma to be controlled at lower doses of corticosteroids. This observation has led to the widespread use of fixed combination inhalers that contain a corticosteroid and a LABA, which have proved to be highly effective in the control of asthma.

Side Effects Adverse effects are not usually a problem with β_2-agonists when given by inhalation. The most common side effects are muscle tremor and palpitations, which are seen more commonly in elderly patients. There is a small fall in plasma potassium due to increased uptake by skeletal muscle cells, but this effect does not usually cause a clinical problem.

Tolerance Tolerance is a potential problem with any agonist given chronically, but while there is downregulation of β_2-receptors, this does not reduce the bronchodilator response as there is a large receptor reserve in airway smooth-muscle cells. By contrast, mast cells become rapidly tolerant, but their tolerance may be prevented by concomitant administration of ICS.

Safety The safety of β_2-agonists has been an important issue. There is an association between asthma mortality and the amount of SABA used, but careful analysis demonstrates that the increased use of rescue SABAs reflects poor asthma control, which is a risk factor for asthma death. The slight excess in mortality that has been associated with the use of LABAs is related to the lack of use of concomitant ICS, as the LABA therapy does not deal with the underlying inflammation. This highlights the importance of always using an ICS when LABAs are given, which is most conveniently achieved by using a combination inhaler.

Anti-Cholinergics Muscarinic receptor antagonists, such as ipratropium bromide, prevent cholinergic nerve–induced bronchoconstriction and mucus secretion. They are much less effective than β_2-agonists in asthma therapy as they inhibit only the cholinergic reflex component of bronchoconstriction, whereas β_2-agonists prevent all bronchoconstrictor mechanisms. Anticholinergics are therefore only used as an additional bronchodilator in patients with asthma that is not controlled on other inhaled medications. High doses may be given by nebulizer in treating acute severe asthma but should only be given following β_2-agonists since they have a slower onset of bronchodilation.

Side effects are not usually a problem as there is little or no systemic absorption. The most common side effect is dry mouth; in elderly patients, urinary retention and glaucoma may also be observed.

Theophylline Theophylline was widely prescribed as an oral bronchodilator several years ago, especially as it was inexpensive. It has now fallen out of favor as side effects are common and inhaled β_2-agonists are much more effective as bronchodilators. The bronchodilator effect is due to inhibition of phosphodiesterases in airway smooth-muscle cells, which increases cyclic AMP, but doses required for bronchodilation commonly cause side effects that are mediated mainly by phosphodiesterase inhibition. There is increasing evidence that theophylline at lower doses has anti-inflammatory effects, and these are likely to be mediated through different molecular mechanisms. There is evidence that theophylline activates the key nuclear enzyme histone deacetylase-2, which is a critical mechanism for switching off activated inflammatory genes.

Clinical Use Oral theophylline is usually given as a slow-release preparation once or twice daily as this gives more stable plasma concentrations than normal theophylline tablets. It may be used as an additional bronchodilator in patients with severe asthma when plasma concentrations of 10–20 mg/L are required, although these concentrations are often associated with side effects. Low doses of theophylline, giving plasma concentrations of 5–10 mg/L, have additive effects to ICSs and are particularly useful in patients with severe asthma. Indeed, withdrawal of theophylline from these patients may result in marked deterioration in asthma control. The drug is well tolerated at low doses. Intravenous aminophylline (a soluble salt of theophylline) was used for the treatment of severe asthma but has now been largely supplemented by inhaled SABAs, which are more effective and have fewer side effects. Aminophylline is occasionally used (via slow intravenous infusion) in patients with severe exacerbations that are refractory to high-dose SABAs.

Side Effects Oral theophylline is well absorbed and is largely inactivated in the liver. Side effects are related to plasma concentrations; measurement of plasma theophylline may be useful in determining the correct dose. The most common side effects—nausea, vomiting, and headaches—are due to phosphodiesterase inhibition. Diuresis and palpitations may also occur, and at high concentrations cardiac arrhythmias, epileptic seizures, and death may occur due to adenosine receptor antagonism. Theophylline side effects are related to plasma concentration and are rarely observed at plasma concentrations below 10 mg/L. Theophylline is metabolized by CYP450 in the liver, and thus plasma concentrations may be elevated by drugs that block CYP450, such as erythromycin and allopurinol. Other drugs may also reduce clearance by other mechanisms leading to increased plasma concentrations **(Table 248-4)**.

TABLE 248-4 FACTORS AFFECTING CLEARANCE OF THEOPHYLLINE

Increased Clearance

- Enzyme induction (rifampicin, phenobarbitone, ethanol)
- Smoking (tobacco, marijuana)
- High protein, low carbohydrate diet
- Barbecued meat
- Childhood

Decreased Clearance

- Enzyme inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, zileuton, zafirlukast)
- Congestive heart failure
- Liver disease
- Pneumonia
- Viral infection and vaccination
- High carbohydrate diet
- Old age

CONTROLLER THERAPIES **Inhaled Corticosteroids** ICSs are by far the most effective controllers for asthma, and their early use has revolutionized asthma therapy.

Mode of Action ICSs are the most effective anti-inflammatory agents used in asthma therapy, reducing the number of inflammatory cells and their activation in the airways. ICSs reduce eosinophils in the airways and sputum, and numbers of activated T lymphocytes and surface mast cells in the airway mucosa. These effects may account for the reduction in AHR that is seen with chronic ICS therapy.

The molecular mechanism of action of corticosteroids involves several effects on the inflammatory process. The major effect of corticosteroids is to switch off the transcription of multiple activated genes that encode inflammatory proteins, such as cytokines, chemokines, adhesion molecules, and inflammatory enzymes. This effect involves several mechanisms, including inhibition of the transcription factors NFκB and AP-1, but an important mechanism is recruitment of histone deacetylase-2 to the inflammatory gene complex, which reverses the histone acetylation associated with increased gene transcription. Corticosteroids also activate anti-inflammatory genes, such as mitogen-activated protein (MAP) kinase phosphatase-1, and increase the expression of β_2-receptors. Most of the metabolic and endocrine side effects of corticosteroids are also mediated through transcriptional activation.

Clinical Use ICSs are by far the most effective controllers in the management of asthma and are beneficial in treating asthma of any severity and age. ICSs are usually given twice daily, but some may be effective once daily in mildly symptomatic patients. ICSs rapidly improve the symptoms of asthma, and lung function improves over several days. They are effective in preventing asthma symptoms, such as EIA and nocturnal exacerbations, but also prevent severe exacerbations. ICSs reduce AHR, but maximal improvement may take several months of therapy. Early treatment with ICSs appears to prevent irreversible changes in airway function that occur with chronic asthma. Withdrawal of ICSs results in slow deterioration of asthma control, indicating that they suppress inflammation and symptoms but do not cure the underlying condition. ICSs are now given as first-line therapy for patients with persistent asthma, but if they do not control symptoms at low doses, it is usual to add an LABA as the next step.

Side Effects Local side effects include hoarseness (dysphonia) and oral candidiasis, which may be reduced with the use of a large-volume spacer device. There has been concern about systemic side effects from lung absorption, but many studies have demonstrated that ICSs have minimal systemic effects **(Fig. 248-6)**. At the highest recommended doses, there may

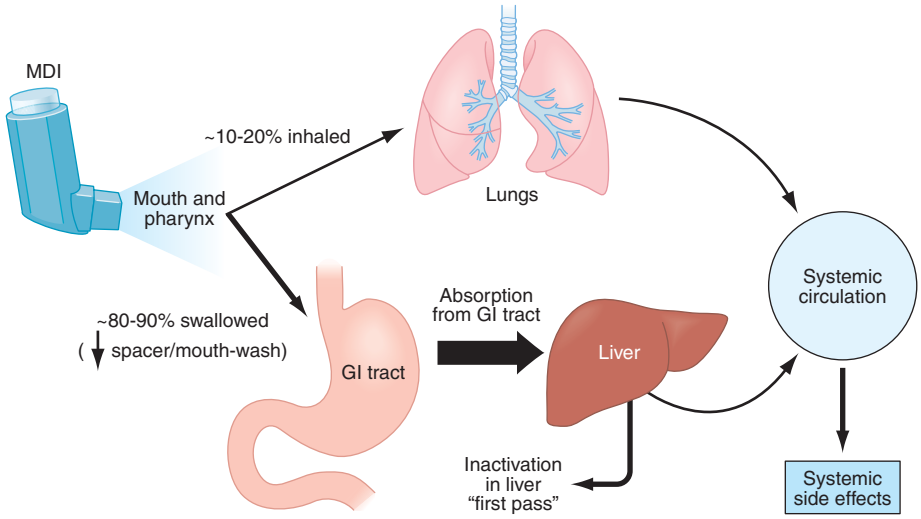

FIGURE 248-6 Pharmacokinetics of inhaled corticosteroids.

be some suppression of plasma and urinary cortisol concentrations, but there is no convincing evidence that long-term treatment leads to impaired growth in children or to osteoporosis in adults. Indeed, effective control of asthma with ICSs reduces the number of courses of oral corticosteroids that are needed and thus reduces systemic exposure to ICSs.

Systemic Corticosteroids Corticosteroids are used intravenously (hydrocortisone or methylprednisolone) for the treatment of acute severe asthma, although several studies now show that oral corticosteroids are as effective and easier to administer. A course of oral corticosteroids (usually prednisone or prednisolone 30–45 mg od for 5–10 days) is used to treat acute exacerbations of asthma; no tapering of the dose is needed. Approximately 1% of asthma patients may require maintenance treatment with oral corticosteroids; the lowest dose necessary to maintaining control needs to be determined. Systemic side effects, including truncal obesity, bruising, osteoporosis, diabetes, hypertension, gastric ulceration, proximal myopathy, depression, and cataracts may be a major problem, and steroid-sparing therapies may be considered if side effects are a significant problem. If patients require maintenance treatment with oral corticosteroids, it is important to monitor bone density so that preventive treatment with bisphosphonates, or estrogen in postmenopausal women, may be initiated if bone density is low. Intramuscular triamcinolone acetonide is a depot preparation that is occasionally used in noncompliant patients, but proximal myopathy is a major problem with this therapy.

Antileukotrienes Cysteinyl-leukotrienes are potent bronchoconstrictors, cause microvascular leakage, and increase eosinophilic inflammation through the activation of cys-LT_1-receptors. These inflammatory mediators are produced predominantly by mast cells and, to a lesser extent, eosinophils in asthma. Antileukotrienes, such as montelukast and zafirlukast, block cys-LT_1-receptors and provide modest clinical benefit in asthma. They are less effective than ICSs in controlling asthma and have less effect on airway inflammation, but are useful as an add-on therapy in some patients not controlled with low doses of inhaled corticosteroids (although they are less effective than LABAs). They are given orally once or twice daily and are well tolerated. Some patients show a better response than others to antileukotrienes, but this has not been convincingly linked to any genomic differences in the leukotriene pathway.

Cromones Cromolyn sodium and nedocromil sodium are asthma controller drugs that appear to inhibit mast cell and sensory nerve activation, and are therefore effective in blocking trigger-induced asthma, such as EIA, and allergen- and sulfur dioxide–induced symptoms. Cromones have relatively little benefit in the long-term control of asthma due to their short duration of action (at least 4 times daily by inhalation). They are very safe, and though they were popular in the treatment of childhood asthma, low doses of ICSs are now preferred as they are more effective and have a proven safety profile.

Steroid-Sparing Therapies Various immunomodulatory treatments have been used to reduce the requirement for oral corticosteroids in patients with severe asthma who have serious side effects with this therapy. Methotrexate, cyclosporine, azathioprine, gold, and intravenous gamma globulin have all been used as steroid-sparing therapies, but none of these treatments has any long-term benefit and each is associated with a relatively high risk of side effects.

Anti-IgE Omalizumab is a blocking antibody that neutralizes circulating IgE without binding to cell-bound IgE; it thus inhibits IgE-mediated reactions. This treatment has been shown to reduce the number of exacerbations in patients with severe asthma and may improve asthma control. However, the treatment is very expensive and only suitable for highly selected patients who are not controlled on maximal doses of inhaler therapy and have a circulating IgE within a specified range. Patients should be given a 3–4 month trial of therapy to show objective benefit. Omalizumab is usually given as a subcutaneous injection every 2–4 weeks and appears not to have significant side effects.

Immunotherapy Specific immunotherapy using injected extracts of pollens or house dust mite has not been very effective in controlling asthma and may cause anaphylaxis. Side effects may be reduced by sublingual dosing. It is not recommended in most asthma treatment guidelines because of lack of evidence of clinical efficacy.

Alternative Therapies Nonpharmacologic treatments, including hypnosis, acupuncture, chiropraxy, breathing control, yoga, and speleotherapy, may be popular with some patients. However, placebo-controlled studies have shown that each of these treatments lacks efficacy and cannot be recommended. However, they are not detrimental and may be used as long as conventional pharmacologic therapy is continued.

Future Therapies It has proved very difficult to discover novel pharmaceutical therapies, particularly as current therapy with corticosteroids and β_2-agonists is so effective in the majority of patients. There, however, is a need for the development of new therapies for patients with refractory asthma who have side effects with systemic corticosteroids. Antagonists of specific mediators have little or no benefit in asthma, apart from antileukotrienes, which have a rather weak effect, presumably reflecting the fact that multiple mediators are involved. Antagonists of chemokine receptors, particularly CCR3, are in development and may be more effective. Novel anti-inflammatory treatments that are in clinical development include inhibitors of phosphodiesterase-4, NFκB, p38 MAP kinase and phosphoinositide-3 kinase. However, these drugs, which act on signal transduction pathways common to many cells, are likely to have troublesome side effects, necessitating their delivery by inhalation. Safer and more effective immunotherapy using T cell peptide fragments of allergens or DNA vaccination are also being investigated. Bacterial products, such as CpG oligonucleotides that stimulate T_H1 immunity or regulatory T cells, are also currently under evaluation.

MANAGEMENT OF CHRONIC ASTHMA

There are several aims of chronic therapy in asthma (Table 248-2). It is important to establish the diagnosis objectively using spirometry or PEF measurements at home. Triggers that worsen asthma control, such as allergens or occupational agents, should be avoided, whereas triggers such as exercise and fog, which result in transient symptoms, provide an indication that more controller therapy is needed.

Stepwise Therapy For patients with mild, intermittent asthma, a short-acting β_2-agonist is all that is required **(Fig. 248-7)**. However, use of a reliever medication more than three times a week indicates the need for regular controller therapy. The treatment of choice for all patients is an ICS given twice daily. It is usual to start with an intermediate dose [e.g., 200 μg bid of beclomethasone dipropionate (BDP) or equivalent] and to decrease the dose if symptoms are controlled after 3 months. If symptoms are not controlled, an LABA should be added, most conveniently by switching to a combination inhaler. The dose of controller should be adjusted accordingly, as judged by the need for a rescue inhaler. Low doses of theophylline or

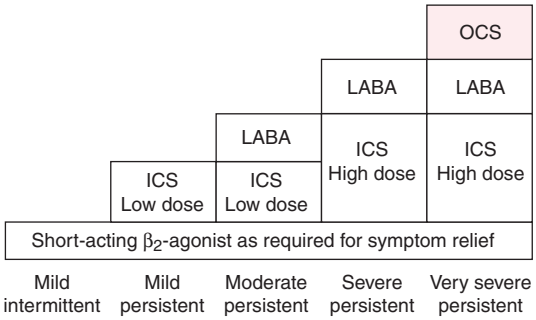

FIGURE 248-7 Step-wise approach to asthma therapy according to the severity of asthma and ability to control symptoms. ICS, inhaled corticosteroid; LABA, long-acting β_2-agonists; OCS, oral corticosteroid.

an antileukotriene may also be considered as an add-on therapy, but these are less effective than LABAs. In patients with severe asthma, low-dose oral theophylline is also helpful, and when there is irreversible airway narrowing, the long-acting anticholinergic tiotropium bromide may be tried. If asthma is not controlled despite the maximal recommended dose of inhaled therapy, it is important to check compliance and inhaler technique. In these patients, maintenance treatment with an oral corticosteroid may be needed, and the lowest dose that maintains control should be used. Occasionally omalizumab may be tried in steroid-dependent asthmatics who are not well controlled. Once asthma is controlled, it is important to slowly decrease therapy in order to find the optimal dose to control symptoms.

Education Patients with asthma need to understand how to use their medications and the difference between reliever and controller therapies. Education may improve compliance, particularly with ICSs. All patients should be taught how to use their inhalers correctly. In particular, they need to understand how to recognize worsening of asthma and how to step up therapy. Written action plans have been shown to reduce hospital admissions and morbidity in adults and children and are recommended particularly in patients with unstable disease who have frequent exacerbations.

ACUTE SEVERE ASTHMA

Exacerbations of asthma are feared by patients and may be life-threatening. One of the main aims of controller therapy is to prevent exacerbations; in this respect, ICS and combination inhalers are very effective.

CLINICAL FEATURES

Patients are aware of increasing chest tightness, wheezing, and dyspnea that are often not or poorly relieved by their usual reliever inhaler. In severe exacerbations patients may be so breathless that they are unable to complete sentences and may become cyanotic. Examination usually shows increased ventilation, hyperinflation, and tachycardia. Pulsus paradoxus may be present, but this is rarely a useful clinical sign. There is a marked fall in spirometric values and PEF. Arterial blood gases on air show hypoxia and Pa_{CO_2} is usually low due to hyperventilation. A normal or rising Pa_{CO_2} is an indication of impending respiratory failure and requires immediate monitoring and therapy. A chest roentgenogram is not usually informative, but may show pneumonia or pneumothorax.

℞ ACUTE SEVERE ASTHMA

A high concentration of oxygen should be given by face mask to achieve oxygen saturation of >90%. The mainstay of treatment is high doses of short-acting inhaled β_2-agonists that are given either by nebulizer or via a metered dose inhaler with a spacer. In severely ill patients with impending respiratory failure, intravenous β_2-agonists may be given. An inhaled anticholinergic may be added if there is not a satisfactory response to β_2-agonists alone, as there are additive effects. In patients who are refractory to inhaled therapies, a slow infusion of aminophylline may be effective, but it is important to monitor blood levels especially if patients have already been treated with oral theophylline. Magnesium sulfate given intravenously or by nebulizer has also been shown to be effective when added to inhaled β_2-agonists, and is relatively well tolerated but is not routinely recommended. Prophylactic intubation may be indicated for impending respiratory failure, when the Pa_{CO_2} is normal or rises. For patients with respiratory failure, it is necessary to intubate and institute ventilation. These patients may benefit from an anesthetic, such as halothane, if they have not responded to conventional bronchodilators. Sedatives should never be given as they may depress ventilation. Antibiotics should not be used routinely unless there are signs of pneumonia.

REFRACTORY ASTHMA

Although most patients with asthma are easily controlled with appropriate medication, a small proportion of patients (approximately 5% of asthmatics) are difficult to control despite maximal inhaled therapy. Some of these patients will require maintenance treatment with oral corticosteroids. In managing these patients, it is important to investigate and correct any mechanisms that may be aggravating asthma. There are two major patterns of difficult asthma: some patients have persistent symptoms and poor lung function, despite appropriate therapy, whereas others may have normal or near-normal lung function but intermittent, severe (sometimes life-threatening) exacerbations.

MECHANISMS

The most common reason for poor control of asthma is noncompliance with medication, particularly ICS. Compliance with ICS may be low because patients do not feel any immediate clinical benefit or may be concerned about side effects. Compliance with ICS is difficult to monitor as there are no useful plasma measurements that can be made. Compliance may be improved by giving the ICS as a combination with an LABA that gives symptom relief. Compliance with oral corticosteroids may be measured by suppression of plasma cortisol and the expected concentration of prednisone/prednisolone in the plasma. There are several factors that may make asthma more difficult to control, including exposure to high, ambient levels of allergens or unidentified occupational agents. Severe rhinosinusitis may make asthma more difficult to control; upper airway disease should be vigorously treated. Gastroesophageal reflux is common among asthmatics due to bronchodilator therapy, but there is little evidence that it is a significant factor in worsening asthma, and treatment of the reflux is not usually effective at improving asthma symptoms. Some patients may have chronic infection with *Mycoplasma pneumoniae* or *Chlamydophila pneumoniae* and benefit from treatment with a macrolide antibiotic. Drugs such as β-adrenergic blockers, aspirin, and other cyclooxygenase (COX) inhibitors may worsen asthma. Some women develop severe premenstrual worsening of asthma, which is unresponsive to corticosteroids and requires treatment with progesterone or gonadotropin-releasing factors. Few systemic diseases make asthma more difficult to control, but hyper- and hypothyroidism may increase asthma symptoms and should be investigated if suspected.

Relatively little is known about the pathology of refractory asthma, as biopsy studies are more difficult in these patients. Some patients show the typical eosinophilic pattern of inflammation, whereas others have a predominantly neutrophilic pattern. There may be an increase in T_H1 cells and CD8 lymphocytes compared to mild asthma and increased expression of TNF-α. Structural changes in the airway, including fibrosis, angiogenesis, and airway smooth-muscle thickening, are more commonly seen in these patients.

DIFFERENTIAL DIAGNOSIS

Some patients who apparently have difficult-to-control asthma also have vocal cord dysfunction, resulting in wheezing or stridor. This symptom is thought to be an attention-seeking hysterical conversion syndrome and may lead to escalating doses of asthma therapy, with some patients taking high doses of oral corticosteroids. It may be recognized by the characteristic discrepancy between tests of forced expiration, such as FEV_1 and PEF, and relatively normal airway resistance. Direct inspection by laryngoscopy may confirm adduction of the vocal cords at the time of symptoms. This condition is usually difficult to manage, but it is important that patients be weaned off oral and in-

haled corticosteroids. Speech therapy is sometimes beneficial. Some patients with COPD may be diagnosed as asthmatic and may show the characteristic poor response to corticosteroids and bronchodilators, but this situation is complicated by the fact that some patients with COPD also have concomitant asthma.

CORTICOSTEROID-RESISTANT ASTHMA

A few patients with asthma show a poor response to corticosteroid therapy and may have various molecular abnormalities that impair the anti-inflammatory action of corticosteroids. Complete resistance to corticosteroids is extremely uncommon and affects <1 in 1000 patients. It is defined by a failure to respond to a high dose of oral prednisone/prednisolone (40 mg od over 2 weeks), ideally with a 2-week run-in with matched placebo. More common is reduced responsiveness to corticosteroids where control of asthma requires oral corticosteroids (corticosteroid-dependent asthma). In all patients with poor responsiveness to corticosteroids, there is a reduction in the response of circulating monocytes and lymphocytes to the anti-inflammatory effects of corticosteroids in vitro and reduced skin blanching in response to topical corticosteroids. There are several mechanisms that have been described, including an excess of the transcription factor AP-1, an increase in the alternatively spliced form of the glucocorticoid receptor GR-β, an abnormal pattern of histone acetylation in response to corticosteroids, a defect in IL-10 production, and a reduction in histone deacetylase activity (as in COPD). These observations suggest that there are likely to be heterogeneous mechanisms for corticosteroid resistance; whether these mechanisms are genetically determined has yet to be determined.

BRITTLE ASTHMA

Some patients show chaotic variations in lung function despite taking appropriate therapy. Some show a persistent pattern of variability and may require oral corticosteroids or, at times, continuous infusion of β_2-agonists (type I brittle asthma), whereas others have generally normal or near-normal lung function but precipitous, unpredictable falls in lung function that may result in death (type 2 brittle asthma). These latter patients are difficult to manage as they do not respond well to corticosteroids, and the worsening of asthma does not reverse well with inhaled bronchodilators. The most effective therapy is subcutaneous epinephrine, which suggests that the worsening is likely to be a localized airway anaphylactic reaction with edema. In some of these patients, there may be allergy to specific foods. These patients should be taught to self-administer epinephrine and should carry a medical warning accordingly.

℞ REFRACTORY ASTHMA

Refractory asthma is difficult to control, by definition. It is important to check compliance and the correct use of inhalers and to identify and eliminate any underlying triggers. Low doses of theophylline may be helpful in some patients, and theophylline withdrawal has been found to worsen many patients. Most of these patients will require maintenance treatment with oral corticosteroids, and the minimal dose that achieves satisfactory control should be determined by careful dose titration. Steroid-sparing therapies are rarely effective. In some patients with allergic asthma, omalizumab is effective, particularly when there are frequent exacerbations. There is some evidence that anti-TNF therapy may be effective, but this is controversial and very expensive. A few patients may benefit from infusions of β_2-agonists. New therapies are needed for these patients, who currently consume a disproportionate amount of health care spending.

SPECIAL CONSIDERATIONS

Although asthma is usually straightforward to manage, there are some situations that may require additional investigation and different therapy.

ASPIRIN-SENSITIVE ASTHMA

A small proportion (approximately 1%) of asthmatics become worse with aspirin and other COX inhibitors, although this is much more commonly seen in severe patients and in those with frequent hospital admission. Aspirin-sensitive asthma is a well-defined subtype of asthma that is usually preceded by perennial rhinitis and nasal polyps in nonatopic patients with a late onset of the disease. Aspirin, even in small doses, characteristically provokes rhinorrhea, conjunctival irritation, facial flushing, and wheezing. There is a genetic predisposition to increased production of cysteinyl-leukotrienes with functional polymorphism of cys-leukotriene synthase. Asthma is triggered by COX inhibitors but is persistent even in their absence. All nonselective COX inhibitors should be avoided, but selective COX-2 inhibitors are apparently safe to use when an anti-inflammatory analgesic is needed. Aspirin-sensitive asthma responds to usual therapy with an ICS. Although antileukotrienes should be effective in these patients, they are no more effective than in allergic asthma. Occasionally aspirin desensitization is necessary, but this should only be undertaken in specialized centers.

ASTHMA IN THE ELDERLY

Asthma may start at any age, including in elderly patients. The principles of management are the same as in other asthmatics, but side effects of therapy may be a problem, including muscle tremor with β_2-agonists and more systemic side effects with ICSs. Comorbidities are more frequent in this age group, and interactions with drugs such as β_2 blockers, COX inhibitors, and agents that may affect theophylline metabolism need to be considered. COPD is more likely in elderly patients and may coexist with asthma. A trial of oral corticosteroids may be very useful in documenting the steroid responsiveness of asthma.

PREGNANCY

Approximately one-third of asthmatic patients who are pregnant improve during the course of a pregnancy, one-third deteriorate, and one-third are unchanged. It is important to maintain good control of asthma since poor control may have adverse effects on fetal development. Compliance may be a problem as there is often concern about the effects of anti-asthma medications on fetal development. The drugs that have been used for many years in asthma therapy have now been shown to be safe and without teratogenic potential. These drugs include short-acting β_2-agonists, ICSs, and theophylline; there is less safety information about newer classes of drugs such as LABAs, antileukotrienes, and anti-IgE. If an oral corticosteroid is needed, it is better to use prednisone rather than prednisolone as it cannot be converted to the active prednisolone by the fetal liver, thus protecting the fetus from systemic effects of the corticosteroid. There is no contraindication to breast-feeding when patients are using these drugs.

CIGARETTE SMOKING

Approximately 20% of asthmatics smoke, which may adversely affect asthma in several ways. Smoking asthmatics have more severe disease, more frequent hospital admissions, a faster decline in lung function, and a higher risk of death from asthma than nonsmoking asthmatics. There is evidence that smoking interferes with the anti-inflammatory actions of corticosteroids, necessitating higher doses for asthma control. Smoking cessation improves lung function and reverses the steroid resistance; thus, vigorous smoking cessation strategies should be used. Some patients report a temporary worsening of asthma when they first stop smoking, which could be due to the loss of the bronchodilating effect of nitric oxide in cigarette smoke.

SURGERY

If asthma is well-controlled, there is no contraindication to general anesthesia and intubation. Patients who are treated with oral corticosteroids will have adrenal suppression and should be treated with an increased dose of oral corticosteroid immediately prior to surgery. Patients with FEV_1 <80% of their normal levels should also be given a boost of oral corticosteroids prior to surgery. High maintenance doses of corticosteroids may be a contraindication to surgery because of increased risks of infection and delayed wound healing.

BRONCHOPULMONARY ASPERGILLOSIS

Bronchopulmonary aspergillosis (BPA) is uncommon and results from an allergic pulmonary reaction to inhaled spores of *Aspergillus fumigatus* and, occasionally, other *Aspergillus* species. A skin prick test to *A. fumigatus* is always positive, whereas serum *Aspergillus* precipitins are low or undetectable. Characteristically, there are fleeting eosinophilic infiltrates in the lungs, particularly in the upper lobes. As airways become blocked with mucoid plugs rich in eosinophils, patients may cough up brown plugs and have hemoptysis. BPA may result in bronchiectasis, particularly affecting central airways, if not suppressed by corticosteroids. Asthma is controlled in the usual way by ICSs, but it is necessary to give a course of oral corticosteroids if there is any sign of worsening or pulmonary shadowing is found. Treatment with the oral antifungal itraconazole is beneficial in preventing exacerbations.

249 Hypersensitivity Pneumonitis and Pulmonary Infiltrates with Eosinophilia

Joel N. Kline, Gary W. Hunninghake

HYPERSENSITIVITY PNEUMONITIS

First described in 1874, hypersensitivity pneumonitis (HP), or extrinsic allergic alveolitis, is an inflammatory disorder of the lung, involving alveolar walls and terminal airways, that is induced, in a susceptible host, by repeated inhalation of a variety of organic agents. Factors responsible for the expression of HP include both those related to the host (susceptibility) and the inciting agent. Causes of HP are typically designated with colorful names denoting the occupational or avocational risk associated with the disease; "farmer's lung" is the term most commonly used for HP due to inhalation of antigens present in moldy hay, such as thermophilic actinomyces, *Micropolyspora faeni*, and *Aspergillus* species. The frequency of HP varies with the environmental exposure and the specific antigen involved.

ETIOLOGY

Agents implicated as causes of HP are diverse and include those listed in Table 249-1. In the United States, the most common types of HP are farmer's lung, bird fancier's lung, and chemical worker's lung. In *farmer's lung*, inhalation of proteins such as thermophilic bacteria and fungal spores that are present in moldy bedding and feed are most commonly responsible for the development of HP. These antigens are probably also responsible for the etiology of *mushroom worker's disease* (moldy composted growth medium is the source of the proteins) and bagassosis (moldy sugar cane is the source). *Bird fancier's lung* (and the related disorders of duck fever, turkey handler's lung, and dove pillow's lung) is a response to inhalation of proteins from feathers and droppings. *Chemical worker's lung* is an example of how simple chemicals, such as isocyanates, may also cause immune-mediated diseases.

PATHOGENESIS

The finding that precipitating antibodies against extracts of moldy hay were demonstrable in most patients with farmer's lung led to the early conclusion that HP was an immune complex–mediated reaction. Subsequent investigations of HP in human beings and animal models provided evidence for the importance of cell-mediated hypersensitivity. The very early (acute) reaction is characterized by an increase in polymorphonuclear leukocytes in the alveoli and small airways. This early lesion is followed by an influx of mononuclear cells into the lung and the formation of granulomas that appear to be the result of a classic delayed (T cell–mediated) hypersensitivity reaction to repeated inhalation of antigen and adjuvant-active materials. Studies in animal models suggest that the disease is a T_H1-mediated immune response to antigen, with interferon γ, interleukin (IL) 12, and possibly IL-18 contributing to disease expression. Most likely, multiple cytokines [including also IL-1β, transforming growth factor (TGF) β, tumor necrosis factor (TNF) α and others] interact to promote HP; their source includes both alveolar macrophages and T lymphocytes in the lung. Recent data support a genetic predisposition to the development of HP; certain polymorphisms of the TNF-α promoter region reportedly confer an enhanced susceptibility to pigeon breeder's disease.

The attraction and accumulation of inflammatory cells in the lung may be due to one or more of the following mechanisms: induction of the adhesion molecules L-selectin and E-selectin, elaboration by dendritic cells of CC chemokine 1 (DC-CK-1/CCL18), and increased expression of CXCR3/CXCL10 by $CD4^+$ and $CD8^+$ lymphocytes. Increased levels of Fas protein and FasL in the lung (which would be expected to suppress inflammation by induction of T cell apoptosis) is counterbalanced by increased expression of the inducible antiapoptotic gene Bcl-xL, resulting in a lower overall level of pulmonary lymphocyte apoptosis in HP patients.

Bronchoalveolar lavage (BAL) in patients with HP consistently demonstrates an increase in T lymphocytes in lavage fluid (a finding that is also observed in patients with other granulomatous lung disorders). Patients with recent or continual exposure to antigen may have an increase in polymorphonuclear leukocytes in lavage fluid; this has been associated with lung fibrosis. A role for oxidant injury has been proposed in HP. Several markers of oxidative stress are reported to be increased during exacerbation of HP and are reduced by treatment with glucocorticoids.

CLINICAL PRESENTATION

The clinical picture is that of an interstitial pneumonitis, which varies from patient to patient and seems related to the frequency and intensity of exposure to the causative antigen and perhaps other host factors. The presentation can be acute, subacute, or chronic. In the *acute* form, symptoms such as cough, fever, chills, malaise, and dyspnea may occur 6 to 8 h after exposure to the antigen and usually clear within a few days if there is no further exposure to antigen. The *subacute* form often appears insidiously over a period of weeks marked by cough and dyspnea and may progress to cyanosis and severe dyspnea requiring hospitalization. In

TABLE 249-1 SELECTED EXAMPLES OF HYPERSENSITIVITY PNEUMONITIS (HP)

Disease	Antigen	Source of Antigen
Bagassosis	Thermophilic actinomycetes[a]	"Moldy" bagasse (sugar cane)
Bird fancier's, breeder's, or handler's lung[b]	Parakeet, pigeon, chicken, turkey proteins	Avian droppings or feathers
Cephalosporium HP	Contaminated basement (sewage)	*Cephalosporium*
Cheese washer's lung	*Penicillium casei*	Moldy cheese
Chemical worker's lung[b]	Isocyanates	Polyurethane foam, varnishes, lacquer
Coffee worker's lung	Coffee bean dust	Coffee beans
Compost lung	*Aspergillus*	Compost
Detergent worker's disease	*Bacillus subtilis* enzymes (subtilisins)	Detergent
Familial HP	*Bacillus subtilis*	Contaminated wood dust in walls
Farmer's lung[b]	Thermophilic actinomycetes[a]	"Moldy" hay, grain, silage
Fish food lung	Unknown	Fish food
Fish meal worker's lung	Fish meal dust	Fish meal
Furrier's lung	Animal fur dust	Animal pelts
Hot tub lung	*Cladosporium* spp., *Mycobacterium avium* complex	Mold on ceiling; contaminated water
Humidifier or air-conditioner lung (ventilation pneumonitis)	*Aureobasidium pullulans*, *Candida albicans*, Thermophilic actinomycetes[a], mycobacterium spp., other microorganisms	Contaminated water in humidification or forced-air air-conditioning systems
Japanese summer-type HP	*Trichosporon cutaneum*, *T. asahii*, and *T. mucoides*	House dust? Bird droppings
Laboratory worker's HP	Male rat urine	Laboratory rat
Lycoperdonosis	*Lycoperdon* puffballs	Puffball spores
Malt worker's lung	*Aspergillus fumigatus* or *A. clavatus*	Moldy barley
Maple bark disease	*Cryptostroma corticale*	Maple bark
Metalworking fluid lung	Mycobacterium spp., *Pseudomonas* spp.	Contaminated metalworking fluid
Miller's lung	*Sitophilus granarius* (wheat weevil)	Infested wheat flour
Miscellaneous medication	Amiodarone, bleomycin, efavirenz, gemcitabine, hydralazine, hydroxyurea, isoniazid, methotrexate, paclitaxel, penicillin, procarbazine, propranolol, riluzole, sirolimus, sulfasalazine	Medication
Mushroom worker's lung	Thermophilic actinomycetes,[a] *Hypsizigus marmoreus*, *Bunashimeji*, and other exotic mushrooms	Mushroom compost; mushrooms
Pituitary snuff taker's lung	Animal proteins	Heterologous pituitary snuff
Potato riddler's lung	Thermophilic actinomycetes,[a] *Aspergillus*	"Moldy" hay around potatoes
Sauna taker's lung	*Aureobasidium* spp., other	Contaminated sauna water
Sausage worker's lung	*Penicillium nalgiovense*	Dry sausage mold
Sequoiosis	*Aureobasidium*, *Graphium* spp.	Redwood sawdust
Streptomyces albus HP	*Streptomyces albus*	Contaminated fertilizer
Suberosis	*Penicillium glabrum* and *Chrysonilia sitophila*	Cork dust
Tap water lung	*Mycobacteria* spp.	Contaminated tap water
Thatched roof disease	*Saccharomonospora viridis*	Dried grasses and leaves
Tobacco worker's disease	*Aspergillus* spp.	Mold on tobacco
Winegrower's lung	*Botrytis cinerea*	Mold on grapes
Wood trimmer's disease	*Rhizopus* spp., *Mucor* spp.	Contaminated wood trimmings
Woodman's disease	*Penicillium* spp.	Oak and maple trees
Woodworker's lung	Wood dust, *Alternaria*	Oak, cedar, pine, and mahogany dusts

[a]Thermophilic actinomycetes species include *Micropolyspora faeni*, *Thermoactinomyces vulgaris*, *T. saccharrii*, *T. viridis*, and *T. candidus*.

[b]Most common causes of hypersensitivity pneumonitis in the United States.

some patients, a subacute form of the disease may persist after an acute presentation of the disorder, especially if there is continued exposure to antigen. In most patients with the acute or subacute form of HP, the symptoms, signs, and other manifestations of HP disappear within days, weeks, or months if the causative agent is no longer inhaled. Transformation to a chronic form of the disease may occur in patients with continued antigen exposure, but the frequency of such progression is uncertain.

The *chronic* form of HP may be clinically indistinguishable from pulmonary fibrosis due to a wide variety of causes. Physical examination may reveal clubbing. This stage may progressively worsen, resulting in dependence on supplemental oxygen, pulmonary hypertension, and respiratory failure. Pulmonary fibrosis is the clinical manifestation of HP with the greatest predictive value for mortality. An indolent, gradually progressive form of the disease can be associated with cough and exertional dyspnea without a prior history consistent with acute or subacute manifestations. Such a gradual onset frequently occurs with low-dose exposure to the antigen.

DIAGNOSIS

All forms of the disease may be associated with elevations in erythrocyte sedimentation rate, C-reactive protein, rheumatoid factor, and serum immunoglobulins. Following acute exposure to antigen, neutrophilia and lymphopenia are frequently present. Eosinophilia is not a feature. Examination for *serum precipitins* against suspected antigens, such as those listed in Table 249-1, is an important part of the diagnostic workup and should be performed on any patient with interstitial lung disease, especially if a suggestive exposure history is elicited. If found, precipitins indicate sufficient exposure to the causative agent for generation of an immunologic response. The diagnosis of HP is not established solely by the presence of precipitins, however, as precipitins are found in sera of many individuals exposed to appropriate antigens who demonstrate no other evidence of HP. False-negative results may occur because of poor-quality antigens or an inappropriate choice of antigens. Extraction of antigens from the suspected source may at times be helpful.

Chest x-ray shows no specific or distinctive changes in HP. It can be normal even in symptomatic patients. The acute or subacute phases may be associated with poorly defined, patchy, or diffuse infiltrates or with discrete, nodular infiltrates. In the chronic phase, the chest x-ray usually shows a diffuse reticulonodular infiltrate. Honeycombing may eventually develop as the condition progresses. Apical sparing is common, suggesting that disease severity correlates with inhaled antigen

FIGURE 249-1 Chest CT scan of a patient with acute hypersensitivity pneumonitis in which scattered regions of ground glass and nodular infiltrates are seen bilaterally. *(Courtesy of JS Wilson; with permission.)*

load, but no particular distribution or pattern is classic for HP. Abnormalities rarely seen in HP include pleural effusion or thickening, and hilar adenopathy. High-resolution chest computed tomography (CT) has become the procedure of choice for imaging of HP, and a consensus is developing as to the typical appearance of the disease. Although pathognomonic features have not been identified, acute HP may appear with confluent alveolar opacification. In subacute disease, centrilobular nodules and "ground glass" changes predominate in the lower lobes, and expiratory views may demonstrate air trapping; this pattern is more common in individuals whose exposure to antigen continues rather than those in whom removal from antigen exposure has occurred. In chronic HP, patchy emphysema is seen more often than interstitial fibrosis; subpleural linear opacities and honeycombing are common, and these changes may be found throughout the lung. Hilar or mediastinal adenopathy is not associated with HP (Fig. 249-1).

Pulmonary function studies in all forms of HP may show a restrictive or an obstructive pattern with loss of lung volumes, impaired diffusion capacity, decreased compliance, and exercise-induced hypoxemia. Resting hypoxemia may also be found. Bronchospasm and bronchial hyperreactivity are sometimes found in acute HP. With antigen avoidance, the pulmonary function abnormalities are usually reversible, but they may gradually increase in severity or may occur rapidly following acute or subacute exposure to antigen.

BAL is used in some centers to aid in diagnostic evaluation. A marked lymphocytic alveolitis on BAL is almost universal, although not pathognomonic. Lymphocytes typically have a decreased helper/suppressor ratio and are activated. Alveolar neutrophilia is also prominent acutely but tends to fade in the absence of recurrent exposure. Bronchoalveolar mastocytosis may correlate with disease activity.

Lung biopsy, obtained through flexible bronchoscopy, open-lung procedures, or thoracoscopy, may be diagnostic. Although the histopathology is distinctive, it may not be pathognomonic of HP (Fig. 249-2). When the biopsy is taken during the active phase of disease, typical findings include an interstitial alveolar infiltrate consisting of plasma cells, lymphocytes, and occasional eosinophils and neutrophils, usually accompanied by loose, noncaseating peribronchial granulomas. Interstitial fibrosis may be present but most often is mild in earlier stages of the disease. Some degree of bronchiolitis is found in about half the cases. Rarely, bronchiolitis obliterans with organizing pneumonia (BOOP) (Chap. 255) may be present. The triad of mononuclear bronchiolitis; interstitial infiltrates of lymphocytes and plasma cells; and single, nonnecrotizing, and randomly scattered parenchymal granulomas without mural vascular involvement is consistent with but not specific for HP.

A *prediction rule* for the clinical diagnosis of HP has been developed by the International HP Study Group. Six significant predictors of HP (exposure to a known antigen, positive predictive antibodies to the antigen, recurrent episodes of symptoms, inspiratory crackles, symptoms developing 4–8 h after exposure, and weight loss) were retrospectively developed then validated in a separate cohort. This diagnostic paradigm has a high predictive value in the diagnosis of HP, without the need for invasive testing. In cases where only a subset of the criteria are fulfilled, the diagnosis is less clearly established. It is clear, however, that the diagnosis of HP is established by (1) consistent symptoms, physical findings, pulmonary function tests, and radiographic tests; (2) a history of exposure to a recognized antigen; and (3) ideally, identification of an antibody to that antigen. In some circumstances, BAL and/or lung biopsy may be needed. The most important tool in diagnosing HP continues to be a high index of suspicion!

DIFFERENTIAL DIAGNOSIS

Chronic HP may often be difficult to distinguish from a number of other interstitial lung disorders (Chap. 255). A negative history for use of relevant drugs and no evidence of a systemic disorder usually exclude the presence of drug-induced lung disease or a collagen vascular disorder. BAL often shows predominance of neutrophils in idiopathic pulmonary fibrosis and a predominance of CD4+ lymphocytes in sarcoidosis. Hilar/paratracheal lymphadenopathy or evidence of multisystem involvement also favors the diagnosis of sarcoidosis. In some patients, a lung biopsy may be required to differentiate chronic HP from other interstitial diseases. The lung disease associated with acute or subacute HP may clinically resemble other disorders that present with systemic symptoms and recurrent pulmonary infiltrates, including the allergic bronchopulmonary mycoses and other eosinophilic pneumonias. Gene cluster analysis of DNA from lung biopsies of patients with fibrotic lung disease has shown a significantly different gene expression profile in HP and idiopathic pulmonary fibrosis (IPF). HP biopsies expressed T cell and other genes related to inflammation, whereas the IPF patients had greater expression of genes associated with pulmonary remodeling, especially epithelial and myofibroblast genes. While this finding may be related to the disease stage in which the disorders were diagnosed, they suggest that such analyses may be clinically useful in the future.

Eosinophilic pneumonia is often associated with asthma and is typified by peripheral eosinophilia; neither of these is a feature of HP. Allergic bronchopulmonary aspergillosis (ABPA) is the most common example of the allergic bronchopulmonary mycoses and is sometimes confused with HP because of the presence of precipitating antibodies

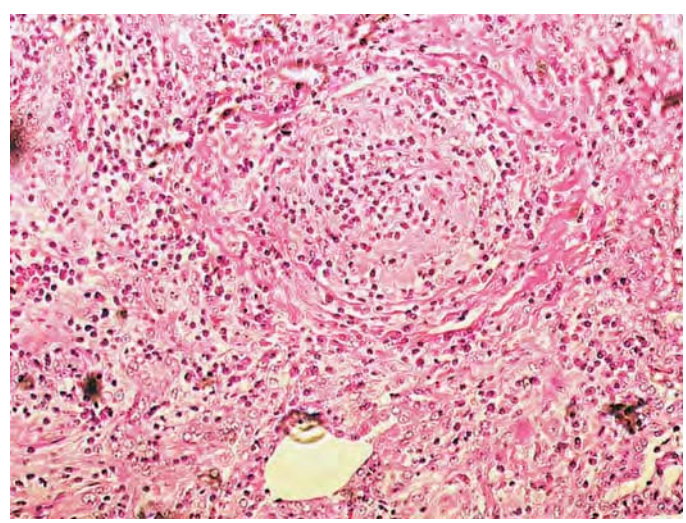

FIGURE 249-2 Open-lung biopsy from a patient with acute hypersensitivity pneumonitis demonstrating loose, nonnecrotizing granulomas and thickened interstitium with an associated interstitial inflammatory response. *(Courtesy of B DeYoung; with permission.)*

to *Aspergillus fumigatus*. ABPA is associated with allergic (atopic) asthma. Acute HP may be confused with *organic dust toxic syndrome* (ODTS), a condition that is more common than HP. ODTS follows heavy exposure to organic dusts and is characterized by transient fever and muscle aches, with or without dyspnea and cough. Serum precipitins are absent, and the chest x-ray is usually normal. This distinction is important, as ODTS is a self-limited disorder without significant long-term sequelae, whereas continued antigen exposure in HP can result in permanent disability. Massive exposure to moldy silage may result in a syndrome termed *pulmonary mycotoxicosis*, with fever, chills, and cough and the presence of pulmonary infiltrates within a few hours of exposure. No previous sensitization is required, and precipitins are absent to *Aspergillus*, the suspected causative agent.

℞ HYPERSENSITIVITY PNEUMONITIS

Because effective treatment depends largely on avoiding the antigen, identification of the causative agent and its source is essential. This is usually possible if the physician takes a careful environmental and occupational history or, if necessary, visits the patient's environment. The simplest way to avoid the incriminated agent is to remove the patient from the environment or the source of the agent from the patient's environment. This recommendation cannot be taken lightly when it completely changes the lifestyle or livelihood of the patient. In many cases, however, the source of exposure (birds, humidifiers) can easily be removed. Pollen masks, personal dust respirators, airstream helmets, and ventilated helmets with a supply of fresh air are increasingly efficient means of purifying inhaled air. If symptoms recur or physiologic abnormalities progress in spite of these measures, then more effective measures to avoid antigen exposure must be pursued. The chronic form of HP typically results from low-grade or recurrent exposure over many months to years, and the lung disease may already be partially or completely irreversible. These patients are usually advised to avoid all possible contact with the offending agent.

Patients with the *acute,* recurrent form of HP usually recover without need for glucocorticoids. *Subacute* HP may be associated with severe symptoms and marked physiologic impairment and may continue to progress for several days despite hospitalization. Urgent establishment of the diagnosis and prompt institution of glucocorticoid treatment are indicated in such patients. Prednisone at a dosage of 1 mg/kg per day or its equivalent is continued for 7 to 14 days and then tapered over the ensuing 2 to 6 weeks at a rate that depends on the patient's clinical status. Patients with *chronic* HP may gradually recover without therapy following environmental control. In many patients, however, a trial of prednisone may be useful to obtain maximal reversibility of the lung disease. Following initial prednisone therapy (1 mg/kg per day for 2 to 4 weeks), the drug is tapered to the lowest dosage that will maintain the functional status of the patient. Many patients will not require or benefit from long-term therapy if there is no further exposure to antigen. Regrettably, available studies demonstrate no effect of glucocorticoid therapy on long-term prognosis of farmer's lung.

PULMONARY INFILTRATES WITH EOSINOPHILIA

Pulmonary infiltrates with eosinophilia (PIE, eosinophilic pneumonias) include distinct individual syndromes characterized by eosinophilic pulmonary infiltrates and, commonly, peripheral blood eosinophilia. Since Loeffler's initial description of a transient, benign syndrome of migratory pulmonary infiltrates and peripheral blood eosinophilia of unknown cause, this group of disorders has been enlarged to include several diseases of both known and unknown etiology (Table 249-2). These diseases may be considered as immunologically mediated lung diseases but are not to be confused with HP, in which eosinophilia is *not* a feature.

When an eosinophilic pneumonia is associated with bronchial asthma, it is important to determine if the patient has atopic asthma and has wheal-and-flare skin reactivity to *Aspergillus* or other relevant fungal antigens. If so, other criteria should be sought for the diagnosis of allergic bronchopulmonary aspergillosis (ABPA) (Table 249-3) or other, rarer examples of allergic bronchopulmonary mycosis such as those caused by *Penicillium, Candida, Curvularia,* or *Helminthosporium* spp.

TABLE 249-2 PULMONARY INFILTRATES WITH EOSINOPHILIA

Etiology Known
Allergic bronchopulmonary mycoses
Parasitic infestations
Drug reactions
Eosinophilia-myalgia syndrome
Idiopathic
Loeffler's syndrome
Acute eosinophilic pneumonia
Chronic eosinophilic pneumonia
Allergic granulomatosis of Churg and Strauss
Hypereosinophilic syndrome

A. fumigatus is the most common cause of ABPA. The chest roentgenogram in ABPA may show transient, recurrent infiltrates or may suggest the presence of proximal bronchiectasis. High-resolution chest CT is a sensitive, noninvasive technique for the recognition of proximal bronchiectasis. The bronchial asthma of ABPA likely involves an IgE-mediated hypersensitivity, whereas the bronchiectasis associated with this disorder is thought to result from a deposition of immune complexes in proximal airways. Adequate treatment usually requires the long-term use of systemic glucocorticoids.

A travel history or evidence of recent immigration should prompt the consideration of parasite-associated disorders. *Tropical eosinophilia* is usually caused by filarial infection; however, eosinophilic pneumonias also occur with other parasites such as *Ascaris, Ancyclostoma* sp., *Toxocara* sp., and *Strongyloides stercoralis.* Tropical eosinophilia due to *Wuchereria bancrofti* or *W. malayi* occurs most commonly in southern Asia, Africa, and South America and is treated successfully with diethylcarbamazine. Even in cases of known foreign travel, identification of the causative agent is not always possible, as exemplified by 18 cases (2 fatal) of acute eosinophilic pneumonia reported among U.S. military personnel deployed in Iraq.

In the United States, *drug-induced eosinophilic pneumonias* are the most common cause of eosinophilic pulmonary infiltrates. These are exemplified by acute reactions to nitrofurantoin, which may begin 2 h to 10 days after nitrofurantoin is started, with symptoms of dry cough, fever, chills, and dyspnea; an eosinophilic pleural effusion accompanying patchy or diffuse pulmonary infiltrates may also occur. Other drugs associated with eosinophilic pneumonias include sulfonamides, penicillin, chlorpropamide, thiazides, tricyclic antidepressants, hydralazine, gold salts, isoniazid, indomethacin, and others. One report has identified anti-TNF-α monoclonal antibody therapy as a cause of eosinophilic pneumonitis. Treatment consists of withdrawal of the incriminated drugs and the use of glucocorticoids, if necessary.

The group of idiopathic eosinophilic pneumonias consists of diseases of varying severity. *Loeffler's syndrome* was originally reported as a benign, acute eosinophilic pneumonia of unknown cause characterized by migrating pulmonary infiltrates and minimal clinical manifestations. In some patients, these clinical characteristics may prove to be

TABLE 249-3 DIAGNOSTIC FEATURES OF ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS (ABPA)

Main Diagnostic Criteria
Bronchial asthma
Pulmonary infiltrates
Peripheral eosinophilia (>1000/μL)
Immediate wheal-and-flare response to *Aspergillus fumigatus*
Serum precipitins to *A. fumigatus*
Elevated serum IgE
Central bronchiectasis
Other Diagnostic Features
History of brownish plugs in sputum
Culture of *A. fumigatus* from sputum
Elevated IgE (and IgG) class antibodies specific for *A. fumigatus*

secondary to parasites or drugs. *Acute eosinophilic pneumonia* is an idiopathic acute febrile illness of <7 days' duration with severe hypoxemia, pulmonary infiltrates, and no history of asthma. *Chronic eosinophilic pneumonia* presents with significant systemic symptoms including fever, chills, night sweats, cough, anorexia, and weight loss of several weeks' to months' duration. The chest x-ray classically shows peripheral infiltrates. Some patients also have bronchial asthma of the intrinsic or nonallergic type. Dramatic clearing of symptoms and chest x-rays is often noted within 48 h after initiation of glucocorticoid therapy.

The *hypereosinophilic syndrome* is characterized by presence of >1500 eosinophils per microliter of peripheral blood for 6 months or longer; lack of evidence for parasitic, allergic, or other known causes of eosinophilia; and signs or symptoms of multisystem organ dysfunction. Consistent features are blood and bone marrow eosinophilia with tissue infiltration by relatively mature eosinophils. The heart may be involved with tricuspid valve abnormalities or endomyocardial fibrosis and a restrictive, biventricular cardiomyopathy (Chap. 231). Other organs affected typically include the lungs, liver, spleen, skin, and nervous system. Therapy of the disorder consists of glucocorticoids and/or hydroxyurea, plus therapy as needed for cardiac dysfunction, which is frequently responsible for much of the morbidity and mortality in this syndrome. Pulmonary eosinophilia has also been associated with T cell lymphoma and has been reported following *lung* and *bone marrow transplantation*.

GLOBAL PICTURE OF HYPERSENSITIVITY PNEUMONITIS AND PULMONARY INFILTRATES WITH EOSINOPHILIA

HP is more prevalent outside of the United States than within, and the range of antigen responses is somewhat different. Internationally, bird-breeder's lung is the most common form of HP. Rather than being associated with avocational exposures, bird-raising practices, highlighted by the emerging threat of avian influenza, lead to substantial exposure to workers involved in poultry husbandry and processing. This increases antigen exposure enormously, in comparison to U.S. workers, and enhances the risk of HP. Importantly, it is the most common cause of pediatric HP and has been reported in individuals as young as 4 years, when it has presented as a chronic cough.

Farmer's lung, one of the earliest reported causes of HP, is now more prevalent outside the United States than within, but it appears to be waning world-wide. This is likely in response to changing agricultural practices; increased use of impermeable barriers in hay storage has reduced the proliferation of thermophilic bacteria, and thus HP.

In certain cases, the international manifestations of HP resemble those of the U.S. disease. Many industrialized nations have increasingly reported HP due to mycobacteria and pseudomonads in contaminated metalworking fluids; the prevalence of these environmental contaminants greatly depends on workplace hygiene practices. Some forms of HP are almost exclusively geographically limited; an example of this is summer-type hypersensitivity pneumonitis in Japan. Likewise, cork worker's pneumonitis (suberosis), caused by exposure to contaminated corks, is almost exclusively seen in Spain and southern Europe, because of the regional cork industry. However, one of the causative antigens (*Chrysonilia sitophila*) is also reported to be an antigen in lung diseases associated with logging in Canada. In Spain, esparto, a member of the grass family, is used as a fiber for the weaving of mats, baskets, and ropes; it is also incorporated into traditional plaster construction. In both of its uses, it has been associated with HP (most likely due to contamination with *A. fumigatus*), again geographically limited because of the utility of the product, though not of the underlying fungal antigen. Exposure to exotic mushrooms is greater in Asia than in the United States, and this has recently been linked to cases of HP.

Pulmonary infiltrates with eosinophilia are also a greater international than U.S. health burden. In this case, parasitic infestation is far more common than drug-induced lung disease, but the manifestations are similar.

250 Environmental Lung Disease

Frank E. Speizer, John R. Balmes

This chapter provides perspectives on ways to assess pulmonary diseases for which environmental or occupational causes are suspected. This assessment is important because removal of the patient from harmful exposure is often the only intervention that might prevent further significant deterioration or lead to improvement in a patient's condition. Furthermore, the identification of an environment-associated disease in a single patient may lead to primary preventive strategies affecting other similarly exposed people who have not yet developed disease.

The exact magnitude of the problem is unknown, but there is no question that large numbers of individuals are at risk for developing serious respiratory disease as a result of occupational or environmental exposures. For example, for the populations over age 15, 15–20% of the burden of asthma and chronic obstructive pulmonary disease (COPD) has been estimated to be due to occupational factors.

HISTORY AND PHYSICAL EXAMINATION

The patient's history is of paramount importance in assessing any potential occupational or environmental exposure. Inquiry into specific work practices should include questions about specific contaminants involved, the availability and use of personal respiratory protection devices, the size and ventilation of workspaces, and whether co-workers have similar complaints. The temporal association of exposure at work and symptoms may provide clues to occupation-related disease. In addition, the patient must be questioned about alternative sources for exposure to potentially toxic agents, including hobbies, home characteristics, exposure to secondhand smoke, and proximity to traffic or industrial facilities. Short-term and long-term exposures to potential toxic agents in the distant past must also be considered.

Many employees are aware of the potential hazards in their workplaces, and many states require that employees be informed about

potentially hazardous exposures. These requirements include the provision of specific information about potential hazardous agents in products being used (Material Safety Data Sheets) and training in personal protective equipment and environmental control procedures. Reminders posted in the workplace may warn workers about hazardous substances. Protective clothing, lockers, and shower facilities may be considered necessary parts of the job. However, the introduction of new processes and/or new chemical compounds may change exposure significantly, and often only the employee on the production line is aware of the change. For the physician who regularly sees patients from a particular industry, a visit to the work site can be very instructive. Alternatively, physicians can request inspections by appropriate federal and/or state authorities.

The physical examination of patients with environment-related lung diseases may help to determine the nature and severity of the pulmonary condition. Unfortunately, these findings do not typically point to the specific causative agent, and other types of information must be used to arrive at an etiologic diagnosis.

PULMONARY FUNCTION TESTS AND CHEST IMAGING

Many mineral dusts produce characteristic alterations in the mechanics of breathing and lung volumes that clearly indicate a restrictive pattern (Chap. 246). Similarly, exposures to a number of organic dusts or chemical agents may result in occupational asthma or COPD. Measurement of change in forced expiratory volume (FEV_1) before and after a working shift can be used to detect an acute bronchoconstrictive or inflammatory response. For example, an acute decrement of FEV_1 over the first work shift of the week is a characteristic feature of cotton textile workers with byssinosis (an obstructive airway disorder with features of both asthma and chronic bronchitis).

The chest radiograph is useful in detecting and monitoring the pulmonary response to mineral dusts, certain metals, and organic dusts capable of inducing hypersensitivity pneumonitis. The International Labour Organisation (ILO) International Classification of Radiographs of Pneumoconioses classifies chest radiographs according to the nature and size of opacities seen and the extent of involvement of the parenchyma. In general, small rounded opacities are seen in silicosis or coal worker's pneumoconiosis and small, linear opacities are seen in asbestosis. The profusion of such opacities is rated using a 12-point scheme. Although useful for epidemiologic studies and screening large numbers of workers, the ILO system can be problematic when applied to an individual worker's chest radiograph. With dusts causing rounded opacities, the degree of involvement on the chest radiograph may be extensive, while pulmonary function may be only minimally impaired. In contrast, in pneumoconiosis causing linear, irregular opacities like those seen in asbestosis, the radiograph may lead to underestimation of the severity of the impairment until relatively late in the disease. For the individual patient with a history of exposure, conventional CT and high-resolution CT (HRCT) have improved the sensitivity of identifying diffuse parenchymal abnormalities of the lung as well as pleural thickening characteristic of asbestos exposure.

Other procedures that may be of use in identifying the role of environment exposures in causing lung disease include evaluation of heavy metal concentrations in urine (cadmium in battery plant workers); skin prick testing or specific IgE antibody titers for evidence of immediate hypersensitivity to agents capable of inducing occupational asthma (flour antigens in bakery workers); specific IgG precipitating antibody titers for agents capable of causing hypersensitivity pneumonitis (pigeon antigens in bird handlers); or assays for specific cell-mediated immune responses (beryllium lymphocyte proliferation testing in nuclear workers or tuberculin skin testing in health care workers). Sometimes, a bronchoscopy to obtain bronchoalveolar lavage fluid and transbronchial biopsy of lung tissue may be required for histologic diagnosis (chronic beryllium disease). Rarely, video-assisted thoracoscopic surgery to obtain a larger sample of lung tissue may be required to determine the specific diagnosis of environment-induced lung disease (hypersensitivity pneumonitis or giant cell interstitial pneumonitis due to cobalt exposure).

MEASUREMENT OF EXPOSURE

If reliable environmental sampling data are available, this information should be used in assessing a patient's exposure. Since many of the chronic diseases result from exposure over many years, current environmental measurements should be combined with work histories to arrive at estimates of past exposure.

In situations where individual exposure to specific agents—either in a work setting or via ambient air pollutants—has been determined, the chemical and physical characteristics of these agents affect both inhaled dose and site of deposition in the respiratory tract. Water-soluble gases such as ammonia or sulfur dioxide are absorbed in the lining fluid of the upper and proximal airways and thus tend to produce irritative and bronchoconstrictive responses. In contrast, nitrogen dioxide and phosgene, which are less soluble, may penetrate to the bronchioles and alveoli in sufficient quantities to produce acute chemical pneumonitis that can be life-threatening (acute respiratory distress syndrome with noncardiogenic pulmonary edema).

Particle size of air contaminants must also be considered. Particles >10–15 μm in diameter, because of their settling velocities in air, do not penetrate beyond the upper airways. Particles <10 μm in size are deposited below the larynx and are primarily created by the burning of fossil fuels or high-temperature industrial processes resulting in condensation products from gases, fumes, or vapors. These particles are divided into three size fractions on the basis of their size characteristics and sources. Particles of ~2.5–10 μm (coarse-mode fraction) contain crustal elements, such as silica, aluminum, and iron. These particles mostly deposit relatively high in the tracheobronchial tree. Although the total mass of an ambient sample is dominated by these larger respirable particles, the number of particles, and therefore the surface area on which potential toxic agents can deposit and be carried to the lower airways, is dominated by particles <2.5 μm (fine-mode fraction). The smallest particles, those <0.1 μm in size, represent the ultrafine fraction and make up the largest number of particles, which tend to remain in the airstream and deposit in the lung only on a random basis as they come into contact with the alveolar walls. Besides the size characteristics of particles and the solubility of gases, the actual chemical composition, mechanical properties, and immunogenicity or infectivity of inhaled material determine in large part the nature of the diseases found among exposed persons.

OCCUPATIONAL EXPOSURES AND PULMONARY DISEASE

Table 250-1 provides broad categories of exposure in the workplace and diseases associated with chronic exposure in these industries.

ASBESTOS-RELATED DISEASES

Asbestos is a generic term for several different mineral silicates, including chrysolite, amosite, anthophyllite, and crocidolite. In addition to workers involved in the production of asbestos products (mining, milling, and manufacturing), many workers in the ship-building and construction trades, including pipe fitters and boilermakers, were occupationally exposed because asbestos was widely used for its thermal and electrical insulation properties. Asbestos also was used in the manufacture of fire-smothering blankets and safety garments, as filler for plastic materials, in cement and floor tiles, and in friction materials, such as brake and clutch linings.

Exposure to asbestos is not limited to persons who directly handle the material. Cases of asbestos-related diseases have been encountered in individuals with only bystander exposure, such as the painter or electrician who worked alongside the insulation worker in a shipyard. Community exposure resulted from the use of asbestos-containing mine or mill tailings as landfill, road surface, and playground material. Finally, exposure can also occur from the disturbance of naturally occurring asbestos (e.g., from increasing residential development in the foothills of the Sierra Mountains in California).

Asbestos was first used extensively in the 1930s. Starting in 1975 it was mostly replaced with synthetic mineral fibers, such as fiberglass or slag wool, but it continues to be used increasingly in the developing world.

TABLE 250-1 CATEGORIES OF OCCUPATIONAL EXPOSURE AND ASSOCIATED RESPIRATORY CONDITIONS

Occupational Exposures	Nature of Respiratory Responses	Comment
Inorganic Dusts		
Asbestos: mining, processing, construction, ship repair	Fibrosis (asbestosis), pleural disease, cancer, mesothelioma	Virtually all new mining and construction with asbestos done in developing countries
Silica: mining, stone cutting, sandblasting, quarrying	Fibrosis (silicosis), PMF, cancer, silicotuberculosis, COPD	Improved protection in United States, persistent risk in developing countries
Coal dust: mining	Fibrosis (coal workers' pneumoconiosis), PMF, COPD	Risk dropping in United States, increasing where new mines open
Beryllium: processing alloys for high-tech industries	Acute pneumonitis, chronic granulomatous disease, lung cancer (highly suspect)	Risk in high-tech industries persists
Other metals: aluminum, chromium, cobalt, nickel, titanium, tungsten carbide, or "hard metal" (contains cobalt)	Wide variety of conditions from acute pneumonitis to lung cancer and asthma	New diseases appear with new process development
Organic Dusts		
Cotton dust: milling, processing	Byssinosis (an asthma-like syndrome), chronic bronchitis, COPD	Increasing risk in developing countries with drop in United States as jobs shift overseas
Grain dust: elevator agents, dock workers, milling, bakers	Asthma, chronic bronchitis, COPD	Risk shifting more to migrant labor pool
Other agricultural dusts: fungal spores, vegetable products, insect fragments, animal dander, bird and rodent feces, endotoxins, microorganisms, pollens	Hypersensitivity pneumonitis (farmers' lung), asthma, chronic bronchitis	Important in migrant labor pool but also resulting from in-home exposures
Toxic chemicals: wide variety of industries, see Table 250-2	Chronic bronchitis, COPD, hypersensitivity pneumonitis, pneumoconiosis, and cancer	Reduced risk with recognized hazards; increasing risk for developing countries where controlled labor practices are less stringent
Other respiratory environmental agents (proven or highly suspect): uranium and radon daughters, environmental tobacco smoke, polycyclic hydrocarbons, biomass fuels, diesel exhaust, welding fumes, woods or wood finishing products	Estimates vary from ~3 to 10% of all lung cancers; in addition chronic bronchitis, COPD, and fibrosis	In-home exposures important, in developing countries disease rates as high or higher in females compared to males

Despite current regulations mandating adequate training for any worker potentially exposed to asbestos, exposure continues among inadequately trained and protected demolition workers. The major health effects from exposure to asbestos are pleural and pulmonary fibrosis and cancers of the respiratory tract, the pleura, and (in rare cases) the peritoneum.

Asbestosis is a diffuse interstitial fibrosing disease of the lung that is directly related to the intensity and duration of exposure. The disease resembles other forms of diffuse interstitial fibrosis (Chap. 255). Usually, moderate to severe exposure has taken place for at least 10 years before the disease becomes manifest and may occur following exposure to any of the asbestiform fiber types.

Physiologic studies reveal a restrictive pattern with a decrease in both lung volumes and diffusing capacity. There may also be evidence of mild airflow obstruction (due to peribronchiolar fibrosis).

The fibrotic lesions are the end result of oxidative injury due to the generation of reactive oxygen species by the transition metals on the surface of the fibers as well as from cells engaged in phagocytosis.

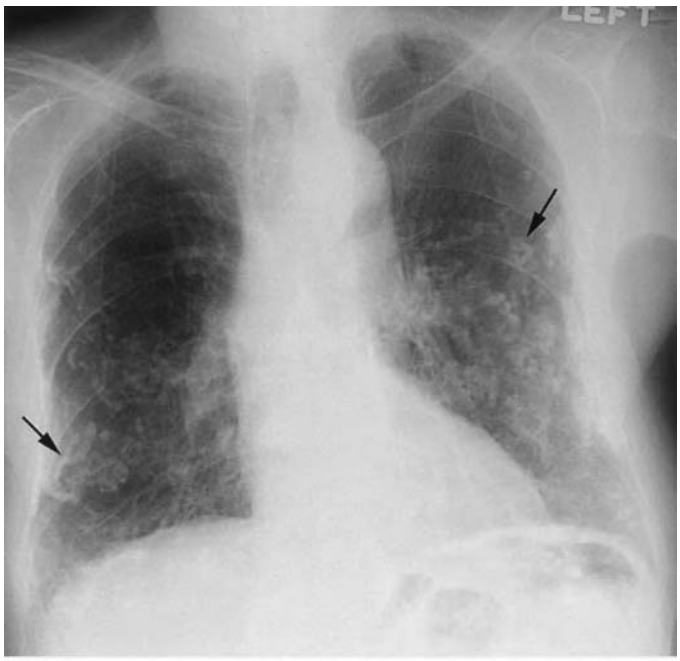
Diagnosis The chest radiograph can be used to detect a number of manifestations of asbestos exposure. Past exposure is specifically indicated by pleural plaques, which are characterized by either thickening or calcification along the parietal pleura, particularly along the lower lung fields, the diaphragm, and the cardiac border. Without additional manifestations, pleural plaques imply only exposure, not pulmonary impairment. Benign pleural effusions may also occur. The fluid is typically a serous or bloody exudate. The effusion may be slowly progressive or may resolve spontaneously. Irregular or linear opacities, usually first noted in the lower lung fields and spreading into the middle and upper lung fields, occur as the disease progresses. An indistinct heart border or a "ground glass" appearance in the lung fields is seen in some cases. In cases in which the x-ray changes are less obvious, HRCT may show distinct changes of subpleural curvilinear lines 5–10 mm in length that appear to be parallel to the pleural surface (Fig. 250-1).

No specific therapy is available for the management of patients with asbestosis. The supportive care is the same as that given to any patient with diffuse interstitial fibrosis from any cause. In general, newly diagnosed cases will have resulted from exposure levels that were present many years before and, in spite of the patients' having left the industry, are attributable to that former exposure. Since the patient may be eligible for compensation within a specific time frame after the diagnosis of an asbestos-related disease is made, the physician making the diagnosis should be certain to inform the patient promptly. On occasion, the physician may have reason to suspect ongoing exposure from a patient's current job description. Such a patient needs to wear appropriate respiratory protective gear according to federal regulation. Casual, nonoccupational exposure to undisturbed sources of asbestos-containing materials—e.g., in walls of schools or other buildings—represents virtually no hazard of asbestosis.

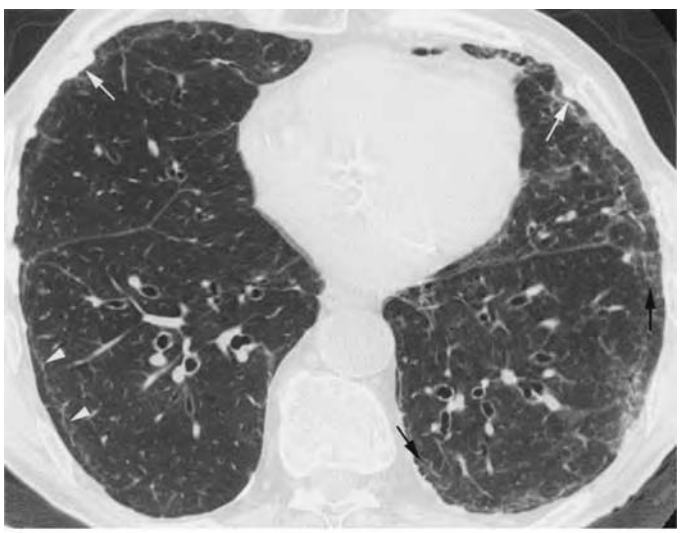
Lung cancer (Chap. 85) is the most frequent cancer associated with asbestos exposure. The excess frequency of lung cancer (all histologic types) in asbestos workers is associated with a minimum latency of 15–19 years between first exposure and development of the disease. Persons with more exposure are at greater risk of disease. In addition, there is a significant multiplicative effect of smoking and asbestos exposure than would be expected from the additive effect of each factor. The use of HRCT in such at-risk individuals to detect lung cancer at an earlier stage is currently under investigation.

Mesotheliomas (Chap. 257), both pleural and peritoneal, are also associated with asbestos exposure. In contrast to lung cancers, these tumors do not appear to be associated with smoking. Relatively short-term asbestos exposures of ≤ 1–2 years or less, occurring up to 40 years in the past, have been associated with the development of mesotheliomas (an observation that emphasizes the importance of obtaining a complete environmental exposure history). While the risk of mesothelioma is much less than for lung cancer among asbestos-exposed workers, over 2,000 cases were reported in the U.S. per year at the start of the 21st century.

Although ~50% of mesotheliomas metastasize, the tumor generally is locally invasive, and death usually results from local extension. Most patients present with effusions that may obscure the underlying pleural tumor. In contrast to the findings in effusion due to other causes, because of the restriction placed on the chest wall, no shift of mediastinal structures toward the opposite side of the chest will be seen. The major diagnostic problem is differentiation from peripherally spreading pulmonary adenocarcinoma or from adenocarcinoma metastasized to pleura from



A



B

FIGURE 250-1 Asbestosis: *A.* Frontal chest radiograph shows bilateral calcified pleural plaques consistent with asbestos-related pleural disease. Poorly defined linear and reticular abnormalities are seen in the lower lobes bilaterally. ***B.*** Axial high-resolution CT of the thorax obtained through the lung bases shows bilateral, subpleural reticulation (*black arrows*), representing fibrotic lung disease due to asbestosis. Subpleural lines are also present (*arrowheads*), characteristic of, though not specific for, asbestosis. Calcified pleural plaques representing asbestos-related pleural disease (*white arrows*) are also evident.

an extrathoracic primary site. Although cytologic examination of pleural fluid may suggest the diagnosis, biopsy of pleural tissue, generally with video-assisted thoracic surgery, and special immunohistochemical staining is usually required. There is no effective therapy.

Since epidemiologic studies have shown that >80% of mesotheliomas may be associated with asbestos exposure, documented mesothelioma in a patient with occupational or environmental exposure to asbestos may be compensable.

SILICOSIS

In spite of the technical adequacy of existing protective equipment, *free silica* (SiO_2), or crystalline quartz, is still a major occupational hazard. The major occupational exposures include: mining; stonecutting; employment

FIGURE 250-2 Acute silicosis. The high-resolution CT scan shows multiple small nodules consistent with silicosis but also diffuse ground-glass densities with thickened intralobular and interlobular septa, producing polygonal shapes. This has been referred to as "crazy paving."

in abrasive industries, such as stone, clay, glass, and cement manufacturing; foundry work; packing of silica flour; and quarrying, particularly of granite. Most often, pulmonary fibrosis due to silica exposure (silicosis) occurs in a dose-response fashion after many years of exposure.

Workers heavily exposed through sandblasting in confined spaces, tunneling through rock with high quartz content (15–25%), or the manufacture of abrasive soaps may develop acute silicosis with as little as 10 months' exposure. The clinical and pathological features of acute silicosis are similar to those of pulmonary alveolar proteinosis (Chap. 255). The chest radiograph may show profuse miliary infiltration or consolidation and there is a characteristic HRCT pattern known as "crazy paving" (Fig. 250-2). The disease may be quite severe and progressive, despite the discontinuation of exposure. Whole-lung lavage may provide symptomatic relief and slow progression.

With long-term, less intense exposure, small rounded opacities in the upper lobes may appear on the chest radiograph after 15–20 years of exposure (*simple silicosis*). Calcification of hilar nodes may occur in as many as 20% of cases and produces a characteristic "eggshell" pattern. Silicotic nodules may be identified more readily by HCRT (Fig. 250-3). The nodular fibrosis may be progressive in the absence of further exposure, with coalescence and formation of nonsegmental conglomerates of irregular masses >1 cm in diameter (*complicated silicosis*). These masses can become quite large and when this occurs the term *progressive massive fibrosis* (PMF) is applied. Significant functional impairment with both restrictive and obstructive components may be associated with this form of silicosis.

Because silica is cytotoxic to alveolar macrophages, patients with silicosis are at greater risk of acquiring lung infections that involve these cells as a primary defense (*Mycobacterium tuberculosis*, atypical mycobacteria and fungi). Because of the increased risk of active tuberculosis, the recommended treatment of latent tuberculosis in these patients is longer. Another potential clinical complication of silicosis is autoimmune connective tissue disorders such as rheumatoid arthritis or scleroderma. In addition, there are sufficient epidemiologic data that the International Agency for Research on Cancer lists silica as a probable lung carcinogen.

Other less hazardous silicates include Fuller's earth, kaolin, mica, diatomaceous earths, silica gel, soapstone, carbonate dusts, and ce-

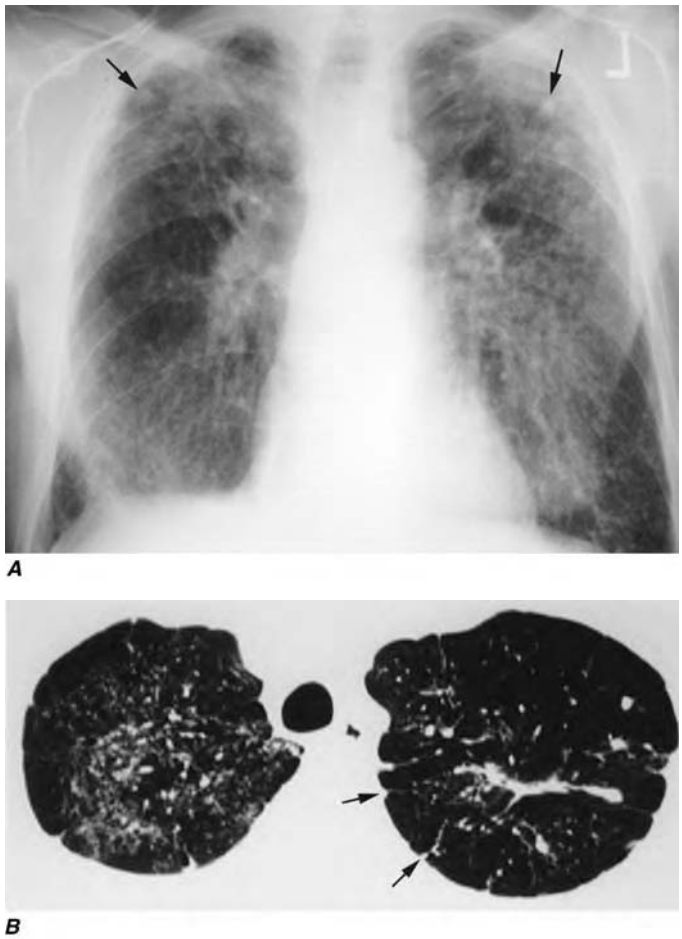


FIGURE 250-3 Chronic silicosis. *A.* Frontal chest radiograph in a patient with silicosis shows variably sized, poorly defined nodules (*arrows*) predominating in the upper lobes, ***B.*** Axial thoracic CT image through the lung apices shows numerous small nodules, more pronounced in the right upper lobe. A number of the nodules are subpleural in location (*arrows*).

ment dusts. The production of fibrosis in workers exposed to these agents is believed to be related either to the free silica content of these dusts or, for substances that contain no free silica, to the potentially large dust loads to which these workers may be exposed.

Other silicates, including *talc dusts*, may be contaminated with asbestos and/or free silica. Fibrosis and/or pleural or lung cancer have been associated with chronic exposure to commercial talc.

COAL WORKER'S PNEUMOCONIOSIS (CWP)

Occupational exposure to *coal dust* can lead to CWP, which has enormous social, economic, and medical significance in every nation in which coal mining is an important industry. Simple radiographically identified CWP is seen in ~10% of all coal miners and in as many as 50% of anthracite miners with more than 20 years' work on the coal face. The prevalence of disease is lower in workers in bituminous coal mines. Since much western U.S. coal is bituminous, CWP is less prevalent in that region.

With prolonged exposure to coal dust (i.e., 15–20 years), small, rounded opacities similar to those of silicosis may develop. As in silicosis, the presence of these nodules (*simple CWP*) is not usually associated with pulmonary impairment. Much of the symptomatology associated with simple CWP appears to be due to the effects of coal dust on the development of chronic bronchitis and COPD (Chap. 254). The effects of coal dust are additive to those of cigarette smoking.

Complicated CWP is manifested by the appearance on the chest radiograph of nodules ranging from 1 cm in diameter to the size of an entire lobe, generally confined to the upper half of the lungs. As in silicosis, this condition can progress to PMF which is accompanied by severe lung function deficits and associated with premature mortality.

Caplan's syndrome (Chap. 314), first described in coal miners but subsequently found in patients with silicosis, includes seropositive rheumatoid arthritis with characteristic pneumoconiotic nodules. Silica has immunoadjuvant properties and is often present in anthracitic coal dust.

CHRONIC BERYLLIUM DISEASE

Beryllium is a light-weight metal with tensile strength, has good electrical conductivity, and is valuable in the control of nuclear reactions through its ability to quench neutrons. Although beryllium may produce an acute pneumonitis, it is far more commonly associated with a chronic granulomatous inflammatory disease that is similar to sarcoidosis (Chap. 322). Unless one inquires specifically about occupational exposures to beryllium in the manufacture of alloys, ceramics, or high-technology electronics in a patient with sarcoidosis, one may miss entirely the etiologic relationship to the occupational exposure. What distinguishes chronic beryllium disease (CBD) from sarcoidosis is evidence of a specific cell-mediated immune response (i.e., delayed hypersensitivity) to beryllium.

The test that usually provides this evidence is the beryllium lymphocyte proliferation test (BeLPT). The BeLPT uses the in vitro proliferation of lymphocytes from blood or bronchoalveolar lavage in the presence of beryllium salts as compared to that of unstimulated cells. Proliferation is usually measured by lymphocyte uptake of radiolabeled thymidine.

Chest imaging findings are similar to those of sarcoidosis (nodules along septal lines) except that hilar adenopathy is somewhat less common. Like sarcoidosis, pulmonary function test results may show restrictive and/or obstructive ventilatory deficits and decreased diffusing capacity. With early disease, both chest imaging studies and pulmonary function tests may be normal. Fiberoptic bronchoscopy with transbronchial lung biopsy is usually required to make the diagnosis of CBD. In a beryllium-sensitized individual, the presence of noncaseating granulomas or monocytic infiltration in lung tissue establishes the diagnosis. Accumulation of beryllium-specific CD4+ T cells occurs in the granulomatous inflammation seen on lung biopsy.

Chronic beryllium disease is one of the best studied examples of gene-environment interaction. Susceptibility to CBD is highly associated with HLA-DP alleles possessing a glutamic acid in position 69 of the β chain. In addition, there is also evidence that a polymorphism in position 308 of the promoter region of tumor necrosis factor α is involved in mediating the severity of the inflammatory response in patients with CBD.

Other metals, including aluminum and titanium dioxide, have been rarely associated with a sarcoid-like reaction in lung tissue. Exposure to dust containing tungsten carbide, also known as "hard metal," may produce giant cell interstitial pneumonitis. Cobalt is a constituent of tungsten carbide and is the likely etiologic agent of both the interstitial pneumonitis and the occupational asthma that may occur. The most common exposures to tungsten carbide occur in tool and dye, saw blade, and drill bit manufacture. Diamond polishing may also involve exposure to cobalt dust. The same Glu69 polymorphism of the HLA-DP β chain that confers increased risk of CBD also appears to increase risk of cobalt-induced giant cell interstitial pneumonitis.

In patients with interstitial lung disease, one should always inquire about exposure to metal fumes and/or dusts. Especially when sarcoidosis appears to be the diagnosis, one should always consider possible CBD.

OTHER INORGANIC DUSTS

Most of the inorganic dusts discussed thus far are associated with the production of either dust macules or interstitial fibrotic changes in the lung. Other inorganic and organic dusts (see categories in Table 250-1), along with some of the dusts previously discussed, are associated with chronic mucous hypersecretion (chronic bronchitis), with or without reduction of expiratory flow rates. Cigarette smoking is the major cause of these conditions and any effort to attribute some com-

ponent of the disease to occupational and environmental exposures must take cigarette smoking into account. Most studies suggest an additive effect of dust exposure and smoking. The pattern of the irritant dust effect is similar to that of cigarette smoking, suggesting that small airway inflammation may be the initial site of pathologic response in those cases and continued exposure may lead to chronic bronchitis and COPD.

ORGANIC DUSTS

Some of the specific diseases associated with organic dusts are discussed in detail in the chapters on asthma (Chap. 248) and hypersensitivity pneumonitis (Chap. 249). Many of these diseases are named for the specific setting in which they are found, e.g., farmer's lung, malt worker's disease, or mushroom worker's disease. Often the temporal relation of symptoms to exposure furnishes the best evidence for the diagnosis. Three occupational groups are singled out for discussion because they represent the largest proportion of people affected by the diseases resulting from organic dusts.

Cotton Dust (Byssinosis) Many persons are exposed occupationally to cotton, flax, or hemp in the production of yarns for cotton, linen, and rope making. Although this discussion focuses on cotton, the same syndrome—albeit somewhat less severe—has been reported in association with exposure to flax, hemp, and jute.

Exposure occurs throughout the manufacturing process but is most pronounced in those portions of the factory involved with the treatment of the cotton prior to spinning—i.e., blowing, mixing, and carding (straightening of fibers). Risk of byssinosis is associated with both cotton dust and endotoxin levels in the workplace environment. Attempts to control dust levels by use of exhaust hoods, general increases in ventilation, and wetting procedures in some settings have been highly successful. However, respiratory protective equipment appears to be required during certain operations to prevent workers from being exposed to levels of cotton dust that exceed the current U.S. permissible exposure level.

Byssinosis is characterized clinically as occasional (early stage) and then regular (late stage) chest tightness toward the end of the first day of the workweek ("Monday chest tightness"). In epidemiologic studies, depending on the level of exposure via the carding room air, up to 80% of employees may show a significant drop in their FEV_1 over the course of a Monday shift.

Initially the symptoms do not recur on subsequent days of the week. However, in 10–25% of workers, the disease may be progressive, with chest tightness recurring or persisting throughout the workweek. After >10 years of exposure, workers with recurrent symptoms are more likely to have an obstructive pattern on pulmonary function testing. The highest grades of impairment are generally seen in smokers.

Reduction of dust exposure is of primary importance to the management of byssinosis. All workers with persistent symptoms or significantly reduced levels of pulmonary function should be moved to areas of lower risk of exposure. Regular surveillance of pulmonary function in cotton dust–exposed workers using spirometry before and after the workshift is required by the Occupational Safety and Health Administration (OSHA) of the U.S. government.

Grain Dust Although the exact number of workers at risk in the United States is not known, at least 500,000 people work in grain elevators, and >2 million farmers are potentially exposed to grain dust. The presentation of obstructive airway disease in grain dust-exposed workers is virtually identical to the characteristic findings in cigarette smokers, i.e., persistent cough, mucous hypersecretion, wheeze and dyspnea on exertion, and reduced FEV_1 and FEV_1/FVC ratio (Chap. 246).

Dust concentrations in grain elevators vary greatly but appear to be >10,000 $\mu g/m^3$; approximately one-third of the particles, by weight, are in the respirable range. The effect of grain dust exposure is additive to that of cigarette smoking, with ~50% of workers who smoke having symptoms. Among nonsmoking grain elevator operators, approximately one-quarter have mucous hypersecretion, about five times the number that would be expected in unexposed nonsmokers. Smoking grain dust–exposed workers are more likely to have obstructive ventilatory deficits on pulmonary function testing. As in byssinosis, endotoxin may play a role in grain dust–induced chronic bronchitis and COPD.

Farmer's Lung This condition results from exposure to moldy hay containing spores of thermophilic actinomycetes that produce a hypersensitivity pneumonitis (Chap. 249). There are few good population-based estimates of the frequency of occurrence of this condition in the United States. However, among farmers in Great Britain, the rate of disease ranges from approximately 10–50 per 1000. The prevalence of disease varies in association with rainfall, which determines the amount of fungal growth, and with differences in agricultural practices related to turning and stacking hay.

The patient with acute farmer's lung presents 4–8 h after exposure with fever, chills, malaise, cough, and dyspnea without wheezing. The history of exposure is obviously essential to distinguish this disease from influenza or pneumonia with similar symptoms. In the chronic form of the disease, the history of repeated attacks after similar exposure is important in differentiating this syndrome from other causes of patchy fibrosis (e.g., sarcoidosis).

A wide variety of other organic dusts are associated with the occurrence of hypersensitivity pneumonitis (Chap. 249). For those patients who present with hypersensitivity pneumonitis, specific and careful inquiry about occupations, hobbies, or other home environmental exposures is necessary to uncover the source of the etiologic agent.

TOXIC CHEMICALS

Exposure to toxic chemicals affecting the lung generally involves gases and vapors. A common accident is one in which the victim is trapped in a confined space where the chemicals have accumulated to toxic levels. In addition to the specific toxic effects of the chemical, the victim will often sustain considerable anoxia, which can play a dominant role in determining whether the individual survives.

Table 250-2 lists a variety of toxic agents that can produce acute and sometimes life-threatening reactions in the lung. All these agents in sufficient concentrations have been demonstrated, at least in animal studies, to affect the lower airways and disrupt alveolar architecture, either acutely or as a result of chronic exposure. Some of these agents may be generated acutely in the environment (see below).

Firefighters and fire victims are at risk of *smoke inhalation*, a numerically important cause of acute cardiorespiratory failure. Smoke inhalation kills more fire victims than does thermal injury. Carbon monoxide poisoning with resulting significant hypoxemia can be life-threatening (**Chap. e35**). The use of synthetic materials (plastic, polyurethanes), which, when burned, may release a variety of other toxic agents (such as cyanide or hydrochloric acid), must be considered when evaluating smoke inhalation victims. Exposed victims may suffer some degree of lower respiratory tract inflammation and/or pulmonary edema.

Exposure to certain highly reactive, low-molecular-weight agents used in the manufacture of synthetic polymers, paints, and coatings (*diisocyanates* in polyurethanes; *aromatic amines* and *acid anhydrides* in epoxies) are associated with a high risk of occupational asthma. Although this occupational asthma manifests clinically as if sensitization has occurred, there is little evidence that an IgE antibody–mediated mechanism is involved. Hypersensitivity pneumonitis–like reactions also have been described in diisocyanate and acid anhydride–exposed workers.

Fluoropolymers, such as Teflon, which at normal temperatures produce no reaction, upon heating become volatilized. The inhaled agents cause a characteristic syndrome of fever, chills, malaise, and occasionally mild wheezing leading to the diagnosis of *polymer fume fever*. A similar self-limited, influenza-like syndrome—*metal fume fever*—results from acute exposure to fumes or smoke containing zinc oxide. The syndrome may begin several hours after work and resolves within 24 h, only to return on repeated exposure. Welding of galvanized steel is the most common exposure leading to metal fume fever.

Two other agents have been recently associated with potentially severe interstitial lung disease. Occupational exposure to nylon flock has

TABLE 250-2 SELECTED COMMON TOXIC CHEMICAL AGENTS AFFECTING THE LUNG

Agent(s)	Selected Exposures	Acute Effects from High or Accidental Exposure	Chronic Effects from Relatively Low Exposure
Acid fumes: H_2SO_4, HNO_3	Manufacture of fertilizers, chlorinated organic compounds, dyes, explosives, rubber products, metal etching, plastics	Mucous membrane irritation, followed by chemical pneumonitis 2–3 days later	Bronchitis and suggestion of mildly reduced pulmonary function in children with lifelong residential exposure to high levels; clinical significance unknown
Acrolein and other aldehydes	By-product of burning plastics, woods, tobacco smoke	Mucous membrane irritant, decrease in lung function	Mutagen in animals, no human data
Ammonia	Refrigeration; petroleum refining; manufacture of fertilizers, explosives, plastics, and other chemicals	Same as for acid fumes	Chronic bronchitis
Anhydrides	Manufacture of resin esters, polyester resins, thermoactivated adhesives	Nasal irritation, cough	Asthma, chronic bronchitis, hypersensitivity pneumonitis
Cadmium fumes	Smelting, soldering, battery production	Mucous membrane irritant, acute respiratory distress syndrome (ARDS)	COPD
Formaldehyde	Manufacture of resins, leathers, rubber, metals, and woods; laboratory workers, embalmers; emission from urethane foam insulation	Same as for acid fumes	Cancers in one species; no data on humans
Halides and acid salts (Cl, Br, F)	Bleaching in pulp, paper, textile industry; manufacture of chemical compounds; synthetic rubber, plastics, disinfectant, rocket fuel, gasoline	Mucous membrane irritation, pulmonary edema; possible reduced FVC 1–2 yrs after exposure	Dryness of mucous membrane, epistaxis, dental fluorosis, tracheobronchitis
Hydrogen sulfide	By-product of many industrial processes, oil, other petroleum processes and storage	Increase in respiratory rate followed by respiratory arrest, lactic acidosis, pulmonary edema, death	Conjunctival irritation, chronic bronchitis, recurrent pneumonitis
Isocyanates (TDI, HDI, MDI)	Production of polyurethane foams, plastics, adhesives, surface coatings	Mucous membrane irritation, dyspnea, cough, wheeze, pulmonary edema	Upper respiratory tract irritation, cough, asthma, allergic alveolitis
Nitrogen dioxide	Silage, metal etching, explosives, rocket fuels, welding, by-product of burning fossil fuels	Cough, dyspnea, pulmonary edema may be delayed 4–12 h; possible result from acute exposure: bronchiolitis obliterans in 2–6 wks	Emphysema in animals, ?chronic bronchitis, associated with reduced lung function in children with lifelong residential exposure, clinical significance unknown
Ozone	Arc welding, flour bleaching, deodorizing, emissions from copying equipment, photochemical air pollutant	Mucous membrane irritant, pulmonary hemorrhage and edema, reduced pulmonary function transiently in children and adults, and increased hospitalization with exposure to summer haze	Chronic eye irritation and slight excess in cardiopulmonary mortality in susceptible individuals
Phosgene	Organic compound, metallurgy, volatilization of chlorine-containing compounds	Delayed onset of bronchiolitis and pulmonary edema	Chronic bronchitis
Sulfur dioxide	Manufacture of sulfuric acid, bleaches, coating of nonferrous metals, food processing, refrigerant, burning of fossil fuels, wood pulp industry	Mucous membrane irritant, epistaxis	?Chronic bronchitis

been shown to induce a lymphocytic bronchiolitis, and workers exposed to diacetyl used to provide "butter" flavor in the manufacture of microwave popcorn have developed bronchiolitis obliterans (Chap. 255).

World Trade Center Disaster A consequence of the attack on the World Trade Center (WTC) on September 11, 2001, was relatively heavy exposure of a large number of firefighters and other rescue workers to the dust generated by the collapse of the buildings. Environmental monitoring and chemical characterization of WTC dust has revealed a wide variety of potentially toxic constituents, although much of the dust was pulverized cement. Possibly because of the high alkalinity of WTC dust significant cough, wheeze, and phlegm production occurred among firefighters and clean-up crews. New cough and wheeze syndromes also occurred among local residents. Initial longitudinal follow-up of New York firefighters suggests that heavier exposure to WTC dust is associated with accelerated decline of lung function.

ENVIRONMENTAL RESPIRATORY CARCINOGENS

In addition to asbestos exposures, other occupational exposures associated with either proven or suspected respiratory carcinogens include those to acrylonitrile, arsenic compounds, beryllium, bis(chloromethyl) ether, chromium (hexavalent), formaldehyde (nasal), isopropyl oil (nasal sinuses), mustard gas, the various ores used to produce pure nickel, polyaromatic hydrocarbons (coke oven emissions and diesel exhaust), secondhand tobacco smoke, silica (both mining and processing), talc (possible asbestos contamination in both mining and milling), vinyl chloride (sarcomas), wood (nasal cancer only), and uranium. The occurrence of excess cancers in uranium miners raises the possibility that a large number of workers are at risk by virtue of exposure to similar radiation hazards. This number includes not only workers involved in processing uranium but also workers exposed in underground mining operations where radon daughters may be emitted from rock formations.

ASSESSMENT OF DISABILITY

Patients who have lung disease may have difficulty continuing to work in their usual jobs because of respiratory symptoms. Such patients frequently seek assistance from their physicians in obtaining compensation for loss of income. *Disability* is the term used to describe the decreased ability to work due to the effects of a medical condition. Physicians are generally able to assess physiologic dysfunction, or *impairment*, but the rating of disability also involves non-medical factors such as the education and employability of the individual. The disability rating scheme differs with the compensation-

granting agency. For example, the U.S. Social Security Administration requires that an individual be unable to do any work (i.e., *total* disability) before he/she will receive income replacement payments. Many state workers' compensation systems allow for payments for *partial* disability. In the Social Security scheme no determination of cause is done, while work-relatedness must be established in workers' compensation systems.

Most commonly the need for disability assessment comes about because of the patient's complaint of shortness of breath. It is important to remember that dyspnea may result from cardiac, hematologic, or neuromuscular diseases in addition to respiratory diseases. For respiratory disability, resting pulmonary function tests (spirometry and diffusing capacity) are used as the initial assessment tool, with cardiopulmonary exercise testing (to assess maximal oxygen consumption) used if the results of the resting tests do not correlate with the patient's symptoms. Methacholine challenge (to assess airways reactivity) can also be useful in patients with asthma who have normal spirometry when evaluated. Some compensation agencies (e.g., Social Security) have proscribed disability classification schemes based on pulmonary function test results. When no specific scheme is proscribed, the *Guidelines of the American Medical Association* should be used.

Evaluating relation to work exposure requires a detailed work history, as previously discussed in this chapter. Occasionally, as with some cases of suspected occupational asthma, challenge to the putative agent in the work environment with repeated pulmonary function measures may be required.

GENERAL ENVIRONMENTAL EXPOSURES

OUTDOOR AIR POLLUTION

In 1971, the U.S. government established national air quality standards for several pollutants believed to be responsible for excess cardiorespiratory diseases. Primary standards regulated by the Environmental Protection Agency (EPA) designed to protect the public health with an adequate margin of safety exist for sulfur dioxide, particulates matter, nitrogen dioxide, ozone, lead, and carbon monoxide. Standards for each of these pollutants are updated regularly through an extensive review process conducted by the EPA. (For details on current standards—*http://www.epa.gov/air/criteria.html.*)

Pollutants are generated from both stationary sources (power plants and industrial complexes) and mobile sources (automobiles), and none of the pollutants occurs in isolation. Furthermore, pollutants may be changed by chemical reactions after being emitted. For example, reducing agents, such as sulfur dioxide and particulate matter from a power plant stack, may react in air to produce acid sulfates and aerosols, which can be transported long distances in the atmosphere. Oxidizing substances, such as oxides of nitrogen and oxidants from automobile exhaust, may react with sunlight to produce ozone. Although originally a problem confined to the southwestern part of the United States, in recent years, at least during the summertime, elevated ozone and acid aerosol levels have been documented throughout the United States. Both acute and chronic effects of these exposures have been documented in large population studies.

The symptoms and diseases associated with air pollution are the same as conditions commonly associated with cigarette smoking. In addition, respiratory illness in early childhood has been associated with chronic exposure to only modestly elevated levels of traffic-related gases and respirable particles. Multiple population-based time-series studies within cities have demonstrated excess cardiopulmonary hospitalizations and mortality. In addition, cohort studies comparing cities that have relatively high levels of particulate exposures with less polluted communities suggest excess morbidity and mortality from cardiorespiratory conditions in long-term residents of the former. These findings have led to stricter U.S. ambient air quality standards for particulate matter as well as greater emphasis on publicizing pollution alerts to encourage individuals with significant cardiopulmonary impairment to stay indoors during high pollution episodes.

INDOOR EXPOSURES

Environmental tobacco smoke (Chap. 390), radon gas, wood smoke, and other biologic agents generated indoors need to be considered. Several studies have shown that the respirable particulate load in any household is directly proportional to the number of cigarette smokers living in the home. Increases in prevalence of respiratory illnesses and reduced levels of pulmonary function measured with simple spirometry have been found in children of smoking parents in a number of studies. Recent meta-analyses for lung cancer, and cardiopulmonary diseases, combining data from the best of the environmental tobacco smoke exposure studies, suggest an ~25% increase in relative risk for each condition, even after adjustment for major potential confounders.

Radon gas is believed to be a risk factor for lung cancer. The main radon product (radon 222) is a gas that results from the decay series of uranium 238, with the immediate precursor being radium 226. The amount of radium in earth materials determines how much radon gas will be emitted. Outdoors, the concentrations are trivial. Indoors, levels are dependent on the sources, the ventilation rate of the space, and the size of the space into which the gas is emitted. Levels associated with excess lung cancer risk may be present in as many as 10% of the houses in the United States. When smokers reside in the household, the problem is potentially greater, since the molecular size of radon particles allows them to readily attach to smoke particles that are inhaled. Fortunately, technology is available for assessing and reducing the level of exposure.

Other indoor exposures associated with an increased risk of atopy and asthma include those to such specific recognized putative biologic agents as cockroach antigen, dust mites, and pet danders. Other indoor chemical agents include formaldehyde, perfumes, and latex particles. Nonspecific responses associated with "tight-building syndrome," in which no particular agent has been implicated, have included a wide variety of complaints, among them respiratory symptoms that are relieved only by avoiding exposure in the building in question. The degree to which "smells" or other sensory stimuli are involved in the triggering of potentially incapacitating psychological or physical responses has yet to be determined, and the long-term consequences of such environmental exposures are as yet unknown.

PORTAL OF ENTRY

The lung is a primary point of entry into the body for a number of toxic agents that affect other organ systems. For example, the lung is a route of entry for benzene (bone marrow), carbon disulfide (cardiovascular and nervous systems), cadmium (kidney), and metallic mercury (kidney, central nervous system). Thus, in any disease state of obscure origin, it is important to consider the possibility of inhaled environmental agents. Such consideration can sometimes furnish the clue needed to identify a specific external cause for a disorder that might otherwise be labeled "idiopathic."

Global Considerations Indoor exposure to *biomass smoke* (wood, dung, crop residues, charcoal) is estimated to be responsible for 2.7% of worldwide disability adjusted life-years (DALYs) lost, due to acute lower respiratory infections in children and COPD and lung cancer in women. This burden of disease places indoor exposure to biomass smoke as the second leading environmental hazard for poor health, just behind unsafe water, sanitation, and hygiene; and is 3.5 times larger than the burden attributed to outdoor air pollution.

More than one-half of the world's population uses biomass fuel for cooking, heating or baking. This occurs predominantly in the rural areas of developing countries. Because many families burn biomass fuels in open stoves, which are highly inefficient, and inside homes with poor ventilation, women and young children are exposed on a daily basis to high levels of smoke. In these homes, 24-h mean levels of fine particulate matter, a component of biomass smoke, have been reported to be 2–30 times higher than the National Ambient Air Quality Standards set by the U.S. EPA.

Epidemiologic studies have consistently shown associations between exposure to biomass smoke and both chronic bronchitis and COPD,

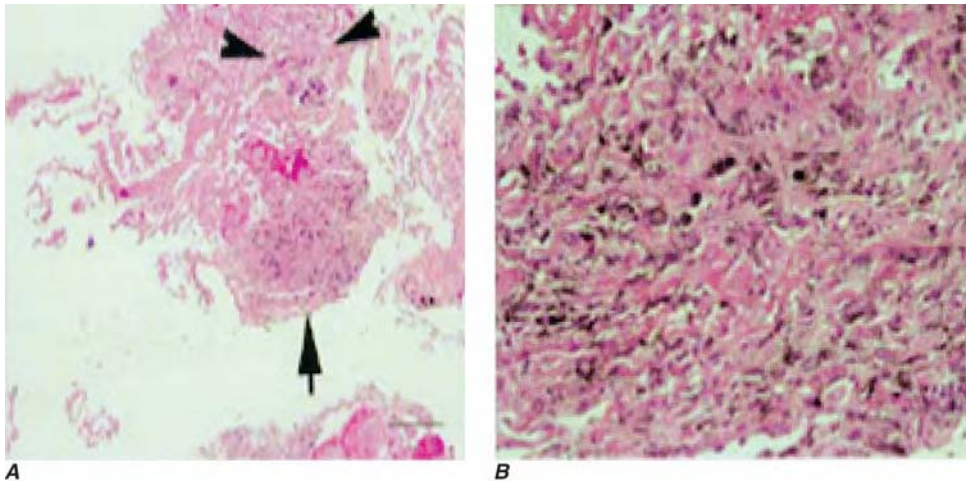

FIGURE 250-4 Histopathologic features of biomass smoke-induced interstitial lung disease. ***A.*** Anthracitic pigment is seen accumulating along alveolar septae (*arrow heads*) and within a pigmented dust macule (*single arrow*), ***B.*** A high-power photomicrograph contains a mixture of fibroblasts and carbon-laden macrophages.

with odds ratios ranging between 3 and 10 and increasing with longer exposures. In addition to the common occupational exposure to biomass smoke of women in developing countries, men from such countries may also be occupationally exposed. Because of increased migration to the United States from developing countries, clinicians need to be aware of the chronic respiratory effects of exposure to biomass smoke, which can also include interstitial lung disease (Fig. 250-4).

251 Pneumonia

Lionel A. Mandell, Richard Wunderink

DEFINITION

Pneumonia is an infection of the pulmonary parenchyma. Despite being the cause of significant morbidity and mortality, pneumonia is often misdiagnosed, mistreated, and underestimated.

In the past, pneumonia was typically classified as community-acquired, hospital-acquired, or ventilator-associated. Over the last decade or two, however, patients presenting to the hospital have often been found to be infected with multidrug-resistant (MDR) pathogens previously associated with hospital-acquired pneumonia. Factors responsible for this phenomenon include the development and widespread use of potent oral antibiotics, earlier transfer of patients out of acute-care hospitals to their homes or various lower-acuity facilities, increased use of outpatient IV antibiotic therapy, general aging of the population, and more extensive immunomodulatory therapies. The potential involvement of these MDR pathogens has led to a revised classification system in which infection is categorized as either community-acquired pneumonia (CAP) or health care–associated pneumonia (HCAP), with subcategories of HCAP including hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP). The conditions associated with HCAP and the likely pathogens are listed in Table 251-1.

Although the new classification system has been helpful in designing empirical antibiotic strategies, it is not without disadvantages. For instance, not all MDR pathogens are associated with all risk factors (Table 251-1). Therefore, this system represents a distillation of multiple risk factors, and each patient must be considered individually. For

TABLE 251-1 CLINICAL CONDITIONS ASSOCIATED WITH AND LIKELY PATHOGENS IN HEALTH CARE–ASSOCIATED PNEUMONIA

Note: MDR, multidrug-resistant; MRSA, methicillin-resistant *Staphylococcus aureus*.

example, the risk of infection with MDR pathogens for a nursing home resident with dementia who can independently dress, ambulate, and eat is quite different from the risk for a patient who is in a chronic vegetative state with a tracheostomy and a percutaneous feeding tube in place. In addition, risk factors for MDR infection do not preclude the development of pneumonia caused by the usual CAP pathogens.

This chapter deals with pneumonia in patients who are not considered to be immunocompromised. **Pneumonia in immunocompromised patients is discussed in other chapters, including Chaps. 82, 126, and 182.**

PATHOPHYSIOLOGY

Pneumonia results from the proliferation of microbial pathogens at the alveolar level and the host's response to those pathogens. Microorganisms gain access to the lower respiratory tract in several ways. The most common is by aspiration from the oropharynx. Small-volume aspiration occurs frequently during sleep (especially in the elderly) and in patients with decreased levels of consciousness. Many pathogens are inhaled as contaminated droplets. Rarely, pneumonia occurs via hematogenous spread (e.g., from tricuspid endocarditis) or by contiguous extension from an infected pleural or mediastinal space.

Mechanical factors are critically important in host defense. The hairs and turbinates of the nares catch larger inhaled particles before they reach the lower respiratory tract, and the branching architecture of the tracheobronchial tree traps particles on the airway lining, where mucociliary clearance and local antibacterial factors either clear or kill the potential pathogen. The gag reflex and the cough mechanism offer critical protection from aspiration. In addition, the normal flora adhering to mucosal cells of the oropharynx, whose components are remarkably constant, prevents pathogenic bacteria from binding and thereby decreases the risk of pneumonia caused by these more virulent bacteria.

When these barriers are overcome or when the microorganisms are small enough to be inhaled to the alveolar level, resident alveolar macrophages are extremely efficient at clearing and killing pathogens. Macrophages are assisted by local proteins (e.g., surfactant proteins A and D) that have intrinsic opsonizing properties or antibacterial or antiviral activity. Once engulfed, the pathogens—even if they are not killed by macrophages—are eliminated via either the mucociliary elevator or the lymphatics and no longer represent an infectious challenge. Only when the capacity of the alveolar macrophages to ingest or kill the microorganisms is exceeded does clinical pneumonia become manifest. In that situation, the alveolar macrophages initiate the inflammatory response to bolster lower respiratory tract defenses. The host inflammatory response, rather than the proliferation of microorganisms, triggers the clinical syndrome of pneumonia. The release of inflammatory mediators, such as interleukin (IL) 1 and tumor necrosis factor (TNF), results in fever. Chemokines, such as IL-8 and granulocyte colony-stimulating factor, stimulate the release of neutrophils and their attraction to the lung, producing both peripheral leukocytosis and increased purulent secretions. Inflammatory mediators released by macrophages and the newly recruited neutrophils create an alveolar capillary leak equivalent to that seen in the acute respiratory distress syndrome (ARDS), although in pneumonia this leak is localized (at least initially). Even erythrocytes can cross the alveolar-capillary membrane, with consequent hemoptysis. The capillary leak results in a radiographic infiltrate and rales detectable on auscultation, and hypoxemia results from alveolar filling. Moreover, some bacterial pathogens appear to interfere with the hypoxic vasoconstriction that would normally occur with fluid-filled alveoli, and this interference can result in severe hypoxemia. Increased respiratory drive in the systemic inflammatory response syndrome (SIRS) leads to respiratory alkalosis. Decreased compliance due to capillary leak, hypoxemia, increased respiratory drive, increased secretions, and occasionally infection-related bronchospasm all lead to dyspnea. If severe enough, the changes in lung mechanics secondary to reductions in lung volume and compliance and the intrapulmonary shunting of blood may cause the patient's death.

PATHOLOGY

Classic pneumonia evolves through a series of pathologic changes. The initial phase is one of *edema*, with the presence of a proteinaceous exudate—and often of bacteria—in the alveoli. This phase is rarely evident in clinical or autopsy specimens because it is so rapidly followed by a *red hepatization* phase. The presence of erythrocytes in the cellular intraalveolar exudate gives this second stage its name, but neutrophils are also present and are important from the standpoint of host defense. Bacteria are occasionally seen in cultures of alveolar specimens collected during this phase. In the third phase, *gray hepatization*, no new erythrocytes are extravasating, and those already present have been lysed and degraded. The neutrophil is the predominant cell, fibrin deposition is abundant, and bacteria have disappeared. This phase corresponds with successful containment of the infection and improvement in gas exchange. In the final phase, *resolution*, the macrophage is the dominant cell type in the alveolar space, and the debris of neutrophils, bacteria, and fibrin has been cleared, as has the inflammatory response.

This pattern has been described best for pneumococcal pneumonia and may not apply to pneumonias of all etiologies, especially viral or *Pneumocystis* pneumonia. In VAP, respiratory bronchiolitis may precede the development of a radiologically apparent infiltrate. Because of the microaspiration mechanism, a bronchopneumonia pattern is most common in nosocomial pneumonias, whereas a lobar pattern is more common in bacterial CAP. Despite the radiographic appearance, viral and *Pneumocystis* pneumonias represent alveolar rather than interstitial processes.

COMMUNITY-ACQUIRED PNEUMONIA

ETIOLOGY

The extensive list of potential etiologic agents in CAP includes bacteria, fungi, viruses, and protozoa. Newly identified pathogens include hantaviruses, metapneumoviruses, the coronavirus responsible for the severe acute respiratory syndrome (SARS), and community-acquired strains of methicillin-resistant *Staphylococcus aureus* (MRSA). Most cases of CAP, however, are caused by relatively few pathogens **(Table 251-2)**. Although *Streptococcus pneumoniae* is most common, other organisms must also be considered in light of the patient's risk factors and severity of illness. In most cases, it is most useful to think of the potential causes as either "typical" bacterial pathogens or "atypical" organisms. The former category includes *S. pneumoniae, Haemophilus influenzae*, and (in selected patients) *S. aureus* and gram-negative bacilli such as *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*. The "atypical" organisms include *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, and *Legionella* spp. as well as respiratory viruses such as influenza viruses, adenoviruses, and respiratory syncytial viruses (RSVs). Data suggest that a virus may be responsible in up to 18% of cases of CAP that require admission to the hospital. The atypical organisms cannot be cultured on standard media, nor can they be seen on Gram's stain. The frequency and importance of atypical pathogens such as *M. pneumoniae* and *C. pneumoniae* in outpatients and *Legionella* in inpa-

TABLE 251-3 EPIDEMIOLOGIC FACTORS SUGGESTING POSSIBLE CAUSES OF COMMUNITY-ACQUIRED PNEUMONIA

Factor	Possible Pathogen(s)
Alcoholism	*Streptococcus pneumoniae*, oral anaerobes, *Klebsiella pneumoniae*, *Acinetobacter* spp., *Mycobacterium tuberculosis*
COPD and/or smoking	*Haemophilus influenzae*, *Pseudomonas aeruginosa*, *Legionella* spp., *S. pneumoniae*, *Moraxella catarrhalis*, *Chlamydophila pneumoniae*
Structural lung disease (e.g., bronchiectasis)	*P. aeruginosa*, *Burkholderia cepacia*, *Staphylococcus aureus*
Dementia, stroke, decreased level of consciousness	Oral anaerobes, gram-negative enteric bacteria
Lung abscess	CA-MRSA, oral anaerobes, endemic fungi, *M. tuberculosis*, atypical mycobacteria
Travel to Ohio or St. Lawrence river valleys	*Histoplasma capsulatum*
Travel to southwestern United States	Hantavirus, *Coccidioides* spp.
Travel to Southeast Asia	*Burkholderia pseudomallei*, avian influenza virus
Stay in hotel or on cruise ship in previous 2 weeks	*Legionella* spp.
Local influenza activity	Influenza virus, *S. pneumoniae*, *S. aureus*
Exposure to bats or birds	*H. capsulatum*
Exposure to birds	*Chlamydophila psittaci*
Exposure to rabbits	*Francisella tularensis*
Exposure to sheep, goats, parturient cats	*Coxiella burnetii*

Note: CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; COPD, chronic obstructive pulmonary disease.

tients have significant implications for therapy. These organisms are intrinsically resistant to all β-lactam agents and must be treated with a macrolide, a fluoroquinolone, or a tetracycline. In the ~10–15% of CAP cases that are polymicrobial, the etiology often includes a combination of typical and atypical pathogens.

Anaerobes play a significant role only when an episode of aspiration has occurred days to weeks before presentation for pneumonia. The combination of an unprotected airway (e.g., in patients with alcohol or drug overdose or a seizure disorder) and significant gingivitis constitutes the major risk factor. Anaerobic pneumonias are often complicated by abscess formation and significant empyemas or parapneumonic effusions.

S. aureus pneumonia is well known to complicate influenza infection. Recently, however, MRSA strains have been reported as primary causes of CAP. While this entity is still relatively uncommon, clinicians must be aware of its potentially serious consequences, such as necrotizing pneumonia. Two important developments have led to this problem: the spread of MRSA from the hospital setting to the community and the emergence of genetically distinct strains of MRSA in the community. These novel community-acquired MRSA (CA-MRSA) strains have infected healthy individuals who have had no association with health care.

Unfortunately, despite a careful history and physical examination as well as routine radiographic studies, it is usually impossible to predict the pathogen in a case of CAP with any degree of certainty; in more than half of cases, a specific etiology is never determined. Nevertheless, it is important to consider epidemiologic and risk factors that might suggest certain pathogens (Table 251-3).

EPIDEMIOLOGY

In the United States, ~80% of the 4 million CAP cases that occur annually are treated on an outpatient basis, and ~20% are treated in the hospital. CAP results in more than 600,000 hospitalizations, 64 million days of restricted activity, and 45,000 deaths annually. The overall yearly cost associated with CAP is estimated at $9–10 billion (U.S.). The incidence rates are highest at the extremes of age. Although the overall annual figure in the United States is 12 cases per 1000 persons, the figure is 12–18 per 1000 among children <4 years of age and 20 per 1000 among persons >60 years of age.

The risk factors for CAP in general and for pneumococcal pneumonia in particular have implications for treatment regimens. Risk factors for CAP include alcoholism, asthma, immunosuppression, institutionalization, and an age of ≥70 years versus 60–69 years. Risk factors for pneumococcal pneumonia include dementia, seizure disorders, heart failure, cerebrovascular disease, alcoholism, tobacco smoking, chronic obstructive pulmonary disease, and HIV infection. CA-MRSA infection is more likely in Native Americans, homeless youths, men who have sex with men, prison inmates, military recruits, children in daycare centers, and athletes such as wrestlers. The Enterobacteriaceae tend to affect patients who have recently been hospitalized and/or received antibiotic therapy or who have comorbidities such as alcoholism, heart failure, or renal failure. *P. aeruginosa* may also infect these patients as well as those with severe structural lung disease. Risk factors for *Legionella* infection include diabetes, hematologic malignancy, cancer, severe renal disease, HIV infection, smoking, male gender, and a recent hotel stay or ship cruise. (Many of these risk factors would now reclassify as HCAP some cases that were previously designated CAP.)

CLINICAL MANIFESTATIONS

CAP can vary from indolent to fulminant in presentation and from mild to fatal in severity. The various signs and symptoms, which depend on the progression and severity of the infection, include both constitutional findings and manifestations limited to the lung and its associated structures. In light of the pathobiology of the disease, many of the findings are to be expected.

The patient is frequently febrile, with a tachycardic response, and may have chills and/or sweats and cough that is either nonproductive or productive of mucoid, purulent, or blood-tinged sputum. In accordance with the severity of infection, the patient may be able to speak in full sentences or may be very short of breath. If the pleura is involved, the patient may experience pleuritic chest pain. Up to 20% of patients may have gastrointestinal symptoms such as nausea, vomiting, and/or diarrhea. Other symptoms may include fatigue, headache, myalgias, and arthralgias.

Findings on physical examination vary with the degree of pulmonary consolidation and the presence or absence of a significant pleural effusion. An increased respiratory rate and use of accessory muscles of respiration are common. Palpation may reveal increased or decreased tactile fremitus, and the percussion note can vary from dull to flat, reflecting underlying consolidated lung and pleural fluid, respectively. Crackles, bronchial breath sounds, and possibly a pleural friction rub may be heard on auscultation. The clinical presentation may not be so obvious in the elderly, who may initially display new-onset or worsening confusion and few other manifestations. Severely ill patients who have septic shock secondary to CAP are hypotensive and may have evidence of organ failure.

DIAGNOSIS

When confronted with possible CAP, the physician must ask two questions: Is this pneumonia, and, if so, what is the etiology? The former question is typically answered by clinical and radiographic methods, whereas the latter requires the aid of laboratory techniques.

Clinical Diagnosis

The differential diagnosis includes both infectious and noninfectious entities such as acute bronchitis, acute exacerbations of chronic bronchitis, heart failure, pulmonary embolism, and radiation pneumonitis. The importance of a careful history cannot be overemphasized. For example, known cardiac disease may suggest worsening pulmonary edema, while underlying carcinoma may suggest lung injury secondary to radiation. Epidemiologic clues, such as recent travel to areas with known endemic pathogens, may alert the physician to specific possibilities (Table 251-3).

Unfortunately, the sensitivity and specificity of the findings on physical examination are less than ideal, averaging 58% and 67%, respectively. Therefore, chest radiography is often necessary to help differentiate CAP from other conditions. Radiographic findings serve as a baseline and may include risk factors for increased severity (e.g., cavitation or

multilobar involvement). Occasionally, radiographic results suggest an etiologic diagnosis. For example, pneumatoceles suggest infection with *S. aureus*, and an upper-lobe cavitating lesion suggests tuberculosis. CT is rarely necessary but may be of value in a patient with suspected postobstructive pneumonia caused by a tumor or foreign body. For cases managed on an outpatient basis, the clinical and radiologic assessment is usually all that is done before treatment is started since most laboratory test results are not available soon enough to influence initial management. In certain cases, however (e.g., influenza virus infection), the availability of rapid point-of-care diagnostic tests and access to specific drugs for treatment and prevention can be very important.

Etiologic Diagnosis The etiology of pneumonia usually cannot be determined on the basis of clinical presentation; instead, the physician must rely upon the laboratory for support. Except for the 2% of CAP patients who are admitted to the intensive care unit (ICU), no data exist to show that treatment directed at a specific pathogen is statistically superior to empirical therapy. The benefits of establishing a microbial etiology can therefore be questioned, particularly in light of the cost of diagnostic testing. However, a number of reasons can be advanced for attempting an etiologic diagnosis. Identification of an unexpected pathogen allows narrowing of the initial empirical regimen, which decreases antibiotic selection pressure and may lessen the risk of resistance. Pathogens with important public safety implications, such as *Mycobacterium tuberculosis* and influenza virus, may be found in some cases. Finally, without culture and susceptibility data, trends in resistance cannot be followed accurately, and appropriate empirical therapeutic regimens are harder to devise.

GRAM'S STAIN AND CULTURE OF SPUTUM The main purpose of the sputum Gram's stain is to ensure that a sample is suitable for culture. However, Gram's staining may also help to identify certain pathogens (e.g., *S. pneumoniae*, *S. aureus*, and gram-negative bacteria) by their characteristic appearance. To be adequate for culture, a sputum sample must have >25 neutrophils and <10 squamous epithelial cells per low-power field. The sensitivity and specificity of the sputum Gram's stain and culture are highly variable; even in cases of proven bacteremic pneumococcal pneumonia, the yield of positive cultures from sputum samples is ≤50%.

Some patients, particularly elderly individuals, may not be able to produce an appropriate expectorated sputum sample. Others may already have started a course of antibiotics, which can interfere with results, at the time a sample is obtained. The inability to produce sputum can be a consequence of dehydration, and the correction of this condition may result in increased sputum production and a more obvious infiltrate on chest radiography. For patients admitted to the ICU and intubated, a deep-suction aspirate or bronchoalveolar lavage sample should be sent to the microbiology laboratory as soon as possible. Since the etiologies in severe CAP are somewhat different from those in milder disease (Table 251-2), the greatest benefit of staining and culturing respiratory secretions is to alert the physician of unsuspected and/or resistant pathogens and to permit appropriate modification of therapy. Other stains and cultures may be useful as well. For suspected tuberculosis or fungal infection, specific stains are available. Cultures of pleural fluid obtained from effusions >1 cm in height on a lateral decubitus chest radiograph may also be helpful.

BLOOD CULTURES The yield from blood cultures, even those obtained before antibiotic therapy, is disappointingly low. Only ~5–14% of cultures of blood from patients hospitalized with CAP are positive, and the most frequently isolated pathogen is *S. pneumoniae*. Since recommended empirical regimens all provide pneumococcal coverage, a blood culture positive for this pathogen has little, if any, effect on clinical outcome. However, susceptibility data may allow a switch from a broader-spectrum regimen (e.g., a fluoroquinolone or β-lactam plus a macrolide) to penicillin in appropriate cases. Because of the low yield and the lack of significant impact on outcome, blood cultures are no longer considered *de rigueur* for all hospitalized CAP patients. Certain high-risk patients—including those with neutropenia secondary to pneumonia, asplenia, or complement deficiencies; chronic liver disease; or severe CAP—should have blood cultured.

ANTIGEN TESTS Two commercially available tests detect pneumococcal and certain *Legionella* antigens in urine. The test for *Legionella pneumophila* detects only serogroup 1, but this serogroup accounts for most community-acquired cases of Legionnaires' disease. The sensitivity and specificity of the *Legionella* urine antigen test are as high as 90% and 99%, respectively. The pneumococcal urine antigen test is also quite sensitive and specific (80% and >90%, respectively). Although false-positive results can be obtained with samples from colonized children, the test is generally reliable. Both tests can detect antigen even after the initiation of appropriate antibiotic therapy and after weeks of illness. Other antigen tests include a rapid test for influenza virus and direct fluorescent antibody tests for influenza virus and RSV, although the test for RSV is only poorly sensitive.

POLYMERASE CHAIN REACTION Polymerase chain reaction (PCR) tests are available for a number of pathogens, including *L. pneumophila* and mycobacteria. In addition, a multiplex PCR can detect the nucleic acid of *Legionella* spp., *M. pneumoniae*, and *C. pneumoniae*. However, the use of these PCR assays is generally limited to research studies.

SEROLOGY A fourfold rise in specific IgM antibody titer between acute- and convalescent-phase serum samples is generally considered diagnostic of infection with the pathogen in question. In the past, serologic tests were used to help identify atypical pathogens as well as some typical but relatively unusual organisms, such as *Coxiella burnetii*. Recently, however, they have fallen out of favor because of the time required to obtain a final result for the convalescent-phase sample.

Rx COMMUNITY-ACQUIRED PNEUMONIA

SITE OF CARE The decision to hospitalize a patient with CAP must take into consideration diminishing health care resources and rising costs of treatment. The cost of inpatient management exceeds that of outpatient treatment by a factor of 20 and accounts for most CAP-related expenditures. Certain patients clearly can be managed at home, and others clearly require treatment in the hospital, but the choice is sometimes difficult. Tools that objectively assess the risk of adverse outcomes, including severe illness and death, may minimize unnecessary hospital admissions and help to identify patients who will benefit from hospital care. There are currently two sets of criteria: the Pneumonia Severity Index (PSI), a prognostic model used to identify patients at low risk of dying; and the CURB-65 criteria, a severity-of-illness score.

To determine the PSI, points are given for 20 variables, including age, coexisting illness, and abnormal physical and laboratory findings. On the basis of the resulting score, patients are assigned to one of five classes with the following mortality rates: class 1, 0.1%; class 2, 0.6%; class 3, 2.8%; class 4, 8.2%; and class 5, 29.2%. Clinical trials have demonstrated that routine use of the PSI results in lower admission rates for class 1 and class 2 patients. Patients in classes 4 and 5 should be admitted to the hospital, while those in class 3 should ideally be admitted to an observation unit until a further decision can be made.

The CURB-65 criteria include five variables: confusion (C); urea >7 mmol/L (U); respiratory rate ≥30/min (R); blood pressure, systolic ≤90 mmHg or diastolic ≤60 mmHg (B); and age ≥65 years (65). Patients with a score of 0, among whom the 30-day mortality rate is 1.5%, can be treated outside the hospital. With a score of 2, the 30-day mortality rate is 9.2%, and patients should be admitted to the hospital. Among patients with scores of ≥3, mortality rates are 22% overall; these patients may require admission to an ICU.

At present, it is difficult to say which assessment tool is superior. The PSI is less practical in a busy emergency-room setting because of the need to assess 20 variables. While the CURB-65 criteria are easily remembered, they have not been studied as extensively. Whichever system is used, these objective criteria must always be tempered by careful consideration of factors relevant to individual patients, including the ability to comply reliably with an oral antibiotic regimen and the resources available to the patient outside the hospital.

RESISTANCE Antimicrobial resistance is a significant problem that threatens to diminish our therapeutic armamentarium. Misuse of antibiotics results in increased antibiotic selection pressure that can affect resistance locally or even globally by clonal dissemination. For CAP, the main resistance issues currently involve *S. pneumoniae* and CA-MRSA.

S. pneumoniae In general, pneumococcal resistance is acquired (1) by direct DNA incorporation and remodeling resulting from contact with closely related oral commensal bacteria, (2) by the process of natural transformation, or (3) by mutation of certain genes.

Pneumococcal strains are classified as sensitive to penicillin if the minimal inhibitory concentration (MIC) is ≤0.06 μg/mL, as intermediate if the MIC is 0.1–1.0 μg/mL, and as resistant if the MIC is ≥2 μg/mL. Strains resistant to drugs from three or more antimicrobial classes with different mechanisms of action are considered MDR isolates. Pneumococcal resistance to β-lactam drugs is due solely to the presence of low-affinity penicillin-binding proteins. The propensity for pneumococcal resistance to penicillin to be associated with reduced susceptibility to other drugs, such as macrolides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP-SMX), is of concern. In the United States, 58.9% of penicillin-resistant pneumococcal isolates from blood cultures are also resistant to macrolides. Penicillin is an appropriate agent for the treatment of pneumococcal infection caused by strains with MICs of ≤1 μg/mL. For infections caused by pneumococcal strains with penicillin MICs of 2–4 μg/mL, the data are conflicting; some studies suggest no increase in treatment failure with penicillin, while others suggest increased rates of death or complications. For strains of *S. pneumoniae* with intermediate levels of resistance, higher doses of the drug should be used. Risk factors for drug-resistant pneumococcal infection include recent antimicrobial therapy, an age of <2 years or >65 years, attendance at day-care centers, recent hospitalization, and HIV infection. Fortunately, resistance to penicillin appears to be reaching a plateau.

In contrast, resistance to macrolides is increasing through several mechanisms, including target-site modification and the presence of an efflux pump. Target-site modification is caused by ribosomal methylation in 23S rRNA encoded by the *ermB* gene and results in resistance to macrolides, lincosamides, and streptogramin B–type antibiotics. This *MLSB phenotype* is associated with high-level resistance, with typical MICs of ≥64 μg/mL. The efflux mechanism encoded by the *mef* gene (*M phenotype*) is usually associated with low-level resistance (MICs, 1–32 μg/mL). These two mechanisms account for ~45% and ~65%, respectively, of resistant pneumococcal isolates in the United States. Some pneumococcal isolates with both the *erm* and *mef* genes have been identified, but the exact significance of this finding is unknown. High-level resistance to macrolides is more common in Europe, whereas lower-level resistance seems to predominate in North America. Although clinical failures with macrolides have been reported, many experts think that these drugs still have a role to play in the management of pneumococcal pneumonia in North America.

Pneumococcal resistance to fluoroquinolones (e.g., ciprofloxacin and levofloxacin) has been reported. Changes can occur in one or both target sites (topoisomerases II and IV); changes in these two sites usually result from mutations in the *gyrA* and *parC* genes, respectively. The increasing number of pneumococcal isolates that, although susceptible to fluoroquinolones, already have a mutation in one target site is of concern. Such organisms may be more likely to undergo a second step mutation that will render them fully resistant to fluoroquinolones. In addition, an efflux pump may play a role in pneumococcal resistance to fluoroquinolones.

CA-MRSA CAP due to MRSA may be caused by infection with the classic hospital-acquired strains or with the more recently identified, genotypically and phenotypically distinct community-acquired strains. Most infections with the former strains have been acquired either directly or indirectly by contact with the health care environment and, although classified as HAP in the past, would now be classified as HCAP. In some hospitals, CA-MRSA strains are displacing the classic hospital-acquired strains—a trend suggesting that the newer strains may be more robust.

Methicillin resistance in *S. aureus* is determined by the *mecA* gene, which encodes for resistance to all β-lactam drugs. At least five *staphylococcal chromosomal cassette mec* (*SCCmec*) types have been described. The typical hospital-acquired strain usually has type II or III, whereas CA-MRSA has a type IV SCC*mec* element. CA-MRSA isolates tend to be less resistant than the older hospital-acquired strains and are often susceptible to TMP-SMX, clindamycin, and tetracycline in addition to vancomycin and linezolid. However, CA-MRSA strains may also carry genes for superantigens, such as enterotoxins B and C and Panton-Valentine leukocidin, a membrane-tropic toxin that can create cytolytic pores in polymorphonuclear neutrophils, monocytes, and macrophages.

Gram-Negative Bacilli A detailed discussion of resistance among gram-negative bacilli is beyond the scope of this chapter (see Chap. 143). Fluoroquinolone resistance among isolates of *Escherichia coli* from the community appears to be increasing. *Enterobacter* spp. are typically resistant to cephalosporins; the drugs of choice for use against these bacteria are usually fluoroquinolones or carbapenems. Similarly, when infections due to bacteria producing extended-spectrum β-lactamases (ESBLs) are documented or suspected, a fluoroquinolone or a carbapenem should be used; these MDR strains are more likely to be involved in HCAP.

INITIAL ANTIBIOTIC MANAGEMENT Since the physician rarely knows the etiology of CAP at the outset of treatment, initial therapy is usually empirical and is designed to cover the most likely pathogens **(Table 251-4)**. In all cases, antibiotic treatment should be initiated as expeditiously as possible.

The CAP treatment guidelines in the United States (summarized in Table 251-4) represent joint statements from the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS); the Canadian guidelines come from the Canadian Infectious Disease Society and the Canadian Thoracic Society. In these guidelines, coverage is always provided

TABLE 251-4 EMPIRICAL ANTIBIOTIC TREATMENT OF COMMUNITY-ACQUIRED PNEUMONIA

Outpatients

Previously healthy and no antibiotics in past 3 months
- A macrolide [clarithromycin (500 mg PO bid) or azithromycin (500 mg PO once, then 250 mg od)] ***or***
- Doxycycline (100 mg PO bid)

Comorbidities or antibiotics in past 3 months: select an alternative from a different class
- A respiratory fluoroquinolone [moxifloxacin (400 mg PO od), gemifloxacin (320 mg PO od), levofloxacin (750 mg PO od)] ***or***
- A β-lactam [preferred: high-dose amoxicillin (1 g tid) or amoxicillin/clavulanate (2 g bid); alternatives: ceftriaxone (1–2 g IV od), cefpodoxime (200 mg PO bid), cefuroxime (500 mg PO bid)] *plus* a macrolide[a]

In regions with a high rate of "high-level" pneumococcal macrolide resistance,[b] consider alternatives listed above for patients with comorbidities.

Inpatients, non-ICU
- A respiratory fluoroquinolone [moxifloxacin (400 mg PO or IV od), gemifloxacin (320 mg PO od), levofloxacin (750 mg PO or IV od)]
- A β-lactam[c] [cefotaxime (1–2 g IV q8h), ceftriaxone (1–2 g IV od), ampicillin (1–2 g IV q4–6h), ertapenem (1 g IV od in selected patients)] ***plus*** a macrolide[d] [oral clarithromycin or azithromycin (as listed above for previously healthy patients) or IV azithromycin (1 g once, then 500 mg od)]

Inpatients, ICU
- A β-lactam[e] [cefotaxime (1–2 g IV q8h), ceftriaxone (2 g IV od), ampicillin-sulbactam (2 g IV q8h)] ***plus***
- Azithromycin or a fluoroquinolone (as listed above for inpatients, non-ICU)

Special concerns

If *Pseudomonas* is a consideration
- An antipneumococcal, antipseudomonal β-lactam [piperacillin/tazobactam (4.5 g IV q6h), cefepime (1–2 g IV q12h), imipenem (500 mg IV q6h), meropenem (1 g IV q8h)] *plus* either ciprofloxacin (400 mg IV q12h) or levofloxacin (750 mg IV od)
- The above β-lactams *plus* an aminoglycoside [amikacin (15 mg/kg od) or tobramycin (1.7 mg/kg od) and azithromycin]
- The above β-lactams[f] *plus* an aminoglycoside *plus* an antipneumococcal fluoroquinolone

If CA-MRSA is a consideration
- Add linezolid (600 mg IV q12h) or vancomycin (1 g IV q12h)

Note: CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; ICU, intensive care unit.

[a]Doxycycline (100 mg PO bid) is an alternative to the macrolide.

[b]MICs of >16 μg/mL in 25% of isolates.

[c]A respiratory fluoroquinolone should be used for penicillin-allergic patients.

[d]Doxycycline (100 mg IV q12h) is an alternative to the macrolide.

[e]For penicillin-allergic patients, use a respiratory fluoroquinolone and aztreonam (2 g IV q8h).

[f]For penicillin-allergic patients, substitute aztreonam.

for the pneumococcus and the atypical pathogens. In contrast, guidelines from some European countries do not always include atypical coverage based on local epidemiologic data. The U.S.-Canadian approach is supported by retrospective data from almost 13,000 patients >65 years of age. Atypical pathogen coverage provided by a macrolide or a fluoroquinolone has been associated with a significant reduction in mortality rates compared with those for β-lactam coverage alone.

Therapy with a macrolide or a fluoroquinolone within the previous 3 months is associated with an increased likelihood of infection with a macrolide- or fluoroquinolone-resistant strain of *S. pneumoniae*. For this reason, a fluoroquinolone-based regimen should be used for patients recently given a macrolide, and vice versa (Table 251-4). Telithromycin, a ketolide derived from the macrolide class, differs from the macrolides in that it binds to bacteria more avidly and at two sites rather than one. This drug is active against pneumococci resistant to penicillins, macrolides, and fluoroquinolones. Its future role in the outpatient management of CAP will depend on the evaluation of its safety by the U.S. Food and Drug Administration.

Once the etiologic agent(s) and susceptibilities are known, therapy may be altered to target the specific pathogen(s). However, this decision is not always straightforward. If blood cultures yield *S. pneumoniae* sensitive to penicillin after 2 days of treatment with a macrolide plus a β-lactam or a fluoroquinolone, should therapy be switched to penicillin? Penicillin alone would not be effective in the potential 15% of cases with atypical co-infection. No standard approach exists. Some experts would argue that pneumococcal coverage by a switch to penicillin is appropriate, while others would opt for continued coverage of both the pneumococcus and atypical pathogens. One compromise would be to continue atypical coverage with either a macrolide or a fluoroquinolone for a few more days and then to complete the treatment course with penicillin alone. In all cases, the individual patient and the various risk factors must be considered.

Management of bacteremic pneumococcal pneumonia is also controversial. Data from nonrandomized studies suggest that combination therapy (e.g., with a macrolide and a β-lactam) is associated with a lower mortality rate than monotherapy, particularly in severely ill patients. The exact reason is unknown, but explanations include possible atypical co-infection or the immunomodulatory effects of the macrolides.

For patients with CAP who are admitted to the ICU, the risk of infection with *P. aeruginosa* or CA-MRSA is increased, and coverage should be considered when a patient has risk factors or a Gram's stain suggestive of these pathogens (Table 251-4). The main risk factors for *P. aeruginosa* infection are structural lung disease (e.g., bronchiectasis) and recent treatment with antibiotics or glucocorticoids. If CA-MRSA infection is suspected, either linezolid or vancomycin should be added to the initial empirical regimen.

Although hospitalized patients have traditionally received initial therapy by the IV route, some drugs—particularly the fluoroquinolones—are very well absorbed and can be given orally from the outset to select patients. For patients initially treated IV, a switch to oral treatment is appropriate as long as the patient can ingest and absorb the drugs, is hemodynamically stable, and is showing clinical improvement.

The duration of treatment for CAP has recently generated considerable interest. Patients have usually been treated for 10–14 days, but recent studies with fluoroquinolones and telithromycin suggest that a 5-day course is sufficient for otherwise uncomplicated CAP. A longer course is required for patients with bacteremia, metastatic infection, or infection with a particularly virulent pathogen, such as *P. aeruginosa* or CA-MRSA. Longer-term therapy should also be considered if initial treatment was ineffective and in most cases of severe CAP. Data from studies with azithromycin, which suggest 3–5 days of treatment for outpatient-managed CAP, cannot be extrapolated to other drugs because of the extremely long half-life of azithromycin.

Patients may be discharged from the hospital once they are clinically stable and have no active medical problems requiring ongoing hospital care. The site of residence after discharge (in a nursing home, at home with family, at home alone) is an important consideration, particularly for elderly patients.

GENERAL CONSIDERATIONS In addition to appropriate antimicrobial therapy, certain general considerations apply in dealing with either CAP or HAP. Adequate hydration, oxygen therapy for hypoxemia, and assisted ventilation when necessary are critical to the success of therapy. Patients with severe CAP who remain hypotensive despite fluid resuscitation may have adrenal insufficiency and may respond to glucocorticoid treatment. Immunomodulatory therapy in the form of drotrecogin alfa (activated) should be considered for CAP patients with persistent septic shock and APACHE II scores of ≥25, particularly if the infection is caused by *S. pneumoniae*.

Failure to Improve Patients who are slow to respond to therapy should be reevaluated at about day 3 (sooner if their condition is worsening rather than simply not improving), and a number of possible scenarios should be considered. (1) Is this a noninfectious condition? (2) If this is an infection, is the correct pathogen being targeted? (3) Is this a superinfection with a new nosocomial pathogen? A number of noninfectious conditions can mimic pneumonia, including pulmonary edema, pulmonary embolism, lung carcinoma, radiation and hypersensitivity pneumonitis, and connective tissue disease involving the lungs. If the patient has CAP and treatment is aimed at the correct pathogen, the lack of response may be explained in a number of ways. The pathogen may be resistant to the drug selected, or a sequestered focus (e.g., a lung abscess or empyema) may be blocking access of the antibiotic(s) to the pathogen. Alternatively, the patient may be getting either the wrong drug or the correct drug at the wrong dose or frequency of administration. It is also possible that CAP is the correct diagnosis but that a different pathogen (e.g., *M. tuberculosis* or a fungus) is the cause. In addition, nosocomial superinfections—both pulmonary and extrapulmonary—are possible explanations for persistence. In all cases of delayed response or deteriorating condition, the patient must be carefully reassessed and appropriate studies initiated. These studies may include such diverse procedures as CT and bronchoscopy.

Complications As in other severe infections, common complications of severe CAP include respiratory failure, shock and multiorgan failure, bleeding diatheses, and exacerbation of comorbid illnesses. Three particularly noteworthy conditions are metastatic infection, lung abscess, and complicated pleural effusion. Metastatic infection (e.g., brain abscess or endocarditis), although unusual, deserves immediate attention by the physician, with a detailed workup and proper treatment. Lung abscess may occur in association with aspiration or with infection caused by a single CAP pathogen, such CA-MRSA, *P. aeruginosa*, or (rarely) *S. pneumoniae*. Aspiration pneumonia is typically a mixed polymicrobial infection involving both aerobes and anaerobes. In either scenario, drainage should be established, and antibiotics that cover the known or suspected pathogens should be administered. A significant pleural effusion should be tapped for both diagnostic and therapeutic purposes. If the fluid has a pH of <7, a glucose level of <2.2 mmol/L, and a lactate dehydrogenase concentration of >1000 U/L or if bacteria are seen or cultured, then the fluid should be drained; a chest tube is usually required.

Follow-Up Fever and leukocytosis usually resolve within 2 and 4 days, respectively, in otherwise healthy patients with CAP, but physical findings may persist longer. Chest radiographic abnormalities are slowest to resolve and may require 4–12 weeks to clear, with the speed of clearance depending on the patient's age and underlying lung disease. For a patient whose condition is improving and who (if hospitalized) has been discharged, a follow-up radiograph can be done ~4–6 weeks later. If relapse or recurrence is documented, particularly in the same lung segment, the possibility of an underlying neoplasm must be considered.

PROGNOSIS

The prognosis of CAP depends on the patient's age, comorbidities, and site of treatment (inpatient or outpatient). Young patients without comorbidity do well and usually recover fully after ~2 weeks. Older patients and those with comorbid conditions can take several weeks longer to recover fully. The overall mortality rate for the outpatient group is <1%. For patients requiring hospitalization, the overall mortality rate is estimated at 10%, with ~50% of the deaths directly attributable to pneumonia.

PREVENTION

The main preventive measure is vaccination. The recommendations of the Advisory Committee on Immunization Practices should be followed for influenza and pneumococcal vaccines. In the event of an influenza outbreak, unprotected patients at risk from complications should be vaccinated immediately and given chemoprophylaxis with either oseltamivir or zanamivir for 2 weeks—i.e., until vaccine-induced antibody levels are sufficiently high. Because of an increased risk of

pneumococcal infection, even among patients without obstructive lung disease, smokers should be strongly encouraged to stop smoking.

HEALTH CARE–ASSOCIATED PNEUMONIA

VENTILATOR-ASSOCIATED PNEUMONIA

Most research on VAP has focused on illness in the hospital setting. However, the information and principles based on this research can be applied to HCAP not associated with ventilator use as well. The main rationale for the new designation *HCAP* is that the pathogens and treatment strategies for VAP are more similar to those for HAP than to those for pure CAP. The greatest difference between VAP and HCAP/HAP—and the greatest similarity of VAP to CAP—is the return to dependence on expectorated sputum for a microbiologic diagnosis, which is further complicated by the frequent colonization with pathogens among patients in the hospital or other health care–associated settings.

Etiology Potential etiologic agents of VAP include both MDR and non-MDR bacterial pathogens (Table 251-5). The non-MDR group is nearly identical to the pathogens found in severe CAP (Table 251-2); it is not surprising that such pathogens predominate if VAP develops in the first 5–7 days of the hospital stay. However, if patients have other risk factors for HCAP, MDR pathogens are a consideration, even early in the hospital course. The relative frequency of individual MDR pathogens can vary significantly from hospital to hospital and even between different critical care units within the same institution. Many hospitals have problems with *P. aeruginosa* and MRSA, but other MDR pathogens are often institution-specific.

Less commonly, fungal and viral pathogens cause VAP, most frequently affecting severely immunocompromised patients. Rarely, community-associated viruses cause miniepidemics, usually when introduced by ill health care workers.

Epidemiology Pneumonia is a common complication among patients requiring mechanical ventilation. Prevalence estimates vary between 6 and 52 cases per 100 patients, depending on the population studied. On any given day in the ICU, an average of 10% of patients will have pneumonia—VAP in the overwhelming majority of cases. The frequency of diagnosis is not static but changes with the duration of mechanical ventilation, with the highest hazard ratio in the first 5 days and a plateau in additional cases (1% per day) after ~2 weeks. However, the cumulative rate among patients who remain ventilated for as long as 30 days is as high as 70%. These rates often do not reflect the recurrence of VAP in the same patient. Once a ventilated patient is transferred to a chronic care facility or to home, the incidence of pneumonia drops significantly, especially in the absence of other risk factors for pneumonia.

Three factors are critical in the pathogenesis of VAP: colonization of the oropharynx with pathogenic microorganisms, aspiration of these organisms from the oropharynx into the lower respiratory tract, and compromise of the normal host defense mechanisms. Most risk factors and their corresponding prevention strategies pertain to one of these three factors (Table 251-6).

TABLE 251-5 MICROBIOLOGIC CAUSES OF VENTILATOR-ASSOCIATED PNEUMONIA

Non-MDR Pathogens	MDR Pathogens
Streptococcus pneumoniae	*Pseudomonas aeruginosa*
Other *Streptococcus* spp.	MRSA
Haemophilus influenzae	*Acinetobacter* spp.
MSSA	Antibiotic-resistant Enterobacteriaceae
Antibiotic-sensitive Enterobacteriaceae	*Enterobacter* spp.
Escherichia coli	ESBL-positive strains
Klebsiella pneumoniae	*Klebsiella* spp.
Proteus spp.	*Legionella pneumophila*
Enterobacter spp.	*Burkholderia cepacia*
Serratia marcescens	*Aspergillus* spp.

Note: ESBL, extended-spectrum β-lactamase; MDR, multidrug-resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *S. aureus*.

TABLE 251-6 PATHOGENIC MECHANISMS AND CORRESPONDING PREVENTION STRATEGIES FOR VENTILATOR-ASSOCIATED PNEUMONIA

Pathogenic Mechanism	Prevention Strategy
Oropharyngeal colonization with pathogenic bacteria	
Elimination of normal flora	Avoidance of prolonged antibiotic courses
Large-volume oropharyngeal aspiration around time of intubation	Short course of prophylactic antibiotics for comatose patients[a]
Gastroesophageal reflux	Postpyloric enteral feeding[b]; avoidance of high gastric residuals, prokinetic agents
Bacterial overgrowth of stomach	Avoidance of gastrointestinal bleeding due to prophylactic agents that raise gastric pH[b]; selective decontamination of digestive tract with nonabsorbable antibiotics[b]
Cross-infection from other colonized patients	Hand washing, especially with alcohol-based hand rub; intensive infection control education[a]; isolation; proper cleaning of reusable equipment
Large-volume aspiration	Endotracheal intubation; avoidance of sedation; decompression of small-bowel obstruction
Microaspiration around endotracheal tube	
Endotracheal intubation	Noninvasive ventilation[a]
Prolonged duration of ventilation	Daily awakening from sedation,[a] weaning protocols[a]
Abnormal swallowing function	Early percutaneous tracheostomy[a]
Secretions pooled above endotracheal tube	Head of bed elevated[a]; continuous aspiration of subglottic secretions with specialized endotracheal tube[a]; avoidance of reintubation; minimization of sedation and patient transport
Altered lower respiratory host defenses	Tight glycemic control[a]; lowering of hemoglobin transfusion threshold; specialized enteral feeding formula

[a]Strategies demonstrated to be effective in at least one randomized controlled trial.
[b]Strategies with negative randomized trials or conflicting results.

The most obvious risk factor is the endotracheal tube (ET), which bypasses the normal mechanical factors preventing aspiration. While the presence of an ET may prevent large-volume aspiration, microaspiration is actually enhanced by secretions pooling above the cuff. The ET and the concomitant need for suctioning can damage the tracheal mucosa, thereby facilitating tracheal colonization. In addition, pathogenic bacteria can form a glycocalyx biofilm on the ET surface that protects them from both antibiotics and host defenses. The bacteria can also be dislodged during suctioning and can reinoculate the trachea, or tiny fragments of glycocalyx can embolize to distal airways, carrying bacteria with them.

In a high percentage of critically ill patients, the normal oropharyngeal flora is replaced by pathogenic microorganisms. The most important risk factors are antibiotic selection pressure, cross-infection from other infected/colonized patients or contaminated equipment, and malnutrition.

How the lower respiratory tract defenses become overwhelmed remains poorly understood. Almost all intubated patients experience microaspiration and are at least transiently colonized with pathogenic bacteria. However, only around one-third of colonized patients develop VAP. Severely ill patients with sepsis and trauma appear to enter a state of immunoparalysis several days after admission to the ICU—a time that corresponds to the greatest risk of developing VAP. The mechanism of this immunosuppression is not clear, although several factors have been suggested. Hyperglycemia affects neutrophil func-

tion, and recent trials suggest that keeping the blood sugar close to normal with exogenous insulin may have beneficial effects, including a decreased risk of infection. More frequent transfusions, especially of leukocyte-depleted red blood cells, also affect the immune response positively.

Clinical Manifestations The clinical manifestations of VAP are generally the same as for all other forms of pneumonia: fever, leukocytosis, increase in respiratory secretions, and pulmonary consolidation on physical examination, along with a new or changing radiographic infiltrate. The frequency of abnormal chest radiographs before the onset of pneumonia in intubated patients and the limitations of portable radiographic technique make interpretation of radiographs more difficult than in patients who are not intubated. Other clinical features may include tachypnea, tachycardia, worsening oxygenation, and increased minute ventilation.

Diagnosis No single set of criteria is reliably diagnostic of pneumonia in a ventilated patient. The inability to identify such patients compromises efforts to prevent and treat VAP and even calls into question estimates of the impact of VAP on mortality rates.

Application of clinical criteria consistently results in overdiagnosis of VAP, largely because of three common findings in at-risk patients: (1) tracheal colonization with pathogenic bacteria in patients with ETs, (2) multiple alternative causes of radiographic infiltrates in mechanically ventilated patients, and (3) the high frequency of other sources of fever in critically ill patients. The differential diagnosis of VAP includes a number of entities, such as atypical pulmonary edema, pulmonary contusion and/or hemorrhage, hypersensitivity pneumonitis, ARDS, and pulmonary embolism. Clinical findings in ventilated patients with fever and/or leukocytosis may have alternative causes, including antibiotic-associated diarrhea, sinusitis, urinary tract infection, pancreatitis, and drug fever. Conditions mimicking pneumonia are often documented in patients in whom VAP has been ruled out by accurate diagnostic techniques. Most of these alternative diagnoses do not require antibiotic treatment; require antibiotics different from those used to treat VAP; or require some additional intervention, such as surgical drainage or catheter removal, for optimal management.

This diagnostic dilemma has led to debate and controversy. The major question is whether a quantitative-culture approach as a means of eliminating false-positive clinical diagnoses is superior to the clinical approach enhanced by principles learned from quantitative-culture studies. The recent IDSA/ATS guidelines for HCAP suggest that either approach is clinically valid.

QUANTITATIVE-CULTURE APPROACH The essence of the quantitative-culture approach is to discriminate between colonization and true infection by determining the bacterial burden. The more distal in the respiratory tree the diagnostic sampling, the more specific the results and therefore the lower the threshold of growth necessary to diagnose pneumonia and exclude colonization. For example, a quantitative endotracheal aspirate yields proximate samples, and the diagnostic threshold is 10^6 cfu/mL. The protected specimen brush method, in contrast, obtains distal samples and has a threshold of 10^3 cfu/mL. Conversely, sensitivity declines as more distal secretions are obtained, especially when they are collected blindly (i.e., by a technique other than bronchoscopy). Additional tests that may increase the diagnostic yield include Gram's stain, differential cell counts, staining for intracellular organisms, and detection of local protein levels elevated in response to infection.

Several studies have compared patient cohorts managed by the various quantitative-culture methods. While these studies documented issues of relative sensitivity and specificity, outcomes were not significantly different for the various groups of patients. The IDSA/ATS guidelines have suggested that all these methods are appropriate and that the choice depends on availability and local expertise.

The Achilles heel of the quantitative approach is the effect of antibiotic therapy. With sensitive microorganisms, a single antibiotic dose can reduce colony counts below the diagnostic threshold. Recent changes in antibiotic therapy are the most significant. After ≥3 days of consistent antibiotic therapy for another infection prior to suspicion of pneumonia, the accuracy of diagnostic tests for pneumonia is unaffected. Conversely, colony counts above the diagnostic threshold during antibiotic therapy suggest that the current antibiotics are ineffective. Even the normal host response may be sufficient to reduce quantitative-culture counts below the diagnostic threshold by the time of sampling. In short, expertise in quantitative-culture techniques is critical, with a specimen obtained as soon as pneumonia is suspected and before antibiotic therapy is initiated or changed.

In a study comparing the quantitative with the clinical approach, use of bronchoscopic quantitative cultures resulted in significantly less antibiotic use at 14 days after study entry and lower rates of mortality and severity-adjusted mortality at 28 days. In addition, more alternative sites of infection were found in patients randomized to the quantitative-culture strategy. A critical aspect of this study was that antibiotic treatment was initiated only in patients whose gram-stained respiratory sample was positive or who displayed signs of hemodynamic instability. Fewer than half as many patients were treated for pneumonia in the bronchoscopy group, and only one-third as many microorganisms were cultured.

TABLE 251-7 CLINICAL PULMONARY INFECTION SCORE (CPIS)

Criterion	Score
Fever (°C)	
≥38.5 but ≤38.9	1
>39 or < 36	2
Leukocytosis	
<4000 or >11,000/μL	1
Bands > 50%	1 (additional)
Oxygenation (mmHg)	
Pa_{O_2}/FI_{O_2} <250 and no ARDS	2
Chest radiograph	
Localized infiltrate	2
Patchy or diffuse infiltrate	1
Progression of infiltrate (no ARDS or CHF)	2
Tracheal aspirate	
Moderate or heavy growth	1
Same morphology on Gram's stain	1 (additional)
Maximal score[a]	12

[a]The progression of the infiltrate is not known and tracheal aspirate culture results are often unavailable at the time of the original diagnosis; thus, the maximal score is initially 8–10.

Note: ARDS, acute respiratory distress syndrome; CHF, congestive heart failure.

CLINICAL APPROACH The lack of specificity of a clinical diagnosis of VAP has led to efforts to improve the diagnostic criteria. The Clinical Pulmonary Infection Score (CPIS) was developed by weighting of the various clinical criteria usually used for the diagnosis of VAP (Table 251-7). Use of the CPIS allows the selection of low-risk patients who may need only short-course antibiotic therapy or no treatment at all. Moreover, studies have demonstrated that the absence of bacteria in gram-stained endotracheal aspirates makes pneumonia an unlikely cause of fever or pulmonary infiltrates. These findings, coupled with a heightened awareness of the alternative diagnoses possible in patients with suspected VAP, can prevent inappropriate treatment for this disease. Furthermore, data show that the absence of an MDR pathogen in tracheal aspirate cultures eliminates the need for MDR coverage when empirical antibiotic therapy is narrowed. Since the most likely explanations for the mortality benefit of bronchoscopic quantitative cultures are decreased antibiotic selection pressure (which reduces the risk of subsequent infection with MDR pathogens) and identification of alternative sources of infection, a clinical diagnostic approach that incorporates such principles may result in similar outcomes.

Rx VENTILATOR-ASSOCIATED PNEUMONIA

Many studies have demonstrated higher mortality rates with inappropriate than with appropriate empirical antibiotic therapy. The key to appropriate

TABLE 251-8 EMPIRICAL ANTIBIOTIC TREATMENT OF HEALTH CARE–ASSOCIATED PNEUMONIA

Patients without Risk Factors for MDR Pathogens
Ceftriaxone (2 g IV q24h) ***or***
Moxifloxacin (400 mg IV q24h), ciprofloxacin (400 mg IV q8h), or levofloxacin (750 mg IV q24h) ***or***
Ampicillin/sulbactam (3 g IV q6h) ***or***
Ertapenem (1 g IV q24h)
Patients with Risk Factors for MDR Pathogens
1. A β-lactam:
Ceftazidime (2 g IV q8h) or cefepime (2 g IV q8–12h) ***or***
Piperacillin/tazobactam (4.5 g IV q6h), imipenem (500 mg IV q6h or 1 g IV q8h), or meropenem (1 g IV q8h) ***plus***
2. A second agent active against gram-negative bacterial pathogens:
Gentamicin or tobramycin (7 mg/kg IV q24h) or amikacin (20 mg/kg IV q24h) ***or***
Ciprofloxacin (400 mg IV q8h) or levofloxacin (750 mg IV q24h) ***plus***
3. An agent active against gram-positive bacterial pathogens:
Linezolid (600 mg IV q12h) ***or***
Vancomycin (15 mg/kg, up to 1 g IV, q12h)

Note: MDR, multidrug-resistant.

antibiotic management of VAP is an appreciation of the patterns of resistance of the most likely pathogens in any given patient.

RESISTANCE If it were not for the risk of infection with MDR pathogens (Table 251-1), VAP could be treated with the same antibiotics used for severe CAP. However, antibiotic selection pressure leads to the frequent involvement of MDR pathogens by selecting either for drug-resistant isolates of common pathogens (MRSA and ESBL-positive Enterobacteriaceae) or for intrinsically resistant pathogens (*P. aeruginosa* and *Acinetobacter* spp.). Frequent use of β-lactam drugs, especially cephalosporins, appears to be the major risk factor for infection with MRSA and ESBL-positive strains.

P. aeruginosa has demonstrated the ability to develop resistance to all routinely used antibiotics. Unfortunately, even if initially sensitive, *P. aeruginosa* isolates have also shown a propensity to develop resistance during treatment. Occasionally, derepression of resistance genes may be the cause of the selection of resistant clones within the large bacterial inoculum associated with most pneumonias. *Acinetobacter*, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia* are intrinsically resistant to many of the empirical antibiotic regimens listed in **Table 251-8**. VAP caused by these pathogens emerges during treatment of other infections, and resistance is always evident at initial diagnosis.

EMPIRICAL THERAPY Recommended options for empirical therapy are listed in Table 251-8. Treatment should be started once diagnostic specimens have been obtained. The major factor in the selection of agents is the presence of risk factors for MDR pathogens. Choices among the various options listed depend on local patterns of resistance and the patient's prior antibiotic exposure.

The majority of patients *without* risk factors for MDR infection can be treated with a single agent. The major difference from CAP is the markedly lower incidence of atypical pathogens in VAP; the exception is *Legionella*, which can be a nosocomial pathogen, especially when there are deficiencies in the treatment of a hospital's potable water supply.

The standard recommendation for patients *with* risk factors for MDR infection is for three antibiotics: two directed at *P. aeruginosa* and one at MRSA. The choice of a β-lactam agent provides the greatest variability in coverage, yet the use of the broadest-spectrum agent—a carbapenem—still represents inappropriate initial therapy in 10–15% of cases.

SPECIFIC TREATMENT Once an etiologic diagnosis is made, broad-spectrum empirical therapy can be modified to address the known pathogen specifically. For patients with MDR risk factors, antibiotic regimens can be reduced to a single agent in more than half of cases and to a two-drug combination in more than one-quarter. Only a minority of cases require a complete course with three drugs. A negative tracheal-aspirate culture or growth below the threshold for quantitative cultures, especially if the sample was obtained before any antibiotic change, strongly suggests that antibiotics should be discontinued. Identification of other confirmed or suspected sites of infection may require ongoing antibiotic therapy, but the spectrum of pathogens (and the corresponding antibiotic choices) may be different from those for VAP. If the CPIS decreases over the first 3 days, antibiotics should be stopped after 8 days. An 8-day course of therapy is just as effective as a 2-week course and is associated with less frequent emergence of antibiotic-resistant strains.

The major controversy regarding specific therapy for VAP concerns the need for ongoing combination treatment of *Pseudomonas* infection. No randomized controlled trials have demonstrated a benefit of combination therapy with a β-lactam and an aminoglycoside, nor have subgroup analyses in other trials found a survival benefit with such a regimen. The unacceptably high rates of clinical failure and death for VAP caused by *P. aeruginosa* despite combination therapy (see "Failure to Improve," below) indicate that better regimens are needed—including, perhaps, aerosolized antibiotics.

VAP caused by MRSA is associated with a 40% clinical failure rate when treated with standard-dose vancomycin. One proposed solution is the use of high-dose individualized treatment, but the risk-to-benefit ratio of this approach is not known. Linezolid appears to be more efficacious than the standard dose of vancomycin, especially in patients with renal insufficiency.

FAILURE TO IMPROVE Treatment failure is not uncommon in VAP, especially in that caused by MDR pathogens. In addition to the 40% failure rate for MRSA infection treated with vancomycin, VAP due to *Pseudomonas* has a 50% failure rate, no matter what the regimen. The causes of clinical failure vary with the pathogen(s) and the antibiotic(s). Inappropriate therapy can usually be minimized by use of the recommended triple-drug regimen (Table 251-8). However, the emergence of β-lactam resistance during therapy is an important problem, especially in infection with *Pseudomonas* and *Enterobacter* spp. Recurrent VAP caused by the same pathogen is possible because the biofilm on ETs allows reintroduction of the microorganism. However, studies of VAP caused by *Pseudomonas* show that approximately half of recurrent cases are caused by a new strain. Inadequate local levels of vancomycin are the likely cause of treatment failure in VAP due to MRSA.

Treatment failure is very difficult to diagnose. Pneumonia due to a new superinfection, the presence of extrapulmonary infection, and drug toxicity must be considered in the differential diagnosis of treatment failure. Serial CPIS appears to track the clinical response accurately, while repeat quantitative cultures may clarify the microbiologic response. A persistently elevated or rising CPIS value by day 3 of therapy is likely to indicate failure. The most sensitive component of the CPIS is improvement in oxygenation.

COMPLICATIONS Apart from death, the major complication of VAP is prolongation of mechanical ventilation, with corresponding increases in length of stay in the ICU and in the hospital. In most studies, an additional week of mechanical ventilation because of VAP is common. The additional expense of this complication warrants costly and aggressive efforts at prevention.

In rare cases, some types of necrotizing pneumonia (e.g., that due to *P. aeruginosa*) result in significant pulmonary hemorrhage. More commonly, necrotizing infections result in the long-term complications of bronchiectasis and parenchymal scarring leading to recurrent pneumonias. The long-term complications of pneumonia are underappreciated. Pneumonia results in a catabolic state in a patient already nutritionally at risk. The muscle loss and general debilitation from an episode of VAP often require prolonged rehabilitation and, in the elderly, commonly result in an inability to return to independent function and the need for nursing home placement.

FOLLOW-UP Clinical improvement, if it occurs, is usually evident within 48–72 h of the initiation of antimicrobial treatment. Because findings on chest radiography often worsen initially during treatment, they are less helpful than clinical criteria as an indicator of clinical response in severe pneumonia. Although no hard and fast rules govern the frequency of follow-up chest radiography in seriously ill patients with pneumonia, assessment every few days in a responding patient seems appropriate. Once the patient has improved substantially and has stabilized, follow-up radiographs may not be necessary for a few weeks.

Prognosis VAP is associated with significant mortality. Crude mortality rates of 50–70% have been reported, but the real issue is attributable mortality. Many patients with VAP have underlying diseases that

would result in death even if VAP did not occur. Attributable mortality exceeded 25% in one matched-cohort study. Patients who develop VAP are at least twice as likely to die as those who do not. Some of the variability in reported figures is clearly related to the type of patient and ICU studied. VAP in trauma patients is not associated with attributable mortality, possibly because many of the patients were otherwise healthy before being injured. However, the causative pathogen also plays a major role. Generally, MDR pathogens are associated with significantly greater attributable mortality than non-MDR pathogens. Pneumonia caused by some pathogens (e.g., *S. maltophilia*) is simply a marker for a patient whose immune system is so compromised that death is almost inevitable.

Prevention (Table 251-6) Because of the significance of the ET as a risk factor for VAP, the most important preventive intervention is to avoid endotracheal intubation or at least to minimize its duration. Successful use of noninvasive ventilation via a nasal or full-face mask avoids many of the problems associated with ETs. Strategies that minimize the duration of ventilation have also been highly effective in preventing VAP.

Unfortunately, a tradeoff in risks is sometimes required. Aggressive attempts to extubate early may result in reintubation(s), which pose a risk of VAP. Heavy continuous sedation increases the risk, but self-extubation because of too little sedation is also a risk. The tradeoff is probably best illustrated by antibiotic therapy. Short-course antibiotic prophylaxis can decrease the risk of VAP in comatose patients requiring intubation, and data suggest that antibiotics decrease VAP rates in general. However, the major benefit appears to be a decrease in the incidence of early-onset VAP, which is usually caused by the less pathogenic non-MDR microorganisms. Conversely, prolonged courses of antibiotics consistently increase the risk of VAP caused by the more lethal MDR pathogens. Despite its virulence and associated mortality, VAP caused by *Pseudomonas* is rare among patients who have not recently received antibiotics.

Minimizing the amount of microaspiration around the ET cuff is also a strategy for avoidance of VAP. Simply elevating the head of the bed (at least 30° above horizontal but preferably 45°) decreases VAP rates. Specially modified ETs that allow removal of the secretions pooled above the cuff may also prevent VAP. The risk-to-benefit ratio of transporting the patient outside the ICU for diagnostic tests or procedures should be carefully considered, since VAP rates are increased among transported patients.

Emphasis on the avoidance of agents that raise gastric pH and on oropharyngeal decontamination has been diminished by the equivocal and conflicting results of more recent clinical trials. The role in the pathogenesis of VAP that is played by the overgrowth of bacterial components of the bowel flora in the stomach has also been downplayed. MRSA and the nonfermenters *P. aeruginosa* and *Acinetobacter* spp. are not normally part of the bowel flora but reside primarily in the nose and on the skin, respectively. Therefore, an emphasis on controlling overgrowth of the bowel flora may be relevant only in certain populations, such as liver transplant recipients and patients who have undergone other major intraabdominal procedures or who have bowel obstruction.

In outbreaks of VAP due to specific pathogens, the possibility of a breakdown in infection control measures (particularly contamination of reusable equipment) should be investigated. Even high rates of pathogens that are already common in a particular ICU may be a result of cross-infection. Education and reminders of the need for consistent infection control practices can minimize this risk.

HOSPITAL-ACQUIRED PNEUMONIA

While significantly less well studied than VAP, HAP in nonintubated patients, both inside and outside the ICU, is similar to VAP. The main differences are in the higher frequency of non-MDR pathogens and the better underlying host immunity in nonintubated patients. The lower frequency of MDR pathogens allows monotherapy in a larger proportion of cases of HAP than of VAP.

The only pathogens that may be more common in the non-VAP population are anaerobes. The greater risk of macroaspiration by nonintubated patients and the lower oxygen tensions in the lower respiratory tract of these patients increase the likelihood of a role for anaerobes. As in the management of CAP, specific therapy targeting anaerobes probably is not indicated unless gross aspiration is a concern.

Diagnosis is even more difficult for HAP in the nonintubated patient than for VAP. Lower respiratory tract samples appropriate for culture are considerably more difficult to obtain from nonintubated patients. Many of the underlying diseases that predispose a patient to HAP are also associated with an inability to cough adequately. Since blood cultures are infrequently positive (<15% of cases), the majority of patients with HAP do not have culture data on which antibiotic modifications can be based. Therefore, de-escalation of therapy is less likely in patients with risk factors for MDR pathogens. Despite these difficulties, the better host defenses in non-ICU patients result in lower mortality rates than are documented for VAP. In addition, the risk of antibiotic failure is lower in HAP.

252 Bronchiectasis and Lung Abscess

Gregory Tino, Steven E. Weinberger

BRONCHIECTASIS

DEFINITION

Bronchiectasis is an abnormal and permanent dilatation of bronchi. It may be either focal, involving airways supplying a limited region of pulmonary parenchyma, or diffuse, involving airways in a more widespread distribution. Recent studies have estimated there to be about 110,000 patients with bronchiectasis in the United States. It is a disorder that typically affects older individuals; approximately two-thirds of patients are women.

PATHOLOGY

The bronchial dilatation of bronchiectasis is associated with destructive and inflammatory changes in the walls of medium-sized airways, often at the level of segmental or subsegmental bronchi. Airway inflammation is primarily mediated by neutrophils and results in upregulation of enzymes such as elastase and matrix metalloproteinases. The normal structural components of the wall, including cartilage, muscle, and elastic tissue, are destroyed and may be replaced by fibrous tissue. The dilated airways frequently contain pools of thick, purulent material, while more peripheral airways are often occluded by secretions or obliterated and replaced by fibrous tissue. Additional microscopic features include bronchial and peribronchial inflammation and fibrosis, ulceration of the bronchial wall, squamous metaplasia, and mucous gland hyperplasia. The parenchyma normally supplied by the affected airways is abnormal, containing varying combinations of fibrosis, emphysema, bronchopneumonia, and atelectasis. As a result of the inflammation, vascularity of the bronchial wall increases, with associated enlargement of the bronchial arteries and anastomoses between the bronchial and pulmonary arterial circulations.

Three different patterns of bronchiectasis have been described. In *cylindrical bronchiectasis*, the involved bronchi appear uniformly dilated and end abruptly at the point that smaller airways are obstructed by secretions. In *varicose bronchiectasis*, the affected bronchi have an irregular or beaded pattern of dilatation resembling varicose veins. In *saccular (cystic) bronchiectasis*, the bronchi have a ballooned appearance at the periphery, ending in blind sacs without recognizable bronchial structures distal to the sacs.

ETIOLOGY AND PATHOGENESIS

Bronchiectasis is a consequence of inflammation and destruction of the structural components of the bronchial wall. Infection is the usual cause of the inflammation; microorganisms such as *Pseudomonas aeruginosa* and *Haemophilus influenzae* produce pigments, proteases, and other toxins that injure the respiratory epithelium and impair mucociliary clearance. The host inflammatory response induces epithelial injury, largely as a result of mediators released from neutrophils. As protection against infection is compromised, the dilated airways become more susceptible to colonization and growth of bacteria. Thus, a reinforcing cycle can result, with inflammation producing airway damage, impaired clearance of microorganisms, and further infection, which then completes the cycle by inciting more inflammation.

Infectious Causes Adenovirus and influenza virus are the main viruses that cause bronchiectasis in association with lower respiratory tract involvement. Virulent bacterial infections, especially with potentially necrotizing organisms such as *Staphylococcus aureus*, *Klebsiella*, and anaerobes, remain important causes of bronchiectasis when antibiotic treatment of a pneumonia is not given or is significantly delayed. Infection with *Bordetella pertussis*, particularly in childhood, has also been classically associated with chronic suppurative airways disease. Bronchiectasis has been reported in patients with HIV infection, perhaps at least partly due to recurrent bacterial infection. Tuberculosis, a major cause of bronchiectasis worldwide, can produce airway dilatation by a necrotizing effect on pulmonary parenchyma and airways and indirectly as a consequence of airway obstruction from bronchostenosis or extrinsic compression by lymph nodes. Nontuberculous mycobacteria are frequently cultured from patients with bronchiectasis, often as secondary infections or colonizing organisms. However, it has also been recognized that these organisms, especially those of the *Mycobacterium avium* complex, can serve as primary pathogens associated with the development and/or progression of bronchiectasis.

Impaired host defense mechanisms are often involved in the predisposition to recurrent infections. The major cause of localized impairment of host defenses is endobronchial obstruction. Bacteria and secretions cannot be cleared adequately from the obstructed airway, which develops recurrent or chronic infection. Slowly growing endobronchial neoplasms such as carcinoid tumors may be associated with bronchiectasis. Foreign-body aspiration is another important cause of endobronchial obstruction, particularly in children. Airway obstruction can also result from bronchostenosis, from impacted secretions, or from extrinsic compression by enlarged lymph nodes.

Generalized impairment of pulmonary defense mechanisms occurs with immunoglobulin deficiency, primary ciliary disorders, or cystic fibrosis (CF). Infections and bronchiectasis are therefore often more diffuse. With panhypogammaglobulinemia, the best described of the immunoglobulin disorders associated with recurrent infection and bronchiectasis, patients often also have a history of sinus or skin infections. Selective deficiency of an IgG subclass, especially IgG2, has also been described in a small number of patients with bronchiectasis.

The primary disorders associated with ciliary dysfunction, termed *primary ciliary dyskinesia*, are responsible for 5–10% of cases of bronchiectasis. Primary ciliary dyskinesia is inherited in an autosomal recessive fashion. Numerous defects are encompassed under this category, including structural abnormalities of the dynein arms, radial spokes, and microtubules; mutations in heavy and intermediate chain dynein have been described in a small number of patients. The cilia become dyskinetic; their coordinated, propulsive action is diminished, and bacterial clearance is impaired. The clinical effects include recurrent upper and lower respiratory tract infections, such as sinusitis, otitis media, and bronchiectasis. Because normal sperm motility also depends on proper ciliary function, males are generally infertile (Chap. 340). Additionally, since visceral rotation during development depends upon proper ciliary motion, the positioning of normally lateralized organs becomes random. As a result, approximately half of patients with primary ciliary dyskinesia fall into the subgroup of *Kartagener's syndrome*, in which situs inversus accompanies bronchiectasis and sinusitis.

In CF (Chap. 253), the tenacious secretions in the bronchi are associated with impaired bacterial clearance, resulting in colonization and recurrent infection with a variety of organisms, particularly mucoid strains of *P. aeruginosa* but also *S. aureus*, *H. influenzae*, *Escherichia coli*, and *Burkholderia cepacia*.

Noninfectious Causes Some cases of bronchiectasis are associated with exposure to a toxic substance that incites a severe inflammatory response. Examples include inhalation of a toxic gas such as ammonia or aspiration of acidic gastric contents, though the latter problem is often also complicated by aspiration of bacteria. An immune response in the airway may also trigger inflammation, destructive changes, and bronchial dilatation. This mechanism is presumably important for bronchiectasis with allergic bronchopulmonary aspergillosis (ABPA), which is due at least in part to an immune response to *Aspergillus* organisms that have colonized the airway (Chap. 249).

In α_1-antitrypsin deficiency, the usual respiratory complication is the early development of panacinar emphysema, but affected individuals may occasionally have bronchiectasis. In the *yellow nail syndrome*, which is due to hypoplastic lymphatics, the triad of lymphedema, pleural effusion, and yellow discoloration of the nails is accompanied by bronchiectasis in approximately 40% of patients.

CLINICAL MANIFESTATIONS

Patients typically present with persistent or recurrent cough and purulent sputum production. Repeated, purulent respiratory tract infections should raise clinical suspicion for bronchiectasis. Hemoptysis occurs in 50–70% of cases and can be due to bleeding from friable, inflamed airway mucosa (Chap. 34). More significant, even massive bleeding is often a consequence of bleeding from hypertrophied bronchial arteries. Systemic symptoms such as fatigue, weight loss, and myalgias can also occur.

When a specific infectious episode initiates bronchiectasis, patients may describe a severe pneumonia followed by chronic cough and sputum production. Alternatively, patients without a dramatic initiating event often describe the insidious onset of symptoms. In some cases, patients are either asymptomatic or have a nonproductive cough, often associated with "dry" bronchiectasis in an upper lobe. Dyspnea or wheezing generally reflects either widespread bronchiectasis or underlying chronic obstructive pulmonary disease. With exacerbations of infection, the amount of sputum increases, and it becomes more purulent and often more bloody; systemic symptoms, including fever, may also be prominent.

Physical examination of the chest overlying an area of bronchiectasis is quite variable. Any combination of crackles, rhonchi, and wheezes may be heard, all of which reflect the damaged airways containing significant secretions. As with other types of chronic intrathoracic infection, clubbing may be present. Patients with severe diffuse disease, particularly those with chronic hypoxemia, may have associated cor pulmonale and right ventricular failure.

RADIOGRAPHIC AND LABORATORY FINDINGS

Though the chest radiograph is important in the evaluation of suspected bronchiectasis, the findings are often nonspecific. At one extreme, the radiograph may be normal with mild disease. Alternatively, patients with saccular bronchiectasis may have prominent cystic spaces, either with or without air-liquid levels, corresponding to the dilated airways. These may be difficult to distinguish from enlarged airspaces due to bullous emphysema or from regions of honeycombing in patients with severe interstitial lung disease. Other findings are due to dilated airways with thickened walls, which result from peribronchial inflammation. These dilated airways are often crowded together in parallel. When seen longitudinally, the airways appear as "tram tracks"; when seen in cross-section, they produce "ring shadows." Because the dilated airways may be filled with secretions, the lumen may appear dense rather than radiolucent, producing an opaque tubular or branched tubular structure.

CT, especially with high-resolution images 1.0–1.5 mm thick, provides an excellent view of dilated airways (Fig. 252-1). Consequently, it is now the standard technique for detecting or confirming the diagnosis of bronchiectasis.

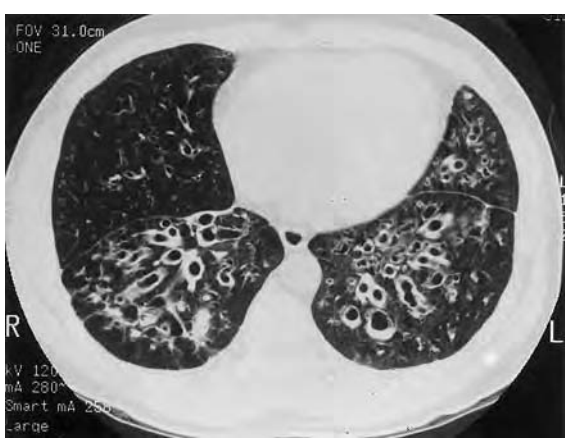

FIGURE 252-1 High-resolution CT scan of bronchiectasis showing dilated airways in both lower lobes and in the lingula. When seen in cross-section, the dilated airways have a ringlike appearance. *(From SE Weinberger: Principles of Pulmonary Medicine, 4th ed. Philadelphia, Saunders, 2004, with permission.)*

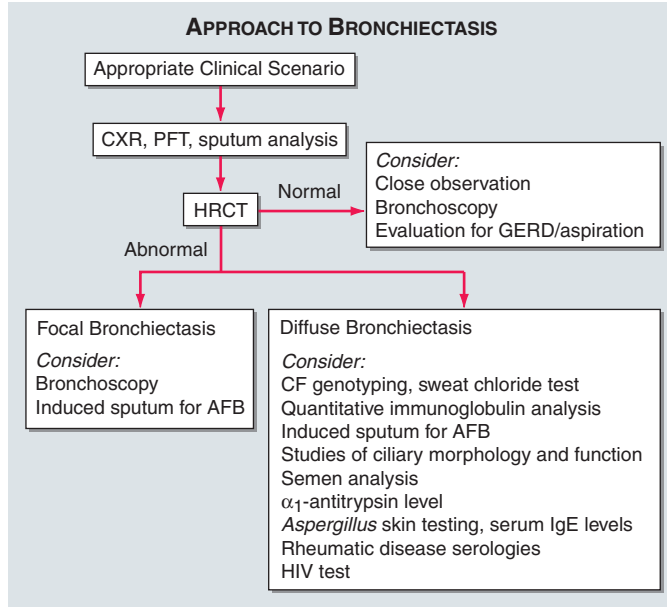

FIGURE 252-2 Diagnostic approach to bronchiectasis. AFB, acid-fast bacilli; CXR, chest X-ray; GERD, gastroesophageal reflux disease; HRCT, high-resolution computed tomography; PFT, pulmonary function testing.

Examination of sputum often reveals an abundance of neutrophils and colonization or infection with a variety of possible organisms. Appropriate staining and culturing of sputum often provide a guide to antibiotic therapy.

When bronchiectasis is focal, fiberoptic bronchoscopy may reveal an underlying endobronchial obstruction. In other cases, upper lobe involvement may be suggestive of either tuberculosis or ABPA. With more widespread disease, measurement of sweat chloride levels for CF, structural or functional assessment of nasal or bronchial cilia or sperm for primary ciliary dyskinesia, and quantitative assessment of immunoglobulins may explain recurrent airway infection.

Pulmonary function tests may demonstrate airflow obstruction as a consequence of diffuse bronchiectasis or associated chronic obstructive lung disease. Bronchial hyperreactivity, e.g., to methacholine challenge, and some reversibility of the airflow obstruction with inhaled bronchodilators are relatively common.

Figure 252-2 illustrates a diagnostic approach based on clinical suspicion and radiographic findings. As the differential diagnosis for focal versus diffuse bronchiectasis is different, the radiographic distribution of disease can serve as a starting point of the diagnostic workup. This algorithm should not imply that all studies be obtained in all patients with bronchiectasis. Rather, the workup should be dictated by a careful assessment of the clinical scenario. In a patient with focal bronchiectasis, for example, documentation of a prior pneumonia in the same location may suffice. Evaluation for immunoglobulin deficiency and CF should be considered for young patients with bronchiectasis and sino-pulmonary disease.

Rx BRONCHIECTASIS

Therapy has several major goals: (1) treatment of infection, particularly during acute exacerbations; (2) improved clearance of tracheobronchial secretions; (3) reduction of inflammation; and (4) treatment of an identifiable underlying problem.

Antibiotics are the cornerstone of bronchiectasis management. For patients with infrequent exacerbations characterized by an increase in quantity and purulence of the sputum, antibiotics are used only during acute episodes. Although choice of an antibiotic should be guided by Gram's stain and culture of sputum, empiric coverage (e.g., with amoxicillin, tri-

methoprim-sulfamethoxazole, or levofloxacin) is often given initially. Infection with *P. aeruginosa* is of particular concern, as it appears to be associated with greater rate of deterioration of lung function and worse quality of life. When *Pseudomonas* is present, oral therapy with a quinolone or parenteral therapy with an aminoglycoside, carbapenem, or third-generation cephalosporin is appropriate based on antibiotic sensitivity patterns. There are no firm guidelines for length of therapy, but a 10–14 day course or longer is typically administered.

A variety of mechanical methods and devices accompanied by appropriate positioning can facilitate drainage in patients with copious secretions. Though commonly employed and probably beneficial, these airway-clearance techniques have been poorly studied, and their efficacy is not proven. Pharmacologic agents are also employed to promote bronchopulmonary hygiene. Mucolytic agents to thin secretions and allow better clearance are controversial. Aerosolized recombinant DNase, which decreases viscosity of sputum by breaking down DNA released from neutrophils, has been shown to improve pulmonary function in CF but may be deleterious and should be avoided in bronchiectasis not associated with CF. Bronchodilators to improve obstruction and aid clearance of secretions are particularly useful in patients with airway hyperreactivity and reversible airflow obstruction.

Although surgical therapy was common in the past, more effective antibiotic and supportive therapy has largely replaced surgery. However, when bronchiectasis is localized and the morbidity is substantial despite adequate medical therapy, surgical resection of the involved region of lung should be considered.

When massive hemoptysis, often originating from the hypertrophied bronchial circulation, does not resolve with conservative therapy, including rest and antibiotics, therapeutic options are either surgical resection or bronchial arterial embolization (Chap. 34). Although resection may be successful if disease is localized, embolization is preferable with widespread disease.

LUNG ABSCESS

Lung abscess is defined as pulmonary parenchymal necrosis and cavitation resulting from infection. The development of a lung abscess implies a high microorganism burden as well as inadequate microbial clearance from the airways. Aspiration is the most common cause; factors that portend an increased risk of aspiration include esophageal dysmotility, seizure disorders, and neurologic conditions causing bulbar dysfunction. Other predisposing conditions for lung abscess include periodontal disease and alcoholism.

MICROBIOLOGY

Anaerobic bacteria are the most common causative organisms for lung abscess. Aerobic or facultative bacteria such as *S. aureus, Klebsiella pneumoniae, Nocardia sp.*, and gram-negative organisms, as well as nonbacterial pathogens like fungi and parasites, may also cause abscess formation. In the immunocompromised host, aerobic bacteria and opportunistic pathogens may predominate. Multiple isolates are more commonly seen in all patients when anaerobic and aerobic cultures are done.

CLINICAL MANIFESTATIONS

The symptoms of lung abscess are typical of pulmonary infection in general and may include cough, purulent sputum production, pleuritic chest pain, fever, and hemoptysis. In anaerobic infection, the clinical course may evolve over an extended period of time, and some patients may be asymptomatic. More acute presentations are typical of infection with aerobic bacteria.

Physical examination is often unrevealing. Rales or evidence of consolidation may be present. Fetid breath and poor dentition may be diagnostic clues. Clubbing or hypertrophic pulmonary osteoarthropathy may occur in chronic cases.

The chest radiograph classically reveals one or two thick-walled cavities in dependent areas of the lung, particularly the upper lobes and posterior segments of the lower lobes (Fig. 252-3). An air-fluid level is often present. CT of the chest is helpful in defining the size and location of the abscess, as well as to evaluate for additional cavities and the presence of pleural disease. Cavitary lesions in nondependent regions like the right middle lobe or anterior segments of the upper lobes should raise the possibility of other etiologies, including malignancy.

FIGURE 252-3 Cross-sectional CT image from a patient with an anaerobic lung abscess showing two contiguous thick-walled cavitary lesions in the right lower lobe with air-fluid levels. *(From WT Miller Jr: Diagnostic Thoracic Imaging. New York, McGraw-Hill, 2006, with permission.)*

Laboratory studies may reveal leukocytosis, anemia, and an elevated erythrocyte sedimentation rate.

DIAGNOSIS

The diagnosis of lung abscess is based on clinical symptoms, identification of predisposing conditions, and chest radiographic findings. The differential diagnosis includes mycobacterial infection, pulmonary sequestration, malignancy, pulmonary infarction, and an infected bulla.

Identification of a causative organism is an ideal but challenging goal. Anaerobic bacteria are particularly difficult to isolate. Blood, sputum cultures, and, when appropriate, pleural fluid cultures should be obtained from patients with lung abscess. The role of fiberoptic bronchoscopy with bronchoalveolar lavage or protected-specimen brush for diagnosis or drainage of lung abscess is controversial. The relatively low yield, especially with anaerobic lung abscess, should be balanced against the risk of rupture of the abscess cavity with spillage into the airways. Bronchoscopy is perhaps most useful to rule out airway obstruction, mycobacterial infection, or malignancy. Other less commonly utilized methods for microbiologic sampling are transtracheal or transthoracic aspiration.

Rx LUNG ABSCESS

For many years, penicillin was the mainstay of empiric antibiotic therapy for lung abscess. Due to the emergence of β-lactamase–producing organisms, clindamycin (150 mg–300 mg every 6 h) is now standard therapy. Other agents, such as carbapenems and β-lactam/β-lactamase inhibitor combinations, may be useful in selected cases. Metronidazole alone is associated with a high treatment failure rate. When possible, the choice of antibiotics should be guided by microbiologic results.

The duration of treatment for lung abscess is controversial. Four to six weeks of antibiotic therapy is typically employed, though a more extended course is favored by some experts. Treatment failure suggests the possibility of a noninfectious etiology.

While surgery has had a limited role in treatment in the antibiotic era, indications include refractory hemoptysis, inadequate response to medical therapy, or the need for a tissue diagnosis when there is concern for a noninfectious etiology.

In general, outcomes for patients with classic anaerobic lung abscess are favorable, with a 90–95% cure rate. Higher mortality rates have been reported in immunocompromised patients, those with significant comorbidities, and infection with *P. aeruginosa*, *S. aureus*, and *K. pneumoniae*.

253 Cystic Fibrosis

Richard C. Boucher

Cystic fibrosis (CF) is a monogenic disorder that presents as a multisystem disease. The first signs and symptoms typically occur in childhood, but about 5% of patients in the United States are diagnosed as adults. Due to improvements in therapy, >41% of patients are now adults (≥18 years old) and 13% are past the age of 30. The median survival is >41 years for patients with CF. Thus, CF is no longer only a pediatric disease, and internists must be prepared to recognize and treat its many complications. This disease is characterized by chronic bacterial infection of the airways that ultimately leads to bronchiectasis and bronchiolectasis, exocrine pancreatic insufficiency and intestinal dysfunction, abnormal sweat gland function, and urogenital dysfunction.

PATHOGENESIS

GENETIC CONSIDERATIONS CF is an autosomal recessive disease resulting from mutations in the gene that encodes the CF transmembrane conductance regulator (CFTR) protein located on chromosome 7. The mutations in the CFTR gene fall into four major classes, as depicted in **Fig. 253-1**. Classes I–III mutations are considered "severe," as indexed by pancreatic insufficiency and high sweat NaCl values (see below). Class IV mutations can be "mild," i.e., associated with pancreatic sufficiency and intermediate/normal sweat NaCl values. Of note, Class I mutations that encode for premature stop codons are important to identify, as they may in the future be treated with agents that promote "read-through" of the stop codon with production of functional CFTR.

The prevalence of CF varies with the ethnic origin of a population. CF is detected in approximately 1 in 3000 live births in the Caucasian population of North America and northern Europe, 1 in 17,000 live births of African Americans, and 1 in 90,000 live births of the Asian population of Hawaii. The most common mutation in the CF gene (~70% of CF chromosomes) is a 3-bp deletion (a Class III mutation) that results in an absence of phenylalanine at amino acid position 508 (ΔF_{508}) of the CF gene protein product, known as CFTR. The large number (>1400) of relatively uncommon (<2% each) mutations identified in the CF gene makes it difficult to use DNA diagnostic technologies for identifying heterozygotes in populations at large.

CFTR PROTEIN

The CFTR protein is a single polypeptide chain, containing 1480 amino acids, that appears to function both as a cyclic AMP–regulated Cl^- channel and, as its name implies, a regulator of other ion channels. The fully processed form of CFTR is found in the plasma membrane in normal epithelia. Biochemical studies indicate that the ΔF_{508} mutation leads to improper processing and intracellular degradation of the CFTR protein. Thus, absence of CFTR in the plasma membrane is central to the molecular pathophysiology of the ΔF_{508} mutation and other Classes I–II mutations. However, Classes III–IV mutations produce CFTR proteins that are fully processed but are nonfunctional or only partially functional in the plasma membrane.

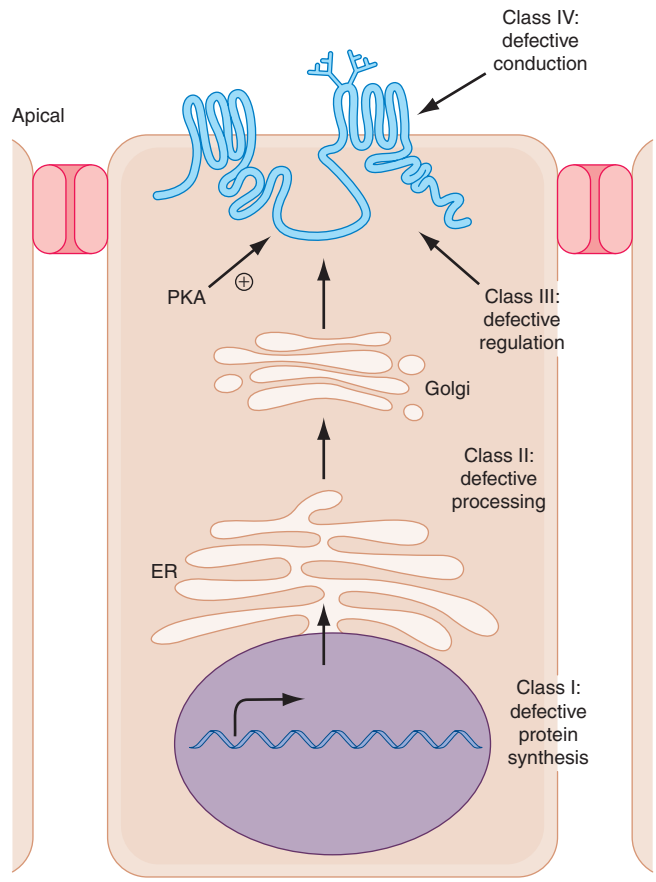

FIGURE 253-1 Schema describing classes of genetic mutations in *CFTR* gene and effects on CFTR protein/function. Note the ΔF_{508} mutation is a Class II mutation and, like Class I mutations, would be predicted to produce no mature CFTR protein in the apical membrane. CFTR, cystic fibrosis transmembrane conductance regulator.

EPITHELIAL DYSFUNCTION

The epithelia affected by CF exhibit different functions in their native state, i.e., some are volume-absorbing (airways and distal intestinal epithelia), and some are salt- but not volume-absorbing (sweat duct), whereas others are volume-secretory (proximal intestine and pancreas). Given this diversity of native activities, it is not surprising that CF produces organ-specific effects on electrolyte and water transport. However, the unifying concept is that all affected tissues express abnormal ion transport function.

ORGAN-SPECIFIC PATHOPHYSIOLOGY

Lung The diagnostic biophysical hallmark of CF airway epithelia is the raised transepithelial electric potential difference (PD). The transepithelial PD reflects both the rate of active ion transport and epithelial resistance to ion flow. CF airway epithelia exhibit abnormalities in both active Na^+ absorption and active Cl^- secretion (Fig. 253-2). The Cl^- secretory defect reflects the absence of cyclic AMP–dependent kinase and protein kinase C–regulated Cl^- transport mediated by CFTR itself. An important observation is that there is also a molecularly distinct Ca^{2+}-activated Cl^- channel (CaCC) expressed in the apical membrane. This channel can substitute for CFTR with regard to Cl^- secretion and may be a potential therapeutic target.

Abnormal regulation of Na^+ absorption is a key feature of CF airway epithelia. This abnormality reflects a second function of CFTR, its function as a tonic inhibitor of the epithelial Na^+ channel. The molecular mechanisms mediating this action of CFTR remain unknown.

Mucus clearance is the primary innate airways defense mechanism against infection by inhaled bacteria. Normal airways vary the rates of active Na^+ absorption and Cl^- secretion to adjust the volume of liquid (water), i.e., "hydration," on airway surfaces for efficient mucus clearance. The central hypothesis of CF airways pathophysiology is that the faulty regulation of Na^+ absorption and inability to secrete Cl^- via CFTR reduce the volume of liquid on airway surfaces; i.e., they are "dehydrated." Both the thickening of mucus and the depletion of the periciliary liquid lead to adhesion of mucus to the airway surface. Mucus adhesion leads to a failure to clear mucus from the airways both by ciliary and airflow-dependent (cough) mechanisms. The absence of a strict correspondence between gene mutation class and severity of lung disease suggests important roles for modifier genes and gene-environmental interactions.

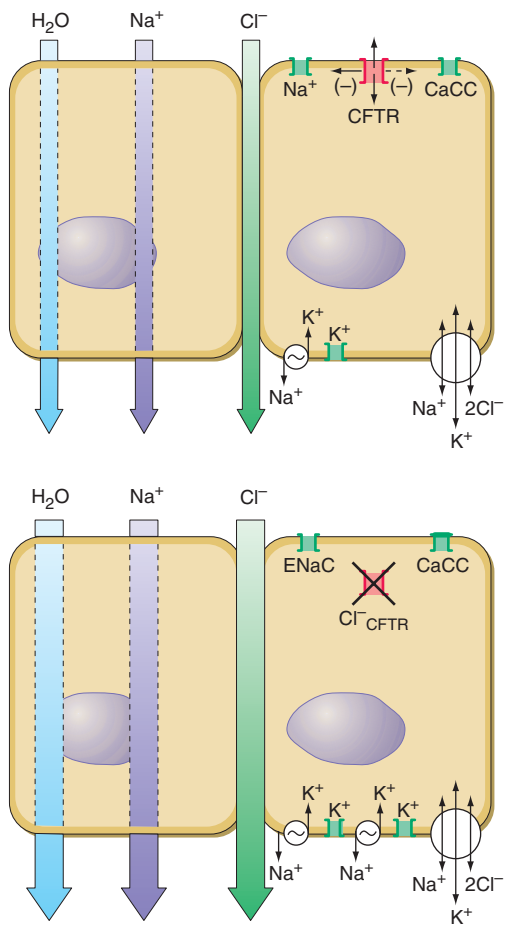

FIGURE 253-2 Comparison of ion transport properties of normal (*top*) and CF (*bottom*) airway epithelia. The vectors describe routes and magnitudes of Na^+ and Cl^- transport that is accompanied by osmotically driven water flow. The normal basal pattern for ion transport is absorption of Na^+ from the lumen via an amiloride-sensitive Na^+ channel. This process is accelerated in CF. The capacity to initiate cyclic AMP–mediated Cl^- secretion is diminished in CF airway epithelia due to absence/dysfunction of the CFTR Cl^- channel. The accelerated Na^+ absorption in CF reflects the absence of CFTR inhibitory effects on Na^+ channels.

The infection that characterizes CF airways involves the mucus layer rather than epithelial or airway wall invasion. The predisposition of CF airways to chronic infection by *Staphylococcus aureus* and *Pseudomonas aeruginosa* is consistent with failure to clear mucus. Recently it has been demonstrated that the O_2 tension is very low in CF mucus, and adaptations to hypoxia are important determinants of the physiology of bacteria in the CF lung. Indeed, both mucus stasis and mucus hypoxia may contribute to the propensity for *Pseudomonas* to grow in biofilm colonies within mucus plaques adherent to CF airway surfaces.

Gastrointestinal Tract The gastrointestinal effects of CF are diverse. In the exocrine pancreas, the absence of the CFTR Cl^- channel in the apical membrane of pancreatic ductal epithelia limits the function of an apical membrane Cl^--HCO_3^- exchanger to secrete bicarbonate and Na^+ (by a passive process) into the duct. The failure to secrete Na^+ HCO_3^- and water leads to retention of enzymes in the pancreas and ultimately destruction of virtually all pancreatic tissue. The CF intestinal epithelium, because of the lack of Cl^- and water secretion, fails to flush secreted mucins and other macromolecules from intestinal crypts. The diminished CFTR-mediated secretion of liquid may be exacerbated by excessive absorption of liquid, reflecting abnormalities of CFTR-mediated regulation of Na^+ absorption (both mediated by Na^+ channels and possibly other Na^+ transporters, e.g., Na^+-H^+ exchangers). Both dysfunctions lead to desiccated intraluminal contents and obstruction of both the small and large intestine. In the hepatobiliary system, defective hepatic ductal salt (Cl^-) and water secretion causes thickened biliary secretions, focal biliary cirrhosis, and bile duct proliferation in approximately 25–30% of patients with CF. The inability of the CF gallbladder epithelium to secrete salt and water can lead to both chronic cholecystitis and cholelithiasis.

Sweat Gland CF patients secrete nearly normal volumes of sweat in the sweat acinus. However, CF patients are not able to absorb NaCl from sweat as it moves through the sweat duct due to the inability to absorb Cl^- across the ductal epithelial cells. This dysfunction in the sweat gland is typically measured by collecting sweat after iontophoresing a cholinergic agonist into the forearm.

CLINICAL FEATURES

Most patients with CF present with signs and symptoms of the disease in childhood. Approximately 20% of patients present within the first 24 h of life with gastrointestinal obstruction, termed *meconium ileus*. Other common presentations within the first year or two of life include respiratory tract symptoms, most prominently cough and/or recurrent pulmonary infiltrates, and failure to thrive. A significant proportion of patients (~5%), however, are diagnosed after age 18.

RESPIRATORY TRACT

Upper respiratory tract disease is almost universal in patients with CF. Chronic sinusitis is common in childhood and leads to nasal obstruction and rhinorrhea. The occurrence of nasal polyps approaches 25% and often requires treatment with topical steroids and/or surgery.

In the lower respiratory tract, the first symptom of CF is cough. With time, the cough becomes persistent and produces viscous, purulent, often greenish-colored sputum. Inevitably, periods of clinical stability are interrupted by "exacerbations," defined by increased cough, weight loss, low-grade fever, increased sputum volume, and decrements in pulmonary function. Over the course of years, the exacerbations become more frequent and the recovery of lost lung function incomplete, leading to respiratory failure.

CF patients exhibit a characteristic sputum microbiology. *Haemophilus influenzae* and *S. aureus* are often the first organisms recovered

from lung secretions in newly diagnosed patients with CF. *P. aeruginosa*, often mucoid and antibiotic-resistant, is typically cultured from lower respiratory tract secretions thereafter. *Burkholderia* (formerly *Pseudomonas cepacia*) is also recovered from CF sputum and is pathogenic. Patient-to-patient spread of certain strains of this organism mandates strict infection control in the hospital. Other gram-negative rods recovered from CF sputum include *Alcaligenes xylosoxidans*, *B. gladioli*, and occasionally mucoid forms of *Proteus*, *Escherichia coli*, and *Klebsiella*. Up to 50% of CF patients have *Aspergillus fumigatus* in their sputum, and up to 10% of these patients exhibit the syndrome of allergic bronchopulmonary aspergillosis. *Mycobacterium tuberculosis* is rare in patients with CF. However, 10–20% of adult patients with CF have sputum cultures positive for nontuberculous mycobacteria, and in some patients these microorganisms are associated with disease.

The first lung-function abnormalities observed in CF children, increased ratios of residual volume to total lung capacity, suggest that small-airways disease is the first functional lung abnormality in CF. As the disease progresses, both reversible and irreversible changes in forced vital capacity (FVC) and forced expiratory volume in 1 s (FEV_1) develop. The reversible component reflects the accumulation of intraluminal secretions and/or airway reactivity, which occurs in 40–60% of patients with CF. The irreversible component reflects chronic destruction of the airway wall and bronchiolitis.

The earliest chest x-ray change in CF lungs is hyperinflation, reflecting small-airways obstruction. Later, signs of luminal mucus impaction, bronchial cuffing, and finally bronchiectasis, e.g., ring shadows, are noted. For reasons that remain speculative, the right upper lobe displays the earliest and most severe changes.

CF pulmonary disease is associated with many intermittent complications. Pneumothorax is common (>10% of patients). The production of small amounts of blood in sputum is common in CF patients with advanced pulmonary disease. Massive hemoptysis is life-threatening. With advanced lung disease, digital clubbing appears in virtually all patients with CF. As late events, respiratory failure and cor pulmonale are prominent features of CF.

GASTROINTESTINAL TRACT

The syndrome of meconium ileus in infants presents with abdominal distention, failure to pass stool, and emesis. The abdominal flat plate can be diagnostic, with small-intestinal air-fluid levels, a granular appearance representing meconium, and a small colon. In children and young adults, a syndrome termed *meconium ileus equivalent* or *distal intestinal obstruction syndrome* (DIOS) occurs. The syndrome presents with right lower quadrant pain, loss of appetite, occasionally emesis, and often a palpable mass. The syndrome can be confused with appendicitis, whose frequency is not increased in CF patients.

Exocrine pancreatic insufficiency occurs in >90% of patients with CF. Insufficient pancreatic enzyme secretion yields the typical pattern of protein and fat malabsorption, with frequent, bulky, foul-smelling stools. Signs and symptoms of malabsorption of fat-soluble vitamins, including vitamins E and K, are also noted. Pancreatic beta cells are spared early, but function decreases with age. This effect, plus inflammation-induced insulin resistance, causes hyperglycemia and a requirement for insulin in >15% of older patients with CF (>35 years).

GENITOURINARY SYSTEM

Late onset of puberty is common in both males and females with CF. The delayed maturational pattern is likely secondary to the effects of chronic lung disease and inadequate nutrition on reproductive endocrine function. More than 95% of male patients with CF are azoospermic, reflecting obliteration of the vas deferens due to defective liquid secretion. Some 20% of CF women are infertile due to effects of chronic lung disease on the menstrual cycle; thick, tenacious cervical mucus that blocks sperm migration; and possibly fallopian tube/uterine wall abnormalities in liquid transport. Most pregnancies produce viable infants, and women with CF are able to breast-feed infants normally.

DIAGNOSIS

The diagnosis of CF rests on the combination of clinical criteria and abnormal CFTR function as demonstrated by sweat tests, nasal PD measurements, and CFTR mutation analysis. Elevated sweat Cl^- values are nearly pathognomonic for CF. The values for the Cl^- (and Na^+) concentrations in sweat vary with age, but typically in adults a Cl^- concentration of >70 meq/L discriminates between patients with CF and those with other lung diseases. DNA analysis of the most common mutations can identify CF mutations in >90% of affected patients. The nasal PD measurement can document CFTR dysfunction if the sweat Cl^- test is normal or borderline and two CF mutations are not identified. DNA analysis is performed routinely in patients with CF because pancreatic genotype-phenotype relationships have been identified, and mutation class-specific treatments are being developed.

Between 1 and 2% of patients with the clinical syndrome of CF have normal sweat Cl^- values. In most of these patients, the nasal transepithelial PD is raised into the diagnostic range for CF, and sweat acini do not secrete in response to injected β-adrenergic agonists. A single mutation of the CFTR gene, 3849 + 10 kb C→T, is associated with most CF patients with normal sweat Cl^- values.

Rx CYSTIC FIBROSIS

The major objectives of therapy for CF are to promote clearance of secretions and control infection in the lung, provide adequate nutrition, and prevent intestinal obstruction. Ultimately, therapies that restore the processing of misfolded mutant CFTR or gene therapy may be the treatments of choice.

LUNG DISEASE More than 95% of CF patients die of complications resulting from lung infection. Theoretically, increasing clearance of adherent mucus should both treat and prevent progression of CF lung disease, whereas antibiotics principally reduce the bacterial burden in the CF lung.

The time-honored techniques for clearing pulmonary secretions are breathing exercises, flutter valves, and chest percussion. Regular use of these maneuvers is effective in preserving lung function. A major advance has been the demonstrated efficacy of inhaled hypertonic saline (7%) in restoring mucus clearance and pulmonary function in short-term studies and its efficacy in reducing acute exacerbations in long-term (1 year) studies. Hypertonic saline is safe but can produce bronchoconstriction in some patients, which can be prevented with coadministered bronchodilators. Studies are ongoing to establish whether inhaled hypertonic saline should be the base therapy for all CF patients.

Pharmacologic agents for increasing mucus clearance are in use and in development. An important adjunct to secretion clearance can be recombinant human DNAse, which degrades the concentrated DNA in CF sputum, increases airflow during short-term administration, and increases the time between pulmonary exacerbations. Most patients receive a therapeutic trial of DNAse for several months to test for efficacy. Clinical trials of experimental drugs aimed at restoring salt and water content of secretions are underway, but these drugs are not yet available for clinical use.

Antibiotics are used for treating lung infection, and their use is guided by sputum culture results. It should be noted, however, that because routine hospital microbiologic cultures are performed under conditions that do not mimic conditions in the CF lung, e.g., hypoxia, clinical efficacy often does not correlate with sensitivity testing. Because of increased total-body clearance and volume of distribution of antibiotics in CF patients, the required doses are higher for patients with CF.

Early intervention with antibiotics in infants with infection may eradicate *P. aeruginosa* for extended periods. In older patients with established infection, suppression of bacterial growth is the therapeutic goal. Azithromycin (250 mg daily or 500 mg three times weekly) is often used chronically, although it is unclear whether its actions are antimicrobial or anti-inflammatory. Inhaled aminoglycosides, e.g., tobramycin 300 mg bid, for alternating monthly intervals are also used. "Mild exacerbations," as defined by increased cough and mucus production, are treated with additional oral antibiotics. Oral agents used to treat *Staphylococcus* include a semisynthetic penicillin or a cephalosporin. Oral ciprofloxacin may reduce pseudomonal bacterial counts and control symptoms, but its clinical utility may be limited by rapid emergence of resistant organisms. Accordingly, it

is often used with an inhaled antibiotic, either tobramycin or colistin (75 mg bid). More severe exacerbations, or exacerbations associated with bacteria resistant to oral antibiotics, require intravenous antibiotics. Intravenous therapy is given both in the hospital and in the outpatient setting. Usually, two drugs with different mechanisms of action (e.g., a cephalosporin and an aminoglycoside) are used to treat *P. aeruginosa* to minimize emergence of resistant organisms. Drug dosage should be monitored so that levels for gentamicin or tobramycin peak at ranges of ~10 μg/mL and exhibit troughs of <2 μg/mL. Antibiotics directed at *Staphylococcus* and/or *H. influenzae* are added, depending on culture results.

Inhaled β-adrenergic agonists can be useful to control airways constriction, but long-term benefit has not been shown. Oral glucocorticoids may reduce airways inflammation, but their long-term use is limited by adverse side effects; however, they may be useful for treating allergic bronchopulmonary aspergillosis.

The chronic damage to airway walls reflects in part the destructive activities of inflammatory enzymes generated in part by inflammatory cells. Specific therapies with antiproteases have not been developed. However, a subset of adolescents with CF may benefit from long-term, high-dose nonsteroidal (ibuprofen) therapy.

A number of pulmonary complications require acute interventions. Atelectasis requires treatment with inhaled hypertonic saline, chest physiotherapy, and antibiotics. Pneumothoraces involving ≤10% of the lung can be observed, but chest tubes are required to expand collapsed, diseased lung. Small-volume hemoptysis typically requires treatment of lung infection and assessment of coagulation and vitamin K status. For massive hemoptysis, bronchial artery embolization should be performed. The most ominous complications of CF are respiratory failure and cor pulmonale. The most effective conventional therapy for these conditions is vigorous medical management of the lung disease and O_2 supplementation. Ultimately, the only effective treatment for respiratory failure in CF is lung transplantation (Chap. 260). The 2-year survival for lung transplantation exceeds 60%, and transplant patient deaths result principally from graft rejection, often involving obliterative bronchiolitis. The transplanted lungs do not develop a CF-specific phenotype.

GASTROINTESTINAL DISEASE Maintenance of adequate nutrition is critical for the health of the CF patient. Most (>90%) CF patients require pancreatic enzyme replacement. Capsules generally contain between 4000 and 20,000 units of lipase. The dose of enzymes (typically no more than 2500 units/kg per meal, to avoid risk of fibrosing colonopathy) should be adjusted on the basis of weight, abdominal symptomatology, and stool character. Replacement of fat-soluble vitamins, particularly vitamins E and K, is usually required. Hyperglycemia most often becomes manifest in the adult and typically requires insulin treatment.

For treatment of the distal intestinal obstruction syndrome, megalodiatrizoate or other hypertonic radiocontrast materials delivered by enema to the terminal ileum are utilized. For control of symptoms, adjustment of pancreatic enzymes and use of salt solutions containing osmotically active agents, e.g. propyleneglycol, is recommended. Persistent symptoms may indicate a diagnosis of gastrointestinal malignancy, which is increased in incidence in patients with CF.

Cholestatic liver disease occurs in about 8% of CF patients. Treatment with urodeoxycholic acid is typically initiated if there is an increase in alkaline phosphatase and gammaglutamyl transpeptidase (GGT) (3× normal), but this treatment has not been shown to influence the course of hepatic disease. End-stage liver disease occurs in about 5% of CF patients and can be treated by transplantation.

OTHER ORGAN COMPLICATIONS Dehydration due to heat-induced salt loss from sweat ducts occurs more readily in CF patients. CF patients also have an increased incidence of osteoarthropy, renal stones, and osteoporosis, particularly following transplant.

PSYCHOSOCIAL FACTORS CF imposes a tremendous burden on patients, and depression is common. Health insurance, career options, family planning, and life expectancy become major issues. Thus, assisting patients with the psychosocial adjustments required by CF is critical.

254 Chronic Obstructive Pulmonary Disease

John J. Reilly, Jr., Edwin K. Silverman, Steven D. Shapiro

Chronic obstructive pulmonary disease (COPD) has been defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD), an international collaborative effort to improve awareness, diagnosis, and treatment of COPD, as a disease state characterized by airflow limitation that is not fully reversible (*http://www.goldcopd.com/*). COPD includes *emphysema*, an anatomically defined condition characterized by destruction and enlargement of the lung alveoli; *chronic bronchitis*, a clinically defined condition with chronic cough and phlegm; and *small airways disease*, a condition in which small bronchioles are narrowed. COPD is present only if chronic airflow obstruction occurs; chronic bronchitis *without* chronic airflow obstruction is *not* included within COPD.

COPD is the fourth leading cause of death and affects >16 million persons in the United States. COPD is also a disease of increasing public health importance around the world. GOLD estimates suggest that COPD will rise from the sixth to the third most common cause of death worldwide by 2020.

RISK FACTORS

CIGARETTE SMOKING

By 1964, the Advisory Committee to the Surgeon General of the United States had concluded that cigarette smoking was a major risk factor for mortality from chronic bronchitis and emphysema. Subsequent longitudinal studies have shown accelerated decline in the volume of air exhaled within the first second of the forced expiratory maneuver (FEV_1) in a dose-response relationship to the intensity of cigarette smoking, which is typically expressed as pack-years (average number of packs of cigarettes smoked per day multiplied by the total number of years of smoking). This dose-response relationship between reduced pulmonary function and cigarette smoking intensity accounts for the higher prevalence rates for COPD with increasing age. The historically higher rate of smoking among males is the likely explanation for the higher prevalence of COPD among males; however, the prevalence of COPD among females is increasing as the gender gap in smoking rates has diminished in the past 50 years.

Although the causal relationship between cigarette smoking and the development of COPD has been absolutely proved, there is considerable

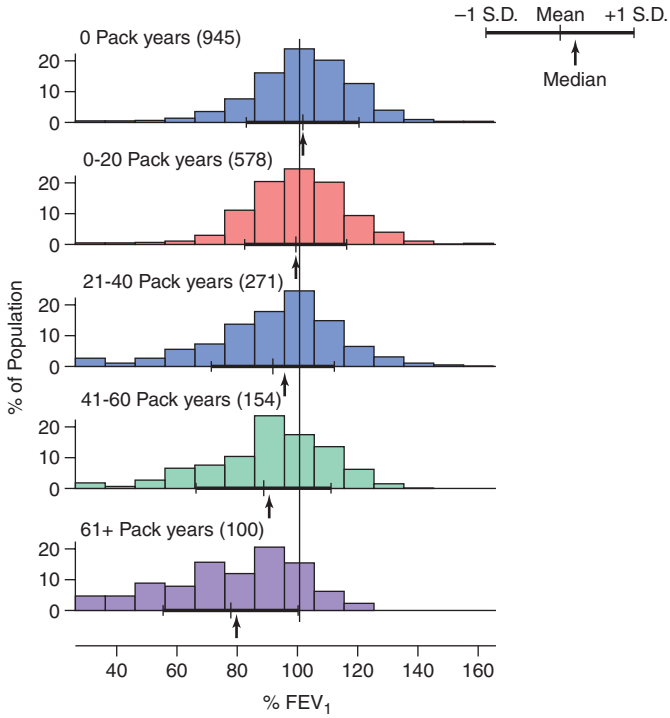

FIGURE 254-1 Distributions of forced expiratory volume in 1 s (FEV_1) values in a general population sample, stratified by pack-years of smoking. Means, medians, and ± 1 standard deviation of percent predicted FEV_1 are shown for each smoking group. Although a dose-response relationship between smoking intensity and FEV_1 was found, marked variability in pulmonary function was observed among subjects with similar smoking histories. (*From R Burrows et al: Am Rev Respir Dis 115:95, 1977; with permission.*)

variability in the response to smoking. Although pack-years of cigarette smoking is the most highly significant predictor of FEV_1 (Fig. 254-1), only 15% of the variability in FEV_1 is explained by pack-years. This finding suggests that additional environmental and/or genetic factors contribute to the impact of smoking on the development of airflow obstruction.

Although cigar and pipe smoking may also be associated with the development of COPD, the evidence supporting such associations is less compelling, likely related to the lower dose of inhaled tobacco byproducts during cigar and pipe smoking.

AIRWAY RESPONSIVENESS AND COPD

A tendency for increased bronchoconstriction in response to a variety of exogenous stimuli, including methacholine and histamine, is one of the defining features of asthma (Chap. 248). However, many patients with COPD also share this feature of airway hyperresponsiveness. The considerable overlap between persons with asthma and those with COPD in airway responsiveness, airflow obstruction, and pulmonary symptoms led to the formulation of the Dutch hypothesis. This suggests that asthma, chronic bronchitis, and emphysema are variations of the same basic disease, which is modulated by environmental and genetic factors to produce these pathologically distinct entities. The alternative British hypothesis contends that asthma and COPD are fundamentally different diseases: Asthma is viewed as largely an allergic phenomenon, while COPD results from smoking-related inflammation and damage. Determination of the validity of the Dutch hypothesis vs. the British hypothesis awaits identification of the genetic predisposing factors for asthma and/or COPD, as well as the interactions between these postulated genetic factors and environmental risk factors.

Longitudinal studies that compared airway responsiveness at the beginning of the study to subsequent decline in pulmonary function have demonstrated that increased airway responsiveness is clearly a significant predictor of subsequent decline in pulmonary function. Thus, airway hyperresponsiveness is a risk factor for COPD.

RESPIRATORY INFECTIONS

These have been studied as potential risk factors for the development and progression of COPD in adults; childhood respiratory infections have also been assessed as potential predisposing factors for the eventual development of COPD. The impact of adult respiratory infections on decline in pulmonary function is controversial, but significant long-term reductions in pulmonary function are not typically seen following an episode of bronchitis or pneumonia. The impact of the effects of childhood respiratory illnesses on the subsequent development of COPD has been difficult to assess due to a lack of adequate longitudinal data. Thus, although respiratory infections are important causes of exacerbations of COPD, the association of both adult and childhood respiratory infections to the development and progression of COPD remains to be proven.

OCCUPATIONAL EXPOSURES

Increased respiratory symptoms and airflow obstruction have been suggested as resulting from general exposure to dust at work. Several specific occupational exposures, including coal mining, gold mining, and cotton textile dust, have been suggested as risk factors for chronic airflow obstruction. However, although nonsmokers in these occupations developed some reductions in FEV_1, the importance of dust exposure as a risk factor for COPD, independent of cigarette smoking, is not certain. Among workers exposed to cadmium (a specific chemical fume), FEV_1, FEV_1/FVC, and DL_{CO} were significantly reduced (FVC, forced vital capacity; DL_{CO}, carbon monoxide diffusing capacity of the lung; Chap. 246), consistent with airflow obstruction and emphysema. Although several specific occupational dusts and fumes are likely risk factors for COPD, the magnitude of these effects appears to be substantially less important than the effect of cigarette smoking.

AMBIENT AIR POLLUTION

Some investigators have reported increased respiratory symptoms in those living in urban compared to rural areas, which may relate to increased pollution in the urban settings. However, the relationship of air pollution to chronic airflow obstruction remains unproven. Prolonged exposure to smoke produced by biomass combustion—a common mode of cooking in some countries—also appears to be a significant risk factor for COPD among women in those countries. However, in most populations, ambient air pollution is a much less important risk factor for COPD than cigarette smoking.

PASSIVE, OR SECOND-HAND, SMOKING EXPOSURE

Exposure of children to maternal smoking results in significantly reduced lung growth. In utero tobacco smoke exposure also contributes to significant reductions in postnatal pulmonary function. Although passive smoke exposure has been associated with reductions in pulmonary function, the importance of this risk factor in the development of the severe pulmonary function reductions in COPD remains uncertain.

GENETIC CONSIDERATIONS Although cigarette smoking is the major environmental risk factor for the development of COPD, the development of airflow obstruction in smokers is highly variable. Severe α_1 antitrypsin (α_1AT) deficiency is a proven genetic risk factor for COPD; there is increasing evidence that other genetic determinants also exist.

α_1 ANTITRYPSIN DEFICIENCY Many variants of the protease inhibitor (PI or SERPINA1) locus that encodes α_1AT have been described. The common M allele is associated with normal α_1AT levels. The S allele, associated with slightly reduced α_1AT levels, and the Z allele, associated with markedly reduced α_1AT levels, also occur with frequencies >1% in most Caucasian populations. Rare individuals inherit null alleles, which lead to the absence of any α_1AT production through a heterogeneous collection of mutations. Individuals with two Z alleles or one Z and one null allele are referred to as Pi^Z, which is the most common form of severe α_1AT deficiency.

Although only 1–2% of COPD patients are found to have severe α_1AT deficiency as a contributing cause of COPD, these patients demonstrate that genetic factors can have a profound influence on the susceptibility for developing COPD. Pi^Z individuals often develop early-onset COPD, but the

ascertainment bias in the published series of Pi^Z individuals—which have usually included many Pi^Z subjects who were tested for α_1AT deficiency because they had COPD—means that the fraction of Pi^Z individuals who will develop COPD and the age-of-onset distribution for the development of COPD in Pi^Z subjects remain unknown. Approximately 1 in 3000 individuals in the United States inherits severe α_1AT deficiency, but only a small minority of these individuals has been recognized. The clinical laboratory test used most frequently to screen for α_1AT deficiency is measurement of the immunologic level of α_1AT in serum (see "Laboratory Findings," below).

A significant percentage of the variability in pulmonary function among Pi^Z individuals is explained by cigarette smoking; cigarette smokers with severe α_1AT deficiency are more likely to develop COPD at early ages. However, the development of COPD in Pi^Z subjects, even among current or ex-smokers, is not absolute. Among Pi^Z nonsmokers, impressive variability has been noted in the development of airflow obstruction. Other genetic and/or environmental factors likely contribute to this variability.

Specific treatment in the form of α_1AT augmentation therapy is available for severe α_1AT deficiency as a weekly intravenous infusion (see "Treatment," below).

The risk of lung disease in heterozygous Pi^{MZ} individuals, who have intermediate serum levels of α_1AT (~60% of Pi^{MM} levels), is controversial. Although previous general population surveys have not typically shown increased rates of airflow obstruction in Pi^{MZ} compared to Pi^{MM} individuals, case-control studies that compared COPD patients to control subjects have usually found an excess of Pi^{MZ} genotypes in the COPD patient group. Several recent large population studies have suggested that Pi^{MZ} subjects are at slightly increased risk for the development of airflow obstruction, but it remains unclear if all Pi^{MZ} subjects are at slightly increased risk for COPD or if a subset of Pi^{MZ} subjects are at substantially increased risk for COPD due to other genetic or environmental factors.

OTHER GENETIC RISK FACTORS Studies of pulmonary function measurements performed in general population samples have suggested that genetic factors other than PI type influence variation in pulmonary function. Familial aggregation of airflow obstruction within families of COPD patients has also been demonstrated.

Association studies have compared the distribution of variants in genes hypothesized to be involved in the development of COPD in COPD patients and control subjects. However, the results have been quite inconsistent, and no genetic determinants of COPD other than severe α_1AT deficiency have been definitively proven using this approach. Genome scan linkage analyses of early-onset COPD families have found evidence for linkage of spirometric phenotypes to several chromosomal regions, but the specific genetic determinants in those regions have yet to be definitively identified.

NATURAL HISTORY

The effects of cigarette smoking on pulmonary function appear to depend on the intensity of smoking exposure, the timing of smoking exposure during growth, and the baseline lung function of the individual; other environmental factors may have similar effects. Although rare individuals may demonstrate precipitous declines in pulmonary function, most individuals follow a steady trajectory of increasing pulmonary function with growth during childhood and adolescence, followed by a gradual decline with aging. Individuals appear to track in their quartile of pulmonary function based upon environmental and genetic factors that put them on different tracks. The risk of eventual mortality from COPD is closely associated with reduced levels of FEV_1. A graphic depiction of the natural history of COPD is shown as a function of the influences on tracking curves of FEV_1 in Fig. 254-2. Death or disability from COPD can result from a normal rate of decline after a reduced growth phase (curve C), an early initiation of pulmonary function decline after normal growth (curve B), or an accelerated decline after normal growth (curve D). The rate of decline in pulmonary function can be modified by changing environmental exposures (i.e., quitting smoking), with smoking cessation at an earlier age providing a more beneficial effect than smoking cessation after marked reductions in pulmonary function have already developed. Genetic factors likely contribute to the level of pulmonary function achieved during growth and to the rate of decline in response to smoking and potentially to other environmental factors as well.

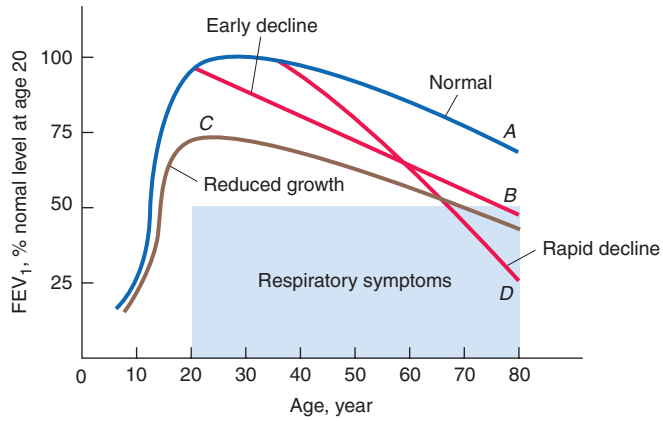

FIGURE 254-2 Hypothetical tracking curves of FEV_1 for individuals throughout their life spans. The normal pattern of growth and decline with age is shown by curve *A*. Significantly reduced FEV_1 (<65% of predicted value at age 20) can develop from a normal rate of decline after a reduced pulmonary function growth phase (curve *C*), early initiation of pulmonary function decline after normal growth (curve *B*), or accelerated decline after normal growth (curve *D*). PATHOPHYSIOLOGY

Persistent reduction in forced expiratory flow rates is the most typical finding in COPD. Increases in the residual volume and the residual volume/total lung capacity ratio, nonuniform distribution of ventilation, and ventilation-perfusion mismatching also occur.

AIRFLOW OBSTRUCTION

Airflow limitation, also known as airflow obstruction, is typically determined by spirometry, which involves forced expiratory maneuvers after the subject has inhaled to total lung capacity (see Fig. 246-4). Key phenotypes obtained from spirometry include FEV_1 and the total volume of air exhaled during the entire spirometric maneuver (FVC). Patients with airflow obstruction related to COPD have a chronically reduced ratio of FEV_1/FVC. In contrast to asthma, the reduced FEV_1 in COPD seldom shows large responses to inhaled bronchodilators, although improvements up to 15% are common. Asthma patients can also develop chronic (not fully reversible) airflow obstruction. Maximal inspiratory flow can be relatively well preserved in the presence of a markedly reduced FEV_1.

Airflow during forced exhalation is the result of the balance between the elastic recoil of the lungs promoting flow and the resistance of the airways limiting flow. In normal lungs, as well as in lungs affected by COPD, maximal expiratory flow diminishes as the lungs empty because the lung parenchyma provides progressively less elastic recoil and because the cross-sectional area of the airways falls, raising the resistance to airflow. The decrease in flow coincident with decreased lung volume is readily apparent on the expiratory limb of a flow-volume curve. In the early stages of COPD, the abnormality in airflow is only evident at lung volumes at or below the functional residual capacity (closer to residual volume), appearing as a scooped-out lower part of the descending limb of the flow-volume curve. In more advanced disease the entire curve has decreased expiratory flow compared to normal.

HYPERINFLATION

Lung volumes are also routinely assessed in pulmonary function testing. In COPD there is often "air trapping" (increased residual volume and increased ratio of residual volume to total lung capacity) and progressive hyperinflation (increased total lung capacity) late in the disease. Hyper-

inflation of the thorax during tidal breathing preserves maximum expiratory airflow, because as lung volume increases, elastic recoil pressure increases and airways enlarge so that airway resistance decreases.

Hyperinflation helps to compensate for airway obstruction. However, hyperinflation can push the diaphragm into a flattened position with a number of adverse effects. First, by decreasing the zone of apposition between the diaphragm and the abdominal wall, positive abdominal pressure during inspiration is not applied as effectively to the chest wall, hindering rib cage movement and impairing inspiration. Second, because the muscle fibers of the flattened diaphragm are shorter than those of a more normally curved diaphragm, they are less capable of generating inspiratory pressures than normal. Third, the flattened diaphragm (with increased radius of curvature, r) must generate greater tension (t) to develop the transpulmonary pressure (p) required to produce tidal breathing. This follows from Laplace's law, $p = 2t/r$. Also, because the thoracic cage is distended beyond its normal resting volume, during tidal breathing the inspiratory muscles must do work to overcome the resistance of the thoracic cage to further inflation instead of gaining the normal assistance from the chest wall recoiling outward toward its resting volume.

GAS EXCHANGE

Although there is considerable variability in the relationships between the FEV_1 and other physiologic abnormalities in COPD, certain generalizations may be made. The Pa_{O_2} usually remains near normal until the FEV_1 is decreased to ~50% of predicted, and even much lower FEV_1s can be associated with a normal Pa_{O_2}, at least at rest. An elevation of Pa_{CO_2} is not expected until the FEV_1 is <25% of predicted and even then may not occur. Pulmonary hypertension severe enough to cause cor pulmonale and right ventricular failure due to COPD occurs only in those individuals who have marked decreases in FEV_1 (<25% of predicted) together with chronic hypoxemia (Pa_{O_2} <55 mmHg), although earlier in the course some elevation of pulmonary artery pressure, particularly with exercise, may occur (Chap. 244).

Nonuniform ventilation and ventilation-perfusion mismatching are characteristic of COPD, reflecting the heterogeneous nature of the disease process within the airways and lung parenchyma. Nitrogen wash-out while breathing 100% oxygen is delayed due to regions that are poorly ventilated, and the profile of the nitrogen wash-out curve is consistent with multiple parenchymal compartments having different wash-out rates due to regional differences in compliance and airway resistance. Ventilation/perfusion mismatching accounts for essentially all of the reduction in Pa_{O_2} that occurs in COPD; shunting is minimal. This finding explains the effectiveness of modest elevations of inspired oxygen in treating hypoxemia due to COPD and therefore the need to consider problems other than COPD when hypoxemia is difficult to correct with modest levels of supplemental oxygen in the patient with COPD.

PATHOLOGY

Cigarette smoke exposure may affect the large airways, small airways (≤2 mm diameter), and alveolar space. Changes in large airways cause cough and sputum, while changes in small airways and alveoli are responsible for physiologic alterations. Emphysema and small airway pathology are both present in most persons with COPD, and their relative contributions to obstruction vary from one person to another.

LARGE AIRWAY

Cigarette smoking often results in mucous gland enlargement and goblet cell hyperplasia. These changes are proportional to cough and mucus production that define chronic bronchitis, but these abnormalities are not related to airflow limitation. Goblet cells not only increase in number but in extent through the bronchial tree. Bronchi also undergo squamous metaplasia, which not only predisposes to carcinogenesis but also disrupts mucociliary clearance. Although not as prominent as in asthma, patients may have smooth-muscle hypertrophy and bronchial hyperreactivity leading to airflow limitation. Neutrophil influx has been associated with purulent sputum of upper respiratory tract infections that hamper patients with COPD. Independent of its proteolytic activity, neutrophil elastase is among the most potent secretagogues identified.

SMALL AIRWAYS

The major site of increased resistance in most individuals with COPD is in airways ≤2 mm diameter. Characteristic cellular changes include goblet cell metaplasia and replacement of surfactant-secreting Clara cells with mucus-secreting and infiltrating mononuclear inflammatory cells. Smooth-muscle hypertrophy may also be present. These abnormalities may cause luminal narrowing by excess mucus, edema, and cellular infiltration. Reduced surfactant may increase surface tension at the air-tissue interface, predisposing to airway narrowing or collapse. Fibrosis in the wall may cause airway narrowing directly or, as in asthma, predispose to hyperreactivity. Respiratory bronchiolitis with mononuclear inflammatory cells collecting in distal airway tissues may cause proteolytic destruction of elastic fibers in the respiratory bronchioles and alveolar ducts where the fibers are concentrated as rings around alveolar entrances.

Because small airway patency is maintained by the surrounding lung parenchyma that provides radial traction on bronchioles at points of attachment to alveolar septa, loss of bronchiolar attachments as a result of extracellular matrix destruction may cause airway distortion and narrowing in COPD. Although the significance of alveolar attachments is not resolved, the concept of decreased alveolar attachments leading to small airway obstruction is appealing because it underscores the mechanistic relationship between loss of elastic recoil and increased resistance to airflow in small airways.

LUNG PARENCHYMA

Emphysema is characterized by destruction of gas-exchanging airspaces, i.e., the respiratory bronchioles, alveolar ducts, and alveoli. Their walls become perforated and later obliterated with coalescence of small distinct airspaces into abnormal and much larger airspaces. Macrophages accumulate in respiratory bronchioles of essentially all young smokers. Bronchoalveolar lavage fluid from such individuals contains roughly five times as many macrophages as lavage from nonsmokers. In smokers' lavage fluid, macrophages comprise >95% of the total cell count, and neutrophils, nearly absent in nonsmokers' lavage, account for 1–2% of the cells. T lymphocytes, particularly CD8+ cells, are also increased in the alveolar space of smokers.

Emphysema is classified into distinct pathologic types, the most important being centriacinar and panacinar. *Centriacinar emphysema*, the type most frequently associated with cigarette smoking, is characterized by enlarged airspaces found (initially) in association with respiratory bronchioles. Centriacinar emphysema is most prominent in the upper lobes and superior segments of lower lobes and is often quite focal. *Panacinar emphysema* refers to abnormally large airspaces evenly distributed within and across acinar units. Panacinar emphysema is usually observed in patients with α_1AT deficiency, which has a predilection for the lower lobes. Distinctions between centriacinar and panacinar emphysema are interesting and may ultimately be shown to have different mechanisms of pathogenesis. However, garden-variety smoking-related emphysema is usually mixed, particularly in advanced cases, and these pathologic classifications are not helpful in the care of patients with COPD.

PATHOGENESIS

Airflow limitation, the major physiologic change in COPD, can result from both small airway obstruction and emphysema, as discussed above. Pathologic findings that can contribute to small airway obstruction are described above, but their relative importance is unknown. Fibrosis surrounding the small airways appears to be a significant contributor. Mechanisms leading to collagen accumulation around the airways in the face of increased collagenase activity remain an enigma. Although seemingly counterintuitive, there are several potential mechanisms whereby a proteinase can predispose to fibrosis,

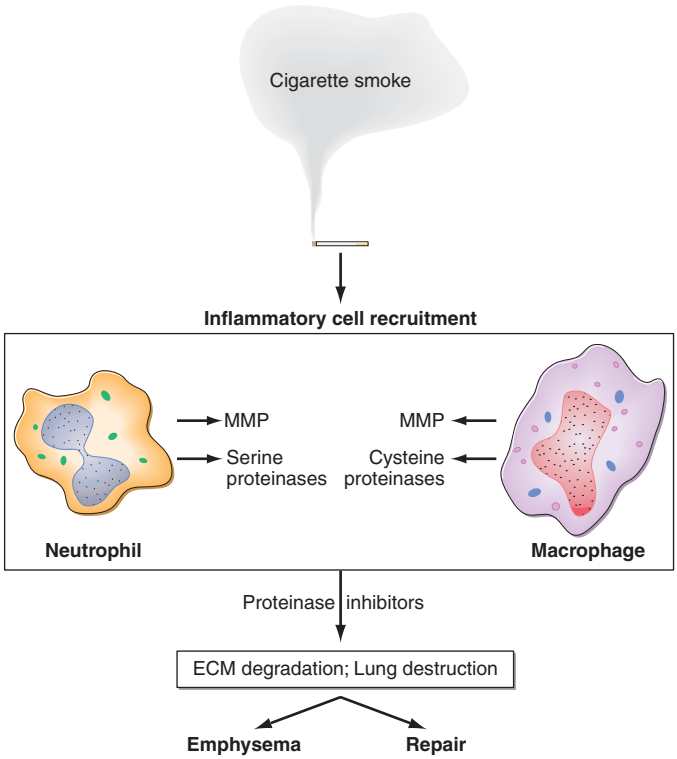

FIGURE 254-3 Pathogenesis of emphysema. Upon long-term exposure to cigarette smoke, inflammatory cells are recruited to the lung; they release proteinases in excess of inhibitors, and if repair is abnormal, this leads to airspace destruction and enlargement or emphysema.

including proteolytic activation of transforming growth factor β (TGF-β) and insulin-like growth factor (IGF) binding protein degradation releasing profibrotic IGF. Largely due to availability of suitable animal models, we know much more about mechanisms involved in emphysema than small airway obstruction.

The pathogenesis of emphysema can be dissected into four interrelated events (Fig. 254-3): (1) Chronic exposure to cigarette smoke may lead to inflammatory cell recruitment within the terminal airspaces of the lung. (2) These inflammatory cells release elastolytic proteinases which damage the extracellular matrix of the lung. (3) Loss of matrix-cell attachment leads to apoptosis of structural cells of the lung. (4) Ineffective repair of elastin and perhaps other extracellular matrix components result in airspace enlargement that defines pulmonary emphysema.

The Elastase:Antielastase Hypothesis Elastin, the principal component of elastic fibers, is a highly stable component of the extracellular matrix that is critical to the integrity of both the small airways and the lung parenchyma. The elastase:antielastase hypothesis proposed in the mid-1960s states that the balance of elastin-degrading enzymes and their inhibitors determines the susceptibility of the lung to destruction resulting in airspace enlargement. This hypothesis was based on the clinical observation that patients with genetic deficiency in α_1AT, the inhibitor of the serine proteinase neutrophil elastase, were at increased risk of emphysema, and that instillation of elastases, including neutrophil elastase, to experimental animals results in emphysema. To this day, the elastase:antielastase hypothesis is the prevailing mechanism for the development of emphysema. However, a complex network of inflammatory cells and additional proteinases that contribute to emphysema have subsequently been identified.

Inflammation and Extracellular Matrix Proteolysis Macrophages patrol the lower airspace under normal conditions. Upon exposure to oxidants from cigarette smoke, histone deacetylase-2 is inactivated, shifting the balance toward acetylated or loose chromatin, exposing nuclear factor κB sites and resulting in transcription of matrix metalloproteinase-9, proinflammatory cytokines interleukin 8 (IL-8), and tumor necrosis factor α (TNF-α); this leads to neutrophil recruitment. CD8+ T-cells are also recruited in response to cigarette smoke and release interferon inducible protein-10 (IP-10, CXCL-7) that in turn leads to macrophage production of macrophage elastase [matrix metalloproteinase-12 (MMP-12)]. Matrix metalloproteinases and serine proteinases, most notably neutrophil elastase, work together by degrading the inhibitor of the other, leading to lung destruction. Proteolytic cleavage products of elastin also serve as a macrophage chemokine, fueling this destructive positive feedback loop.

Concomitant cigarette smoke-induced loss of cilia in the airway epithelium predisposes to bacterial infection with neutrophilia. Surprisingly, in end-stage lung disease, long after smoking cessation there remains an exuberant inflammatory response, suggesting that mechanisms of cigarette smoke-induced inflammation that initiate the disease differ from mechanisms that sustain inflammation after smoking cessation.

Collagen turnover in COPD is complex. The three collagenases (MMP-1, MMP-8, and MMP-13) that initiate the cleavage of interstitial collagens are also induced in both inflammatory cells and structural cells in COPD. While collagen is disrupted as alveolar units are obliterated, overall there is a net increase in collagen content in the COPD lung, with prominent accumulation in the airway submucosa.

Cell Death Airspace enlargement with loss of alveolar units obviously requires disappearance of both extracellular matrix and cells. Traditional theories suggest that inflammatory cell proteinases degrade lung extracellular matrix as the primary event, with subsequent loss of cell anchoring leading to apoptosis. Animal models have used endothelial and epithelial cell death as a means to generate transient airspace enlargement. Whether apoptosis is a primary or secondary event in COPD remains to be determined.

Ineffective Repair The ability of the adult lung to repair damaged alveoli appears limited. Whether the process of septation that is responsible for alveogenesis during lung development can be reinitiated is not clear. In animal models, treatment with all-trans retinoic acid has resulted in some repair. Also, lung resection results in compensatory lung growth in the remaining lung in animal models. In addition to restoring cellularity following injury, it appears difficult for an adult to completely restore an appropriate extracellular matrix, particularly functional elastic fibers.

CLINICAL PRESENTATION

HISTORY

The three most common symptoms in COPD are cough, sputum production, and exertional dyspnea. Many patients have such symptoms for months or years before seeking medical attention. Although the development of airflow obstruction is a gradual process, many patients date the onset of their disease to an acute illness or exacerbation. A careful history, however, usually reveals the presence of symptoms prior to the acute exacerbation. The development of exertional dyspnea, often described as increased effort to breathe, heaviness, air hunger, or gasping, can be insidious. It is best elicited by a careful history focused on typical physical activities and how the patient's ability to perform them has changed. Activities involving significant arm work, particularly at or above shoulder level, are particularly difficult for patients with COPD. Conversely, activities that allow the patient to brace the arms and use accessory muscles of respiration are better tolerated. Examples of such activities include pushing a shopping cart, walking on a treadmill, or pushing a wheelchair. As COPD advances, the principal feature is worsening dyspnea on exertion with increasing intrusion on the ability to perform vocational or avocational activities. In the most advanced stages, patients are breathless doing simple activities of daily living.

Accompanying worsening airflow obstruction is an increased frequency of exacerbations (described below). Patients may also develop resting hypoxemia and require institution of supplemental oxygen.

TABLE 254-1 GOLD CRITERIA FOR COPD SEVERITY

GOLD Stage	Severity	Symptoms	Spirometry
0	At Risk	Chronic cough, sputum production	Normal
I	Mild	With or without chronic cough or sputum production	FEV_1/FVC <0.7 and FEV_1 ≥80% predicted
IIA	Moderate	With or without chronic cough or sputum production	FEV_1/FVC <0.7 and 50%≤ FEV_1 <80% predicted
III	Severe	With or without chronic cough or sputum production	FEV_1/FVC <0.7 and 30%≤ FEV_1 <50% predicted
IV	Very Severe	With or without chronic cough or sputum production	FEV_1/FVC <0.7 and FEV_1 <30% predicted *or* FEV_1 <50% predicted with respiratory failure or signs of right heart failure

Note: GOLD, Global Initiative for Chronic Obstructive Pulmonary Disease (COPD).

PHYSICAL FINDINGS

In the early stages of COPD, patients usually have an entirely normal physical examination. Current smokers may have signs of active smoking, including an odor of smoke or nicotine staining of fingernails. In patients with more severe disease, the physical examination is notable for a prolonged expiratory phase and expiratory wheezing. In addition, signs of hyperinflation include a barrel chest and enlarged lung volumes with poor diaphragmatic excursion as assessed by percussion. Patients with severe airflow obstruction may also exhibit use of accessory muscles of respiration, sitting in the characteristic "tripod" position to facilitate the actions of the sternocleidomastoid, scalene, and intercostal muscles. Patients may develop cyanosis, visible in the lips and nail beds.

Although traditional teaching is that patients with predominant emphysema, termed "pink puffers," are thin and noncyanotic at rest and have prominent use of accessory muscles, and patients with chronic bronchitis are more likely to be heavy and cyanotic ("blue bloaters"), current evidence demonstrates that most patients have elements of both bronchitis and emphysema and that the physical examination does not reliably differentiate the two entities.

Advanced disease may be accompanied by systemic wasting, with significant weight loss, bitemporal wasting, and diffuse loss of subcutaneous adipose tissue. This syndrome has been associated with both inadequate oral intake and elevated levels of inflammatory cytokines (TNF-α). Such wasting is an independent poor prognostic factor in COPD. Some patients with advanced disease have paradoxical inward movement of the rib cage with inspiration (Hoover's sign), the result of alteration of the vector of diaphragmatic contraction on the rib cage as a result of chronic hyperinflation.

Signs of overt right heart failure, termed *cor pulmonale*, are relatively infrequent since the advent of supplemental oxygen therapy.

Clubbing of the digits is not a sign of COPD, and its presence should alert the clinician to initiate an investigation for causes of clubbing. In this population, the development of lung cancer is the most likely explanation for newly developed clubbing.

LABORATORY FINDINGS

The hallmark of COPD is airflow obstruction (discussed above). Pulmonary function testing shows airflow obstruction with a reduction in FEV_1 and FEV_1/FVC (Chap. 246). With worsening disease severity, lung volumes may increase, resulting in an increase in total lung capacity, functional residual capacity, and residual volume. In patients with emphysema, the diffusing capacity may be reduced, reflecting the parenchymal destruction characteristic of the disease. The degree of airflow obstruction is an important prognostic factor in COPD and is the basis for the GOLD disease classification (Table 254-1). More recently it has been shown that a multifactorial index incorporating airflow obstruction, exercise performance, dyspnea, and body mass index is a better predictor of mortality than pulmonary function alone.

While arterial blood gases and oximetry are not sensitive (discussed above), they may demonstrate resting or exertional hypoxemia. Arterial blood gases provide additional information about alveolar ventilation and acid-base status by measuring arterial P_{CO_2} and pH. The change in pH with P_{CO_2} is 0.08 units/10 mmHg acutely and 0.03 units/10 mmHg in the chronic state. Knowledge of the arterial pH therefore allows the classification of ventilatory failure, defined as P_{CO_2} >45 mmHg, into acute or chronic conditions. The arterial blood gas is an important component of the evaluation of patients presenting with symptoms of an exacerbation. An elevated hematocrit suggests the presence of chronic hypoxemia, as does the presence of signs of right ventricular hypertrophy.

Radiographic studies may assist in the classification of the type of COPD. Obvious bullae, paucity of parenchymal markings, or hyperlucency suggest the presence of emphysema. Increased lung volumes and flattening of the diaphragm suggest hyperinflation but do not provide information about chronicity of the changes. Computed tomography (CT) scan is the current definitive test for establishing the presence or absence of emphysema in living subjects (Fig. 254-4). From a practical perspective, the CT scan does little to influence therapy of COPD except in those individuals considering surgical therapy for their disease (described below).

Recent guidelines have suggested testing for α_1AT deficiency in all subjects with COPD or asthma with chronic airflow obstruction. Measurement of the serum α_1AT level is a reasonable initial test. For subjects with low α_1AT levels, the definitive diagnosis of α_1AT deficiency requires PI type determination. This is typically performed by isoelectric focusing of serum, which reflects the genotype at the PI locus for the common alleles and many of the rare PI alleles as well. Molecular genotyping of DNA can be performed for the common PI alleles (M, S, and Z).

FIGURE 254-4 Chest CT scan of a patient with COPD who underwent a left single-lung transplant. Note the reduced parenchymal markings in the right lung (*left side of figure*) as compared to the left lung, representing emphysematous destruction of the lung, and mediastinal shift to the left, indicative of hyperinflation.

Rx CHRONIC OBSTRUCTIVE PULMONARY DISEASE

STABLE PHASE COPD Only three interventions—smoking cessation, oxygen therapy in chronically hypoxemic patients, and lung volume reduction surgery in selected patients with emphysema—have been demonstrated to influence the natural history of patients with COPD. There is currently suggestive, but not definitive, evidence that the use of inhaled glucocorticoids may alter mortality (but not lung function). All other current therapies are directed at improving symptoms and decreasing the frequency and severity of exacerbations. The institution of these therapies should involve an assessment of symptoms, potential risks, costs, and benefits of therapy. This should be followed by an assessment of response to therapy, and a decision should be made whether or not to continue treatment.

PHARMACOTHERAPY Smoking Cessation (See also Chap. 390) It has been shown that middle-aged smokers who were able to successfully stop smoking experienced a significant improvement in the rate of decline in pulmonary function, returning to annual changes similar to that of nonsmoking patients. Thus, all patients with COPD should be strongly urged to quit and educated about the benefits of quitting. An emerging body of evidence demonstrates that combining pharmacotherapy with traditional supportive approaches considerably enhances the chances of successful smoking cessation. There are two principal pharmacologic approaches to the problem: bupropion, originally developed as an antidepressant medication, and nicotine replacement therapy. The latter is available as gum, transdermal patches, inhaler, and nasal spray. Current recommendations from the U.S. Surgeon General are that all adult, nonpregnant smokers considering quitting be offered pharmacotherapy, in the absence of any contraindication to treatment.

Bronchodilators In general, bronchodilators are used for symptomatic benefit in patients with COPD. The inhaled route is preferred for medication delivery as the incidence of side effects is lower than that seen with the use of parenteral medication delivery.

Anticholinergic Agents While regular use of ipratopium bromide does not appear to influence the rate of decline of lung function, it improves symptoms and produces acute improvement in FEV_1. Tiotropium, a long-acting anticholinergic, has been shown to improve symptoms and reduce exacerbations. Side effects are minor, and a trial of inhaled anticholinergics is recommended in symptomatic patients with COPD.

Beta Agonists These provide symptomatic benefit. The main side effects are tremor and tachycardia. Long-acting inhaled β agonists, such as salmeterol, have benefits comparable to ipratopium bromide. Their use is more convenient than short-acting agents. The addition of a β agonist to inhaled anticholinergic therapy has been demonstrated to provide incremental benefit. A recent report in asthma suggests that those patients, particularly African Americans, using a long-acting β agonist without concomitant inhaled corticosteroids have an increased risk of deaths from respiratory causes. The applicability of these data to patients with COPD is unclear.

Inhaled Glucocorticoids Several trials have failed to find a beneficial effect for the regular use of inhaled glucocorticoids on the rate of decline of lung function, as assessed by FEV_1. Patients studied included those with mild to severe airflow obstruction and current and ex-smokers. Patients with significant acute response to inhaled β agonists were excluded from these trials. Their use has been associated with increased rates of oropharyngeal candidiasis and an increased rate of loss of bone density. Some analyses suggest that inhaled glucocorticoids reduce exacerbation frequency by ~25%. A more recent meta-analysis suggests that they may also reduce mortality by ~25%. A definitive conclusion regarding the mortality benefits awaits the results of ongoing prospective trials. A trial of inhaled glucocorticoids should be considered in patients with frequent exacerbations, defined as two or more per year, and in patients who demonstrate a significant amount of acute reversibility in response to inhaled bronchodilators.

Oral Glucocorticoids The chronic use of oral glucocorticoids for treatment of COPD is not recommended because of an unfavorable benefit/risk ratio. The chronic use of oral glucocorticoids is associated with significant side effects, including osteoporosis, weight gain, cataracts, glucose intolerance, and increased risk of infection. A recent study demonstrated that patients tapered off chronic low-dose prednisone (~10 mg/d) did not experience any adverse effect on the frequency of exacerbations, health-related quality of life, or lung function. On average, patients lost ~4.5 kg (~10 lb) when steroids were withdrawn.

Theophylline Theophylline produces modest improvements in expiratory flow rates and vital capacity and a slight improvement in arterial oxygen and carbon dioxide levels in patients with moderate to severe COPD. Nausea is a common side effect; tachycardia and tremor have also been reported.

Oxygen Supplemental O_2 is the only pharmacologic therapy demonstrated to decrease mortality in patients with COPD. For patients with resting hypoxemia (resting O_2 saturation <88% or <90% with signs of pulmonary hypertension or right heart failure), the use of O_2 has been demonstrated to have a significant impact on mortality. Patients meeting these criteria should be on continual oxygen supplementation, as the mortality benefit is proportional to the number of hours/day oxygen is used. Various delivery systems are available, including portable systems that patients may carry to allow mobility outside the home.

Supplemental O_2 is commonly prescribed for patients with exertional hypoxemia or nocturnal hypoxemia. Although the rationale for supplemental O_2 in these settings is physiologically sound, the benefits of such therapy are not well substantiated.

Other Agents *N*-acetyl cysteine has been used in patients with COPD for both its mucolytic and antioxidant properties. A prospective trial failed to find any benefit with respect to decline in lung function or prevention of exacerbations. Specific treatment in the form of intravenous α_1AT augmentation therapy is available for individuals with severe α_1AT deficiency. Despite sterilization procedures for these blood-derived products and the absence of reported cases of viral infection from therapy, some physicians recommend hepatitis B vaccination prior to starting augmentation therapy. Although biochemical efficacy of α_1AT augmentation therapy has been shown, a randomized controlled trial of α_1AT augmentation therapy has never proven the efficacy of augmentation therapy in reducing decline of pulmonary function. Eligibility for α_1AT augmentation therapy requires a serum α_1AT level <11 μM (approximately 50 mg/dL). Typically, Pi^Z individuals will qualify, although other rare types associated with severe deficiency (e.g., null-null) are also eligible. Since only a fraction of individuals with severe α_1AT deficiency will develop COPD, α_1AT augmentation therapy is not recommended for severely α_1AT-deficient persons with normal pulmonary function and a normal chest CT scan.

NONPHARMACOLOGIC THERAPIES General Medical Care Patients with COPD should receive the influenza vaccine annually. Polyvalent pneumococcal vaccine is also recommended, although proof of efficacy in this patient population is not definitive.

Pulmonary Rehabilitation This refers to a treatment program that incorporates education and cardiovascular conditioning. In COPD, pulmonary rehabilitation has been demonstrated to improve health-related quality of life, dyspnea, and exercise capacity. It has also been shown to reduce rates of hospitalization over a 6–12-month period.

Lung Volume Reduction Surgery (LVRS) Surgery to reduce the volume of lung in patients with emphysema was first introduced with minimal success in the 1950s and was reintroduced in the 1990s. The operation may be performed via either a median sternotomy or a thoracoscopic approach. Patients are excluded if they have significant pleural disease, a pulmonary artery systolic pressure >45 mmHg, extreme deconditioning, congestive heart failure, or other severe comorbid conditions. Recent data demonstrate that patients with an FEV_1 <20% of predicted and either diffusely distributed emphysema on CT scan or DL_{CO} <20% of predicted have an increased mortality after the procedure and thus are not candidates for LVRS.

The National Emphysema Treatment trial demonstrated that LVRS offers both a mortality benefit and a symptomatic benefit in certain patients with emphysema. The anatomic distribution of emphysema and postrehabilitation exercise capacity are important prognostic characteristics. Patients with upper lobe–predominant emphysema and a low postrehabilitation exercise capacity are most likely to benefit from LVRS.

Lung Transplantation (See also Chap. 260) COPD is the single leading indication for lung transplantation (Fig. 254-4). Current recommendations are that candidates for lung transplantation should be <65 years; have severe disability despite maximal medical therapy; and be free of comorbid conditions such as liver, renal, or cardiac disease. In contrast to

LVRS, the anatomic distribution of emphysema and the presence of pulmonary hypertension are not contraindications to lung transplantation. Unresolved issues concerning lung transplantation and COPD include whether single- or double-lung transplant is the preferred procedure.

EXACERBATIONS OF COPD Exacerbations are a prominent feature of the natural history of COPD. Exacerbations are commonly considered to be episodes of increased dyspnea and cough and change in the amount and character of sputum. They may or may not be accompanied by other signs of illness, including fever, myalgias, and sore throat. Self-reported health-related quality of life correlates with frequency of exacerbations more closely than it does with the degree of airflow obstruction. Economic analyses have shown that >70% of COPD-related health care expenditures go to emergency department visits and hospital care; this translates to >$10 billion annually in the United States. The frequency of exacerbations increases as airflow obstruction increases; patients with moderate to severe airflow obstruction [GOLD stages III,IV (Table 254-1)] have 1–3 episodes per year.

The approach to the patient experiencing an exacerbation includes an assessment of the severity of the patient's illness, both acute and chronic components; an attempt to identify the precipitant of the exacerbation; and the institution of therapy.

Precipitating Causes and Strategies to Reduce Frequency of Exacerbations A variety of stimuli may result in the final common pathway of airway inflammation and increased symptoms that are characteristic of COPD exacerbations. Bacterial infections play a role in many, but by no means all, episodes. Viral respiratory infections are present in approximately one-third of COPD exacerbations. In a significant minority of instances (20–35%), no specific precipitant can be identified.

Despite the frequent implication of bacterial infection, chronic suppressive or "rotating" antibiotics are not beneficial in patients with COPD. This is in contrast to their apparent efficacy in patients with significant bronchiectasis. In patients with bronchiectasis due to cystic fibrosis, suppressive antibiotics have been shown to reduce frequency of hospital admissions.

The role of anti-inflammatory therapy in reducing exacerbation frequency is less well studied. Chronic oral glucocorticoids are not recommended for this purpose. Inhaled glucocorticoids did reduce the frequency of exacerbations by 25–30% in some analyses. The use of inhaled glucocorticoids should be considered in patients with frequent exacerbations or those who have an asthmatic component, i.e., significant reversibility on pulmonary function testing or marked symptomatic improvement after inhaled bronchodilators.

Patient Assessment An attempt should be made to establish the severity of the exacerbation as well as the severity of preexisting COPD. The more severe either of these two components, the more likely that the patient will require hospital admission. The history should include quantification of the degree of dyspnea by asking about breathlessness during activities of daily living and typical activities for the patient. The patient should be asked about fever; change in character of sputum; any ill contacts; and associated symptoms such as nausea, vomiting, diarrhea, myalgias, and chills. Inquiring about the frequency and severity of prior exacerbations can provide important information.

The physical examination should incorporate an assessment of the degree of distress of the patient. Specific attention should be focused on tachycardia, tachypnea, use of accessory muscles, signs of perioral or peripheral cyanosis, the ability to speak in complete sentences, and the patient's mental status. The chest examination should establish the presence or absence of focal findings, degree of air movement, presence or absence of wheezing, asymmetry in the chest examination (suggesting large airway obstruction or pneumothorax mimicking an exacerbation), and the presence or absence of paradoxical motion of the abdominal wall.

Patients with severe underlying COPD who are in moderate or severe distress or those with focal findings should have a chest x-ray. Approximately 25% of x-rays in this clinical situation will be abnormal, with the most frequent findings being pneumonia and congestive heart failure. Patients with advanced COPD, those with a history of hypercarbia, those with mental status changes (confusion, sleepiness), or those in significant distress should have an arterial blood gas measurement. The presence of hypercarbia, defined as a P_{CO_2} >45 mmHg, has important implications for treatment (discussed below). In contrast to its utility in the management of exacerbations of asthma, measurement of pulmonary function has not been demonstrated to be helpful in the diagnosis or management of exacerbations of COPD.

There are no definitive guidelines concerning the need for inpatient treatment of exacerbations. Patients with respiratory acidosis and hypercarbia, significant hypoxemia, or severe underlying disease or those whose living situation is not conducive to careful observation and the delivery of prescribed treatment should be admitted to the hospital.

ACUTE EXACERBATIONS **Bronchodilators** Typically, patients are treated with an inhaled β agonist, often with the addition of an anticholinergic agent. These may be administered separately or together, and the frequency of administration depends on the severity of the exacerbation. Patients are often treated initially with nebulized therapy, as such treatment is often easier to administer in older patients or to those in respiratory distress. It has been shown, however, that conversion to metered-dose inhalers is effective when accompanied by education and training of patients and staff. This approach has significant economic benefits and also allows an easier transition to outpatient care. The addition of methylxanthines (such as theophylline) to this regimen can be considered, although convincing proof of its efficacy is lacking. If added, serum levels should be monitored in an attempt to minimize toxicity.

Antibiotics Patients with COPD are frequently colonized with potential respiratory pathogens and it is often difficult to identify conclusively a specific species of bacteria responsible for a particular clinical event. Bacteria frequently implicated in COPD exacerbations include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. In addition, *Mycoplasma pneumoniae* or *Chlamydia pneumoniae* are found in 5–10% of exacerbations. The choice of antibiotic should be based on local patterns of antibiotic susceptibility of the above pathogens as well as the patient's clinical condition. Most practitioners treat patients with moderate or severe exacerbations with antibiotics, even in the absence of data implicating a specific pathogen.

Glucocorticoids Among patients admitted to the hospital, the use of glucocorticoids has been demonstrated to reduce the length of stay, hasten recovery, and reduce the chance of subsequent exacerbation or relapse for a period of up to 6 months. One study demonstrated that 2 weeks of glucocorticoid therapy produced benefit indistinguishable from 8 weeks of therapy. The GOLD guidelines recommend 30–40 mg of oral prednisolone or its equivalent for a period of 10–14 days. Hyperglycemia, particularly in patients with preexisting diagnosis of diabetes, is the most frequently reported acute complication of glucocorticoid treatment.

Oxygen Supplemental O_2 should be supplied to keep arterial saturations ≥90%. Hypoxic respiratory drive plays a small role in patients with COPD. Studies have demonstrated that in patients with both acute and chronic hypercarbia, the administration of supplemental O_2 does not reduce minute ventilation. It does, in some patients, result in modest increases in arterial P_{CO_2}, chiefly by altering ventilation-perfusion relationships within the lung. This should not deter practitioners from providing the oxygen needed to correct hypoxemia.

Mechanical Ventilatory Support The initiation of noninvasive positive pressure ventilation (NIPPV) in patients with respiratory failure, defined as Pa_{CO_2} >45 mmHg, results in a significant reduction in mortality, need for intubation, complications of therapy, and hospital length of stay. Contraindications to NIPPV include cardiovascular instability, impaired mental status or inability to cooperate, copious secretions or the inability to clear secretions, craniofacial abnormalities or trauma precluding effective fitting of mask, extreme obesity, or significant burns.

Invasive (conventional) mechanical ventilation via an endotracheal tube is indicated for patients with severe respiratory distress despite initial therapy, life-threatening hypoxemia, severe hypercapnia and/or acidosis, markedly impaired mental status, respiratory arrest, hemodynamic instability, or other complications. The goal of mechanical ventilation is to correct the aforementioned conditions. Factors to consider during mechanical ventilatory support include the need to provide sufficient expiratory time in patients with severe airflow obstruction and the presence of auto-PEEP (positive end-expiratory pressure) which can result in patients having to generate significant respiratory effort to trigger a breath during a demand mode of ventilation. The mortality of patients requiring mechanical ventilatory support is 17–30% for that particular hospitalization. For patients age >65 admitted to the intensive care unit for treatment, the mortality

doubles over the next year to 60%, regardless of whether mechanical ventilation was required.

255 Interstitial Lung Diseases

Talmadge E. King, Jr.

Patients with interstitial lung diseases (ILDs) come to medical attention mainly because of the onset of progressive exertional dyspnea or a persistent, nonproductive cough. Hemoptysis, wheezing, and chest pain may be present. Often, the identification of interstitial opacities on chest x-ray focuses the diagnostic approach toward one of the ILDs.

ILDs represent a large number of conditions that involve the parenchyma of the lung—the alveoli, the alveolar epithelium, the capillary endothelium, and the spaces between these structures, as well as the perivascular and lymphatic tissues. This heterogeneous group of disorders is classified together because of similar clinical, roentgenographic, physiologic, or pathologic manifestations. These disorders are often associated with considerable morbidity and mortality, and there is little consensus regarding the best management of most of them.

ILDs have been difficult to classify because > 200 known individual diseases are characterized by diffuse parenchymal lung involvement, either as the primary condition or as a significant part of a multiorgan process, as may occur in the connective tissue diseases (CTDs). One useful approach to classification is to separate the ILDs into two groups based on the major underlying histopathology: (1) those associated with predominant inflammation and fibrosis, and (2) those with a predominantly granulomatous reaction in interstitial or vascular areas (Table 255-1). Each of these groups can be further subdivided according to whether the cause is known or unknown. For each ILD there may be an acute phase, and there is usually a chronic one as well. Rarely, some are recurrent, with intervals of subclinical disease.

Sarcoidosis (Chap. 322), idiopathic pulmonary fibrosis (IPF), and pulmonary fibrosis associated with CTDs (Chaps. 313–319) are the most common ILDs of unknown etiology. Among the ILDs of known cause, the largest group comprises occupational and environmental exposures, especially the inhalation of inorganic dusts, organic dusts, and various fumes or gases (Chaps. 249 and 250) (Table 255-2). A clinical diagnosis is possible for many forms of ILD, especially if an occupational and environmental history is aggressively pursued. For other forms, tissue examination, usually obtained by thoracoscopic lung biopsy, is critical to confirmation of the diagnosis. High-resolution computed tomography (HRCT) scanning improves diagnostic accuracy as experience with histologic-image correlation is perfected.

PATHOGENESIS

The ILDs are nonmalignant disorders and are not caused by identified infectious agents. The precise pathway(s) leading from injury to fibrosis is not known. Although there are multiple initiating agent(s) of in-

TABLE 255-1 MAJOR CATEGORIES OF ALVEOLAR AND INTERSTITIAL INFLAMMATORY LUNG DISEASE

Lung Response: Alveolitis, Interstitial Inflammation, and Fibrosis	
Known Cause	
Asbestos	Radiation
Fumes, gases	Aspiration pneumonia
Drugs (antibiotics, amiodarone, gold) and chemotherapy drugs	Residual of adult respiratory distress syndrome
Unknown Cause	
Idiopathic interstitial pneumonias	Pulmonary alveolar proteinosis
Idiopathic pulmonary fibrosis (usual interstitial pneumonia)	Lymphocytic infiltrative disorders (lymphocytic interstitial pneumonitis associated with connective tissue disease)
Desquamative interstitial pneumonia	Eosinophilic pneumonias
Respiratory bronchiolitis-associated interstitial lung disease	Lymphangioleiomyomatosis
Acute interstitial pneumonia (diffuse alveolar damage)	Amyloidosis
Cryptogenic organizing pneumonia (bronchiolitis obliterans with organizing pneumonia)	Inherited diseases
Nonspecific interstitial pneumonia	Tuberous sclerosis, neurofibromatosis, Niemann-Pick disease, Gaucher's disease, Hermansky-Pudlak syndrome
Connective tissue diseases	Gastrointestinal or liver diseases (Crohn's disease, primary biliary cirrhosis, chronic active hepatitis, ulcerative colitis)
Systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, systemic sclerosis, Sjögren's syndrome, polymyositis-dermatomyositis	Graft-vs.-host disease (bone marrow transplantation; solid organ transplantation)
Pulmonary hemorrhage syndromes	
Goodpasture's syndrome, idiopathic pulmonary hemosiderosis, isolated pulmonary capillaritis	
Lung Response: Granulomatous	
Known Cause	
Hypersensitivity pneumonitis (organic dusts)	Inorganic dusts: beryllium, silica
Unknown Cause	
Sarcoidosis	Bronchocentric granulomatosis
Langerhans' cell granulomatosis (eosinophilic granuloma of the lung)	Lymphomatoid granulomatosis
Granulomatous vasculitides	
Wegener's granulomatosis, allergic granulomatosis of Churg-Strauss	

TABLE 255-2 ESTIMATED RELATIVE FREQUENCY OF THE INTERSTITIAL LUNG DISEASES

Diagnosis	Relative Frequency, %
Idiopathic interstitial pneumonias	40
Idiopathic pulmonary fibrosis	55
Nonspecific interstitial pneumonia	25
Respiratory bronchiolitis—ILD and desquamative interstitial pneumonia	15
Cryptogenic organizing pneumonia	3
Acute interstitial pneumonia	<1
Occupational and environmental	26
Sarcoidosis	10
Connective tissue diseases	9
Drug and radiation	1
Pulmonary hemorrhage syndromes	<1
Other	13

jury, the immunopathogenic responses of lung tissue are limited, and the mechanisms of repair have common features (Fig. 255-1).

As mentioned above, the two major histopathologic patterns are a granulomatous pattern and a pattern in which inflammation and fibrosis predominate.

Granulomatous Lung Disease This process is characterized by an accumulation of T lymphocytes, macrophages, and epithelioid cells organized into discrete structures (granulomas) in the lung parenchyma. The granulomatous lesions can progress to fibrosis. Many patients with granulomatous lung disease remain free of severe impairment of lung function, or, when symptomatic, they improve after treatment. The main differential diagnosis is between sarcoidosis (Chap. 322) and hypersensitivity pneumonitis (Chap. 249).

Inflammation and Fibrosis The initial insult is an injury to the epithelial surface causing inflammation in the air spaces and alveolar walls (Fig. 255-2). If the disease becomes chronic, inflammation spreads to adjacent portions of the interstitium and vasculature and eventually causes interstitial fibrosis. Important histopathologic patterns found in the ILDs include: usual interstitial pneumonia (UIP), nonspecific interstitial pneumonia, respiratory bronchiolitis, organizing pneumonia [bronchiolitis obliterans with organizing pneumonia (BOOP) pattern], diffuse alveolar damage (acute or organizing), desquamative interstitial pneumonia, and lymphocytic interstitial pneumonia. The development of irreversible scarring (fibrosis) of alveolar walls, airways, or vasculature is the most feared outcome in all of these conditions because it is often progressive and leads to significant derangement of ventilatory function and gas exchange.

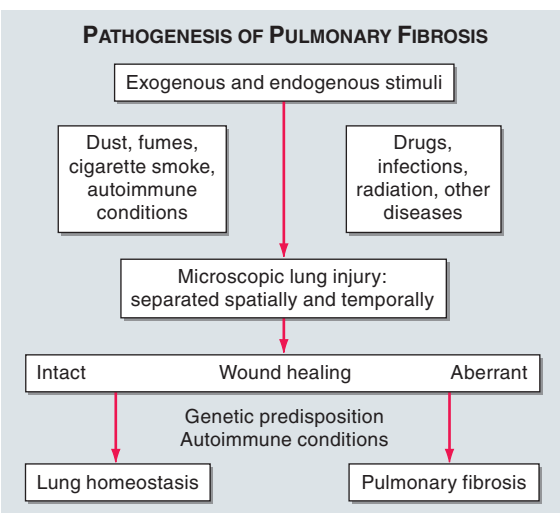

FIGURE 255-1 Proposed mechanism for the pathogenesis of pulmonary fibrosis. The lung is naturally exposed to repetitive injury from a variety of exogenous and endogenous stimuli. Several local and systemic factors (e.g., fibroblasts, circulating fibrocytes, chemokines, growth factors, and clotting factors) contribute to tissue healing and functional recovery. Dysregulation of this intricate network through genetic predisposition, autoimmune conditions, or superimposed diseases can lead to aberrant wound healing with the result of pulmonary fibrosis. Alternatively, excessive injury to the lung may overwhelm even intact reparative mechanisms and lead to pulmonary fibrosis. *(From S Garantziotis, et al: J Clin Invest 114:319, 2004.)*

History • ***DURATION OF ILLNESS*** *Acute presentation* (days to weeks), while unusual, occurs with allergy (drugs, fungi, helminths), acute interstitial pneumonia (AIP), eosinophilic pneumonia, and hypersensitivity pneumonitis. These conditions may be confused with atypical pneumonias because of diffuse alveolar opacities on chest x-ray. *Subacute presentation* (weeks to months) may occur in all ILDs but is seen especially in sarcoidosis, drug-induced ILDs, the alveolar hemorrhage syndromes, cryptogenic organizing pneumonia (COP), and the acute immunologic pneumonia that complicates systemic lupus erythematosus (SLE) or polymyositis. In most ILDs the symptoms and signs form a *chronic presentation* (months to years). Examples include IPF, sarcoidosis, pulmonary Langerhans cell histiocytosis (PLCH) (also known as Langerhans cell granulomatosis, eosinophilic granuloma, or histiocytosis X), pneumoconioses, and CTDs. *Episodic presentations* are unusual and include eosinophilic pneumonia, hypersensitivity pneumonitis, COP, vasculitides, pulmonary hemorrhage, and Churg-Strauss syndrome.

AGE Most patients with sarcoidosis, ILD associated with CTD, lymphangioleiomyomatosis (LAM), PLCH, and inherited forms of ILD (familial IPF, Gaucher's disease, Hermansky-Pudlak syndrome) present between the ages of 20 and 40 years. Most patients with IPF are older than 50 years.

GENDER LAM and pulmonary involvement in tuberous sclerosis occur exclusively in premenopausal women. Also, ILD in Hermansky-Pudlak syndrome and in the CTDs is more common in women; an exception is ILD in rheumatoid arthritis (RA), which is more common in men. Because of occupational exposures, pneumoconioses also occur more frequently in men.

FAMILY HISTORY Family associations (with an autosomal dominant pattern) have been identified in tuberous sclerosis and neurofibromatosis. An autosomal recessive pattern of inheritance occurs in Niemann-Pick disease, Gaucher's disease, and the Hermansky-Pudlak syndrome. Familial clustering has been increasingly identified in sarcoidosis. Familial lung fibrosis has been associated with mutations in the surfactant protein C gene and is characterized by several patterns of interstitial pneumonia, including nonspecific interstitial pneumonia, desquamative interstitial pneumonia, and UIP.

SMOKING HISTORY Two-thirds to 75% of patients with IPF have a history of smoking. Patients with PLCH, desquamative interstitial pneumonia (DIP), Goodpasture's syndrome, respiratory bronchiolitis, and pulmonary alveolar proteinosis are almost always current or former smokers.

OCCUPATION AND ENVIRONMENTAL HISTORY A strict chronologic listing of the patient's lifelong employment must be sought, including specific duties and known exposures. In hypersensitivity pneumonitis (see Fig. 249-1), respiratory symptoms, fever, chills, and an abnormal chest roentgenogram are often temporally related to a hobby (pigeon breeder's disease) or to the workplace (farmer's lung) (Chap. 249). Symptoms may diminish or disappear after the patient leaves the site of exposure for several days; similarly, symptoms may reappear on returning to the exposure site.

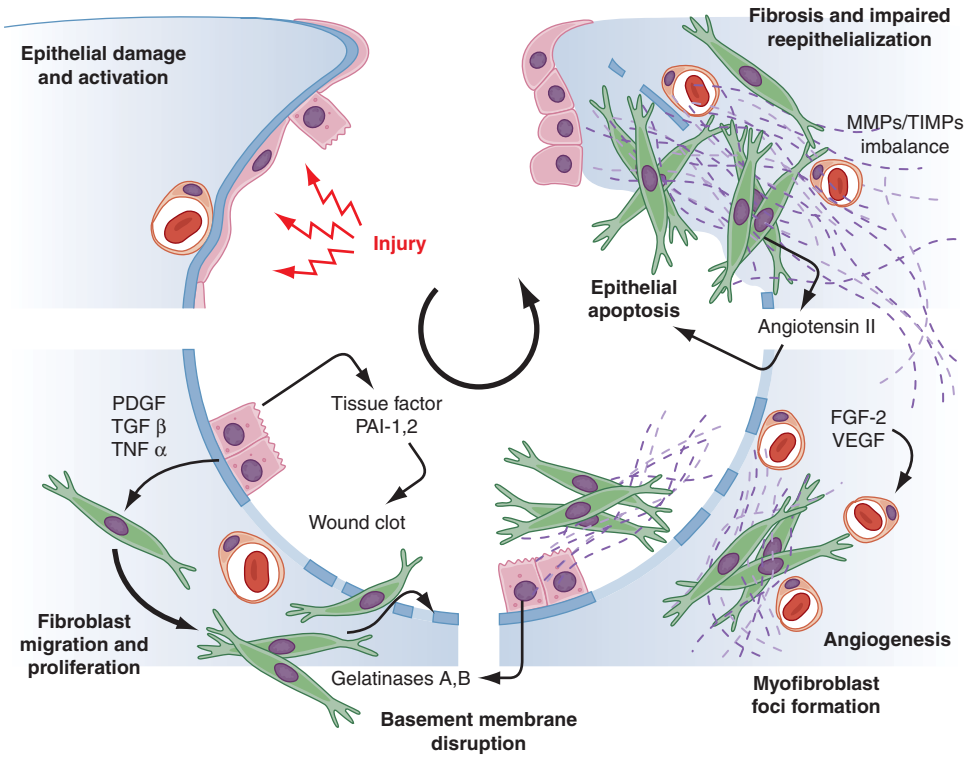

FIGURE 255-2 Cellular bases for the pathogenesis of interstitial lung disease. Multiple microinjuries damage and activate alveolar epithelial cells (*top left*), which in turn induce an antifibrinolytic environment in the alveolar spaces, enhancing wound clot formation. Alveolar epithelial cells secrete growth factors and induce migration and proliferation of fibroblasts and differentiation into myofibroblasts (*bottom left*). Subepithelial myofibroblasts and alveolar epithelial cells produce gelatinases that may increase basement membrane disruption and allow fibroblast–myofibroblast migration (*bottom right*). Angiogenic factors induce neovascularization. Both intraalveolar and interstitial myofibroblasts secrete extracellular matrix proteins, mainly collagens. An imbalance between interstitial collagenases and tissue inhibitors of metalloproteinases provokes the progressive deposit of extracellular matrix (*top right*). Signals responsible for myofibroblast apoptosis seem to be absent or delayed in usual interstitial pneumonia, increasing cell survival. Myofibroblasts produce angiotensinogen that as angiotensin II provokes alveolar epithelial cell death, further impairing reepithelialization. Abbreviations: FGF-2, fibroblast growth factor 2; MMPs, metalloproteinases; PAI-1, PAI-2, plasminogen activator inhibitor 1, 2; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor β; TIMPs, tissue inhibitors of metalloproteinases; TNF-α, tumor necrosis factor α; VEGF, vascular endothelial growth factor. *(From M Selman et al: Ann Intern Med 134:136, 2001; with permission.)*

OTHER IMPORTANT PAST HISTORY Parasitic infections may cause pulmonary eosinophilia, and therefore a travel history should be taken in patients with known or suspected ILD. History of risk factors for HIV infection should be elicited from all patients with ILD because several processes may occur at the time of initial presentation or during the clinical course, e.g., HIV infection, BOOP, AIP, lymphocytic interstitial pneumonitis, or diffuse alveolar hemorrhage.

RESPIRATORY SYMPTOMS AND SIGNS

Dyspnea is a common and prominent complaint in patients with ILD, especially the idiopathic interstitial pneumonias, hypersensitivity pneumonitis, COP, sarcoidosis, eosinophilic pneumonias, and PLCH. Some patients, especially patients with sarcoidosis, silicosis, PLCH, hypersensitivity pneumonitis, lipoid pneumonia, or lymphangitis carcinomatosis, may have extensive parenchymal lung disease on chest x-ray without significant dyspnea, especially early in the course of the illness. Wheezing is an uncommon manifestation of ILD but has been described in patients with chronic eosinophilic pneumonia, Churg-Strauss syndrome, respiratory bronchiolitis, and sarcoidosis. Clinically significant chest pain is uncommon in most ILDs. However, substernal discomfort is common in sarcoidosis. Sudden worsening of dyspnea, especially if associated with acute chest pain, may indicate a spontaneous pneumothorax, which occurs in PLCH, tuberous sclerosis, LAM, and neurofibromatosis. Frank hemoptysis and blood-streaked sputum are rarely presenting manifestations of ILD but can be seen in the diffuse alveolar hemorrhage (DAH) syndromes, LAM, tuberous sclerosis, and the granulomatous vasculitides. Fatigue and weight loss are common in all ILDs.

PHYSICAL EXAMINATION

The findings are usually not specific. Most commonly, physical examination reveals tachypnea and bibasilar end-inspiratory dry crackles, which are common in most forms of ILD associated with inflammation but are less likely to be heard in the granulomatous lung diseases. Crackles may be present in the absence of radiographic abnormalities on the chest radiograph. Scattered late inspiratory high-pitched rhonchi—so-called inspiratory squeaks—are heard in patients with bronchiolitis. The cardiac examination is usually normal except in the mid or late stages of the disease, when findings of pulmonary hypertension and cor pulmonale may become evident (Chap. 244). Cyanosis and clubbing of the digits occur in some patients with advanced disease.

LABORATORY

Antinuclear antibodies and anti-immunoglobulin antibodies (rheumatoid factors) are identified in some patients, even in the absence of a defined CTD. A raised lactate dehydrogenase (LDH) level is a nonspecific finding common to ILDs. Elevation of the serum angiotensin-converting enzyme level is common in sarcoidosis. Serum precipitins confirm exposure when hypersensitivity pneumonitis is suspected, although they are not diagnostic of the process. Antineutrophil cytoplasmic or anti-basement membrane antibodies are useful if vasculitis is suspected. The electrocardiogram is usually normal unless pulmonary hypertension is present; then it demonstrates right-axis deviation, right ventricular hypertrophy, or right atrial enlargement or hypertrophy. Echocardiography also reveals right ventricular dilatation and/or hypertrophy in the presence of pulmonary hypertension.

CHEST IMAGING STUDIES

Chest X-ray ILD may be first suspected based on an abnormal chest radiograph, which most commonly reveals a bibasilar reticular pattern. A nodular or mixed pattern of alveolar filling and increased reticular markings may also be present. A subgroup of ILDs exhibit nodular opacities with a predilection for the upper lung zones [sarcoidosis, PLCH, chronic hypersensitivity pneumonitis, silicosis, berylliosis, RA (necrobiotic nodular form), ankylosing spondylitis]. The chest x-ray correlates poorly with the clinical or histopathologic stage of the disease. The radiographic finding of honeycombing correlates with pathologic findings of small cystic spaces and progressive fibrosis; when present, it portends a poor prognosis. In most cases, the chest radiograph is nonspecific and usually does not allow a specific diagnosis.

Computed Tomography High-resolution computed tomography (HRCT) is superior to the plain chest x-ray for early detection and confirma-

FIGURE 255-3 Idiopathic pulmonary fibrosis. High-resolution CT image shows bibasal, peripheral predominant reticular abnormality with traction bronchiectasis and honeycombing. The lung biopsy showed the typical features of usual interstitial pneumonia.

tion of suspected ILD (Fig. 255-3). Also, HRCT allows better assessment of the extent and distribution of disease, and it is especially useful in the investigation of patients with a normal chest radiograph. Coexisting disease is often best recognized on HRCT scanning, e.g., mediastinal adenopathy, carcinoma, or emphysema. In the appropriate clinical setting HRCT may be sufficiently characteristic to preclude the need for lung biopsy in IPF, sarcoidosis, hypersensitivity pneumonitis, asbestosis, lymphangitic carcinoma, and PLCH. When a lung biopsy is required, HRCT scanning is useful for determining the most appropriate area from which biopsy samples should be taken.

PULMONARY FUNCTION TESTING

Spirometry and Lung Volumes Measurement of lung function is important in assessing the extent of pulmonary involvement in patients with ILD. Most forms of ILD produce a restrictive defect with reduced total lung capacity (TLC), functional residual capacity, and residual volume (Chap. 246). Forced expiratory volume in one second (FEV_1) and forced vital capacity (FVC) are reduced, but these changes are related to the decreased TLC. The FEV_1/FVC ratio is usually normal or increased. Lung volumes decrease as lung stiffness worsens with disease progression. A few disorders produce interstitial opacities on chest x-ray and obstructive airflow limitation on lung function testing (uncommon in sarcoidosis and hypersensitivity pneumonitis, while common in tuberous sclerosis and LAM). Pulmonary function studies have proven to have prognostic value in patients with idiopathic interstitial pneumonias, particularly, IPF or nonspecific interstitial pneumonia (NSIP).

Diffusing Capacity A reduction in the diffusing capacity of the lung for carbon monoxide (DL_{CO}) is a common but nonspecific finding in most ILDs. This decrease is due, in part, to effacement of the alveolar capillary units but, more importantly, to mismatching of ventilation and perfusion ($\dot{V}/\dot{Q}$). Lung regions with reduced compliance due to either fibrosis or cellular infiltration may be poorly ventilated but may still maintain adequate blood flow, and the ventilation-perfusion mismatch in these regions acts like true venous admixture. The severity of the reduction in DL_{CO} does not correlate with disease stage.

Arterial Blood Gas The resting arterial blood gas may be normal or reveal hypoxemia (secondary to a mismatching of ventilation to perfusion) and respiratory alkalosis. A normal arterial O_2 tension (or saturation by oximetry) at rest does not rule out significant hypoxemia during exercise or sleep. CO_2 retention is rare and is usually a manifestation of end-stage disease.

CARDIOPULMONARY EXERCISE TESTING

Because hypoxemia at rest is not always present and because severe exercise-induced hypoxemia may go undetected, it is useful to perform exercise testing with measurement of arterial blood gases to detect abnormalities of gas exchange. Arterial oxygen desaturation, a failure to decrease dead space appropriately with exercise [i.e., a high V_D/V_T ratio (Chap. 246)], and an excessive increase in respiratory rate with a lower-than-expected recruitment of tidal volume provide useful information about physiologic abnormalities and extent of disease. Serial assessment of resting and exercise gas exchange is an excellent method for following disease activity and responsiveness to treatment, especially in patients with IPF. Increasingly, the 6-min walk test is used to obtain a global evaluation of submaximal exercise capacity in patients with ILD. The walk distance and level of oxygen desaturation tend to correlate with the patient's baseline lung function.

FIBEROPTIC BRONCHOSCOPY AND BRONCHOALVEOLAR LAVAGE (BAL)

In selected diseases (e.g., sarcoidosis, hypersensitivity pneumonitis, DAH syndrome, cancer, pulmonary alveolar proteinosis), cellular analysis of BAL fluid may be useful in narrowing the differential diagnostic possibilities among various types of ILD (Table 255-3). The role for BAL in defining the stage of disease and assessment of disease progression or response to therapy remains poorly understood, and the usefulness of BAL in the clinical assessment and management remains to be established.

TISSUE AND CELLULAR EXAMINATION

Lung biopsy is the most effective method for confirming the diagnosis and assessing disease activity. The findings may identify a more treatable process than originally suspected, particularly chronic hypersensitivity pneumonitis, COP, respiratory bronchiolitis–associated ILD, or sarcoidosis. Biopsy should be obtained before initiation of treatment. A definitive diagnosis avoids confusion and anxiety later in the clinical course if the patient does not respond to therapy or suffers serious side effects from it.

TABLE 255-3 DIAGNOSTIC VALUE OF BRONCHOALVEOLAR LAVAGE IN INTERSTITIAL LUNG DISEASE

Condition	Bronchoalveolar Lavage Finding
Sarcoidosis	Lymphocytosis; CD4:CD8 ratio >3.5 most specific of diagnosis
Hypersensitivity pneumonitis	Marked lymphocytosis (>50%)
Organizing pneumonia	Foamy macrophages; mixed pattern of increased cells characteristic; decreased CD4:CD8 ratio
Eosinophilic lung disease	Eosinophils >25%
Diffuse alveolar bleeding	Hemosiderin-laden macrophages, red blood cells
Diffuse alveolar damage, drug toxicity	Atypical hyperplastic type II pneumocytes
Opportunistic infections	*Pneumocystis carinii*, fungi, cytomegalovirus-transformed cells
Lymphangitic carcinomatosis, alveolar cell carcinoma, pulmonary lymphoma	Malignant cells
Alveolar proteinosis	Milky effluent, foamy macrophages and lipoproteinaceous intraalveolar material (periodic acid–Schiff stain positive)
Lipoid pneumonia	Fat globules in macrophages
Pulmonary Langerhans' cell histiocytosis	Increased CD1+ Langerhans' cells Electron microscopy demonstrating Birbeck granule in lavaged macrophage (expensive and difficult to perform)
Asbestos-related pulmonary disease	Dust particles, ferruginous bodies
Berylliosis	Positive lymphocyte transformation test to beryllium
Silicosis	Dust particles by polarized light microscopy
Lipoidosis	Accumulation of specific lipopigment in alveolar macrophages

Fiberoptic bronchoscopy with multiple transbronchial lung biopsies (four to eight biopsy samples) is often the initial procedure of choice, especially when sarcoidosis, lymphangitic carcinomatosis, eosinophilic pneumonia, Goodpasture's syndrome, or infection is suspected. If a specific diagnosis is not made by transbronchial biopsy, then surgical lung biopsy by video-assisted thoracic surgery or open thoracotomy is indicated. Adequate-sized biopsies from multiple sites, usually from two lobes, should be obtained. Relative contraindications to lung biopsy include serious cardiovascular disease, honeycombing and other roentgenographic evidence of diffuse end-stage disease, severe pulmonary dysfunction, or other major operative risks, especially in the elderly.

℞ INTERSTITIAL LUNG DISEASE

Although the course of ILD is variable, progression is common and often insidious. All treatable possibilities should be carefully considered. Since therapy does not reverse fibrosis, the major goals of treatment are permanent removal of the offending agent, when known, and early identification and aggressive suppression of the acute and chronic inflammatory process, thereby reducing further lung damage.

Hypoxemia (Pa_{O_2} < 55 mmHg) at rest and/or with exercise should be managed by supplemental oxygen. If cor pulmonale develops, diuretic therapy and phlebotomy may occasionally be required (Chaps. 227 and 244).

DRUG THERAPY Glucocorticoids are the mainstay of therapy for suppression of the alveolitis present in ILD, but the success rate is low. There have been no placebo-controlled trials of glucocorticoids in ILD, so there is no direct evidence that steroids improve survival in many of the diseases for which they are commonly used. Glucocorticoid therapy is recommended for symptomatic ILD patients with eosinophilic pneumonias, COP, CTD, sarcoidosis, acute inorganic dust exposures, acute radiation pneumonitis, DAH, and drug-induced ILD. In organic dust disease, glucocorticoids are recommended for both the acute and chronic stages.

The optimal dose and proper length of therapy with glucocorticoids in the treatment of most ILDs are not known. A common starting dose is prednisone, 0.5–1 mg/kg in a once-daily oral dose (based on the patient's lean body weight). This dose is continued for 4–12 weeks, at which time the patient is reevaluated. If the patient is stable or improved, the dose is tapered to 0.25–0.5 mg/kg and is maintained at this level for an additional 4–12 weeks depending on the course. Rapid tapering or a shortened course of glucocorticoid treatment can result in recurrence. If the patient's condition continues to decline while on glucocorticoids, a second agent (see below) is often added and the prednisone dose is lowered to or maintained at 0.25 mg/kg per day.

Cyclophosphamide and azathioprine (1–2 mg/kg lean body weight per day), with or without glucocorticoids, have been tried with variable success in IPF, vasculitis, and other ILDs. An objective response usually requires at least 8–12 weeks to occur. In situations in which these drugs have failed or could not be tolerated, other agents, including methotrexate, colchicine, penicillamine, and cyclosporine, have been tried. However, their role in the treatment of ILDs remains to be determined.

Many cases of ILD are chronic and irreversible despite the therapy discussed above, and lung transplantation may then be considered (Chap. 260).

INDIVIDUAL FORMS OF ILD

IDIOPATHIC PULMONARY FIBROSIS

IPF is the most common form of idiopathic interstitial pneumonia. Separating IPF from other forms of lung fibrosis is an important step in the evaluation of all patients presenting with ILD. IPF has a distinctly poor response to therapy and a bad prognosis.

Clinical Manifestations Exertional dyspnea, a nonproductive cough, and inspiratory crackles with or without digital clubbing may be present on physical examination. The HRCT lung scans typically show patchy, predominantly basilar, subpleural reticular opacities, often associated with traction bronchiectasis and honeycombing (Fig. 255-3). Atypical findings that should suggest an alternative diagnosis include: extensive ground-glass abnormality, nodular opacities, upper or mid-zone predominance, and prominent hilar or mediastinal lymphadenopathy. Pulmonary function tests often reveal a restrictive pattern, a reduced DL_{CO}, and arterial hypoxemia that is exaggerated or elicited by exercise.

Histologic Findings Confirmation of the presence of the UIP pattern on histologic examination is essential to confirm this diagnosis. Transbronchial biopsies are not helpful in making the diagnosis of UIP, and surgical biopsy is usually required. The histologic hallmark and chief diagnostic criterion of UIP is a heterogeneous appearance at low magnification with alternating areas of normal lung, interstitial inflammation, foci of proliferating fibroblasts, dense collagen fibrosis, and honeycomb changes. These histologic changes affect the peripheral, subpleural parenchyma most severely. The interstitial inflammation is usually patchy and consists of a lymphoplasmacytic infiltrate in the alveolar septa, associated with hyperplasia of type 2 pneumocytes. The fibrotic zones are composed mainly of dense collagen, although scattered foci of proliferating fibroblasts are a consistent finding. The extent of fibroblastic proliferation is predictive of disease progression. Areas of honeycomb change are composed of cystic fibrotic air spaces that are frequently lined by bronchiolar epithelium and filled with mucin. Smooth-muscle hyperplasia is commonly seen in areas of fibrosis and honeycomb change. A fibrotic pattern with some features similar to UIP may be found in the chronic stage of several specific disorders such as: pneumoconioses (e.g., asbestosis), radiation injury, certain drug-induced lung diseases (e.g., nitrofurantoin), chronic aspiration, sarcoidosis, chronic hypersensitivity pneumonitis, organized chronic eosinophilic pneumonia, and PLCH. Commonly, other histopathologic features are present in these situations thus allowing separation of these lesions from the UIP-like pattern. Consequently, the term *UIP* is used for those patients in whom the lesion is idiopathic and not associated with another condition.

Patients with IPF may suffer acute deterioration secondary to infections, pulmonary embolism, pneumothorax, or heart failure. These patients also commonly suffer an accelerated phase of rapid clinical decline that is associated with a poor prognosis (so-called acute exacerbations of IPF). These acute exacerbations are defined by: worsening of dyspnea within a few days to 4 weeks; newly developing diffuse radiographic opacities; worsening hypoxemia; and absence of infectious pneumonia, heart failure, and sepsis. The rate of these acute exacerbations ranges from 10–57%, apparently depending on the length of follow-up. During these episodes, the histopathologic pattern of diffuse alveolar damage is often found on the background of UIP.

℞ IDIOPATHIC PULMONARY FIBROSIS

No therapy has been found to be effective in the management of acute exacerbations of IPF. Often mechanical ventilation is required but is usually not successful, with a hospital mortality rate of up to three-fourths of the patients. In those that survive, a recurrence of acute exacerbation is common and usually results in death at those times.

Lung transplantation should be considered for those patients who experience progressive deterioration despite optimal medical management and who meet the established criteria (Chap. 260).

NONSPECIFIC INTERSTITIAL PNEUMONIA (NSIP)

This condition defines a subgroup of the idiopathic interstitial pneumonias that can be distinguished clinically and pathologically from UIP, desquamative interstitial pneumonia (DIP), AIP, and idiopathic BOOP. Importantly, many cases with this histopathologic pattern occur in the context of an underlying disorder, such as a connective tissue disease, drug-induced ILD, or chronic hypersensitivity pneumonitis. Idiopathic NSIP is a subacute restrictive process with a presentation similar to IPF but usually at a younger age, most commonly in women who have never smoked. It is often associated with a febrile illness. HRCT shows bilateral, subpleural ground-glass opacities, often

FIGURE 255-4 Nonspecific interstitial pneumonia. High-resolution CT through the lower lung shows volume loss with extensive ground-glass abnormality, reticular abnormality and traction bronchiectasis. There is sparing on the lung immediately adjacent to the pleura. Histology showed a combination of inflammation and mild fibrosis.

associated with lower lobe volume loss (Fig. 255-4). Patchy areas of airspace consolidation and reticular abnormalities may be present, but honeycombing is unusual. The key histopathologic features of NSIP are the uniformity of interstitial involvement across the biopsy section, and this may be predominantly cellular or fibrosing. There is less temporal and spatial heterogeneity than in UIP and little or no honeycombing is found. The cellular variant is rare. Unlike patients with IPF (UIP), the majority of patients with NSIP have a good prognosis (5-year mortality rate estimated at <15%) with most showing improvement after treatment with glucocorticoids, often used in combination with azathioprine.

ACUTE INTERSTITIAL PNEUMONIA (AIP, HAMMAN-RICH SYNDROME)

AIP is a rare, fulminant form of lung injury characterized histologically by diffuse alveolar damage on lung biopsy. Most patients are older than 40 years. AIP is similar in presentation to the acute respiratory distress syndrome (ARDS) (Chap. 262) and probably corresponds to the subset of cases of idiopathic ARDS. The onset is usually abrupt in a previously healthy individual. A prodromal illness, usually lasting 7–14 days before presentation, is common. Fever, cough, and dyspnea are frequent manifestations at presentation. Diffuse, bilateral, airspace opacification is present on chest radiograph. HRCT scans show bilateral, patchy, symmetric areas of ground-glass attenuation. Bilateral areas of air-space consolidation may also be present. A predominantly subpleural distribution may be seen. The diagnosis of AIP requires the presence of a clinical syndrome of idiopathic ARDS and pathologic confirmation of organizing diffuse alveolar damage. Therefore, lung biopsy is required to confirm the diagnosis. Most patients have moderate to severe hypoxemia and develop respiratory failure. Mechanical ventilation is often required. The mortality rate is high (>60%), with most patients dying within 6 months of presentation. Recurrences have been reported. However, those who recover often have substantial improvement in lung function. The main treatment is supportive. It is not clear that glucocorticoid therapy is effective.

CRYPTOGENIC ORGANIZING PNEUMONIA

Also known as *idiopathic BOOP*, COP is a clinicopathologic syndrome of unknown etiology. The onset is usually in the fifth and sixth decades. The presentation may be of a flulike illness with cough, fever, malaise, fatigue, and weight loss. Inspiratory crackles are frequently present on examination. Pulmonary function is usually impaired, with a restrictive defect and arterial hypoxemia being most common. The roentgenographic manifestations are distinctive, revealing bilateral, patchy, or diffuse alveolar opacities in the presence of normal lung volume. Recurrent and migratory pulmonary opacities are common. HRCT shows areas of air-space consolidation, ground-glass opacities, small nodular opacities, and bronchial wall thickening and dilation. These changes occur more frequently in the periphery of the lung and in the lower lung zone. Lung biopsy shows granulation tissue within small airways, alveolar ducts, and airspaces, with chronic inflammation in the surrounding alveoli. Glucocorticoid therapy induces clinical recovery in two-thirds of patients. A few patients have rapidly progressive courses with fatal outcomes despite glucocorticoids.

Foci of organizing pneumonia (i.e., a "BOOP pattern") is a nonspecific reaction to lung injury found adjacent to other pathologic processes or as a component of other primary pulmonary disorders (e.g., cryptococcosis, Wegener's granulomatosis, lymphoma, hypersensitivity pneumonitis, and eosinophilic pneumonia). Consequently, the clinician must carefully reevaluate any patient found to have this histopathologic lesion to rule out these possibilities.

ILD ASSOCIATED WITH CIGARETTE SMOKING

Desquamative Interstitial Pneumonia DIP is a rare but distinct clinical and pathologic entity found exclusively in cigarette smokers. The histologic hallmark is the extensive accumulation of macrophages in intraalveolar spaces with minimal interstitial fibrosis. The peak incidence is in the fourth and fifth decades. Most patients present with dyspnea and cough. Lung function testing shows a restrictive pattern with reduced D_{LCO} and arterial hypoxemia. The chest x-ray and HRCT scans usually show diffuse hazy opacities. Clinical recognition of DIP is important because the process is associated with a better prognosis (10-year survival rate is ~70%) and a better response to smoking cessation and systemic glucocorticoids than IPF.

Respiratory Bronchiolitis–Associated ILD Respiratory bronchiolitis–associated ILD (RB-ILD) is considered to be a subset of DIP and is characterized by the accumulation of macrophages in peribronchial alveoli. The clinical presentation is similar to DIP. Rales are often heard on chest examination and occur throughout inspiration; sometimes they continue into expiration. The process is seen best on HRCT lung scanning which shows bronchial wall thickening, centrilobular nodules, ground-glass opacity, and emphysema with air trapping. RB-ILD appears to resolve in most patients following smoking cessation alone.

Pulmonary Langerhans Cell Histiocytosis (PLCH) This is a rare, smoking-related, diffuse lung disease that primarily affects men between the ages of 20 and 40 years. The clinical presentation varies from an asymptomatic state to a rapidly progressive condition. The most common clinical manifestations at presentation are cough, dyspnea, chest pain, weight loss, and fever. Pneumothorax occurs in ~25% of patients. Hemoptysis and diabetes insipidus are rare manifestations. The radiographic features vary with the stage of the disease. The combination of ill-defined or stellate nodules (2–10 mm in diameter), reticular or nodular opacities, bizarre-shaped upper zone cysts, preservation of lung volume, and sparing of the costophrenic angles are characteristics of PLCH. HRCT that reveals a combination of nodules and thin-walled cysts is virtually diagnostic of PLCH. The most frequent pulmonary function abnormality is a markedly reduced D_{LCO}, although varying degrees of restrictive disease, airflow limitation, and diminished exercise capacity may occur. The characteristic histopathologic finding in PLCH is the presence of nodular sclerosing lesions that contain Langerhans' cells accompanied by mixed cellular infiltrates. The nodular lesions are poorly defined and are distributed in a bronchiolocentric fashion with intervening normal lung parenchyma. As the disease progresses, fibrosis progresses to involve adjacent lung tissue leading to pericicatricial airspace enlargement, which accounts for the concomitant cystic changes. Discontinuance of smoking is the key treatment, resulting in clinical improvement in one-third of patients. Most patients with PLCH suffer persistent or progressive disease. Death due to respiratory failure occurs in ~10% of patients.

ILD ASSOCIATED WITH CONNECTIVE TISSUE DISORDERS

Clinical findings suggestive of a CTD (musculoskeletal pain, weakness, fatigue, fever, joint pains or swelling, photosensitivity, Raynaud's phenomenon, pleuritis, dry eyes, dry mouth) should be sought in any patient with ILD. The CTDs may be difficult to rule out since the pulmonary manifestations occasionally precede the more typical systemic manifestations by months or years. The most common form of pulmonary involvement is the nonspecific interstitial pneumonia histopathologic pattern. However, determining the precise nature of lung involvement in most of the CTDs is difficult due to the high incidence of lung involvement caused by disease-associated complications of esophageal dysfunction (predisposing to aspiration and secondary infections), respiratory muscle weakness (atelectasis and secondary infections), complications of therapy (opportunistic infections), and associated malignancies.

Progressive Systemic Sclerosis (PSS) (See also Chap. 316) Clinical evidence of ILD is present in about one-half of patients with PSS, and pathologic evidence in three-quarters. Pulmonary function tests show a restrictive pattern and impaired diffusing capacity, often before any clinical or radiographic evidence of lung disease appears. Pulmonary vascular disease alone or in association with pulmonary fibrosis, pleuritis, or recurrent aspiration pneumonitis is strikingly resistant to current modes of therapy.

Rheumatoid Arthritis (RA) (See also Chap. 314) ILD associated with RA is more common in men. Pulmonary manifestations of RA include pleurisy with or without effusion, ILD in up to 20% of cases, necrobiotic nodules (nonpneumoconiotic intrapulmonary rheumatoid nodules) with or without cavities, Caplan's syndrome (rheumatoid pneumoconiosis), pulmonary hypertension secondary to rheumatoid pulmonary vasculitis, BOOP, and upper airway obstruction due to crico-arytenoid arthritis.

Systemic Lupus Erythematosus (SLE) (See also Chap. 313) Lung disease is a common complication in SLE. Pleuritis with or without effusion is the most common pulmonary manifestation. Other lung manifestations include the following: atelectasis, diaphragmatic dysfunction with loss of lung volumes, pulmonary vascular disease, pulmonary hemorrhage, uremic pulmonary edema, infectious pneumonia, and BOOP. Acute lupus pneumonitis characterized by pulmonary capillaritis leading to alveolar hemorrhage is uncommon. Chronic, progressive ILD is uncommon. It is important to exclude pulmonary infection. Although pleuropulmonary involvement may not be evident clinically, pulmonary function testing, particularly D_{LCO}, reveals abnormalities in many patients with SLE.

Polymyositis and Dermatomyositis (PM/DM) (See also Chap. 383) ILD occurs in ~10% of patients with PM/DM. Diffuse reticular or nodular opacities with or without an alveolar component occur radiographically, with a predilection for the lung bases. ILD occurs more commonly in the subgroup of patients with an anti-Jo-1 antibody that is directed to histidyl tRNA synthetase. Weakness of respiratory muscles contributing to aspiration pneumonia may be present. A rapidly progressive illness characterized by diffuse alveolar damage may cause respiratory failure.

Sjögren's Syndrome (See also Chap. 317) General dryness and lack of airways secretion cause the major problems of hoarseness, cough, and bronchitis. Lymphocytic interstitial pneumonitis, lymphoma, pseudolymphoma, bronchiolitis, and bronchiolitis obliterans are associated with this condition. Lung biopsy is frequently required to establish a precise pulmonary diagnosis. Glucocorticoids have been used in the management of ILD associated with Sjögren's syndrome with some degree of clinical success.

DRUG-INDUCED ILD

Many classes of drugs have the potential to induce diffuse ILD, which is manifest most commonly as exertional dyspnea and nonproductive cough. A detailed history of the medications taken by the patient is needed to identify drug-induced disease, including over-the-counter medications, oily nose drops, or petroleum products (mineral oil). In most cases, the pathogenesis is unknown, although a combination of direct toxic effects of the drug (or its metabolite) and indirect inflammatory and immunologic events are likely. The onset of the illness may be abrupt and fulminant, or it may be insidious, extending over weeks to months. The drug may have been taken for several years before a reaction develops (e.g., amiodarone), or the lung disease may occur weeks to years after the drug has been discontinued (e.g., carmustine). The extent and severity of disease are usually dose-related. Treatment consists of discontinuation of any possible offending drug and supportive care.

EOSINOPHILIC PNEUMONIA

(See Chap. 249)

PULMONARY ALVEOLAR PROTEINOSIS (PAP)

Although not strictly an ILD, PAP resembles and is therefore considered with these conditions. It has been proposed that a defect in macrophage function, more specifically an impaired ability to process surfactant, may play a role in the pathogenesis of PAP. This diffuse disease is characterized by the accumulation of an amorphous, periodic acid–Schiff-positive lipoproteinaceous material in the distal air spaces. There is little or no lung inflammation, and the underlying lung architecture is preserved. Mutant mice lacking the gene for granulocyte-macrophage colony-stimulating factor (GM-CSF) have a similar accumulation of surfactant and surfactant apoprotein in the alveolar spaces. Moreover, reconstitution of the respiratory epithelium of GM-CSF knockout mice with the GM-CSF gene completely corrects the alveolar proteinosis. Data from BAL studies in patients suggest that PAP is an autoimmune disease with neutralizing antibody of immunoglobulin G isotype against GM-CSF. These findings suggest that neutralization of GM-CSF bioactivity by the antibody causes dysfunction of alveolar macrophages, which results in reduced surfactant clearance. There are three distinct classes of PAP: acquired (>90% of all cases), congenital, and secondary. *Congenital PAP* is transmitted in an autosomal recessive manner and is caused by homozygosity for a frame shift mutation (121ins2) in the *SP-B* gene, which leads to an unstable SP-B mRNA, reduced protein levels, and *secondary disturbances of SP-C processing. Secondary PAP* is rare among adults and is caused by lysinuric protein intolerance, acute silicosis and other inhalational syndromes, immunodeficiency disorders, and malignancies (almost exclusively of hematopoietic origin) and hematopoietic disorders.

The typical age of presentation is 30–50 years, and males predominate. The clinical presentation is usually insidious and manifested by progressive exertional dyspnea, fatigue, weight loss, and low-grade fever. A nonproductive cough is common, but occasionally expectoration of "chunky" gelatinous material may occur. Polycythemia, hypergammaglobulinemia, and increased LDH levels are frequent. Markedly elevated serum levels of lung surfactant proteins A and D have been found in PAP. Radiographically, bilateral symmetric alveolar opacities located centrally in mid and lower lung zones result in a "bat-wing" distribution. HRCT shows a ground-glass opacification and thickened intralobular structures and interlobular septa. Whole-lung lavage(s) through a double-lumen endotracheal tube provides relief to many patients with dyspnea or progressive hypoxemia and also may provide long-term benefit.

PULMONARY LYMPHANGIOLEIOMYOMATOSIS

Pulmonary LAM is a rare condition that afflicts premenopausal women and should be suspected in young women with "emphysema," recurrent pneumothorax, or chylous pleural effusion. It is often misdiagnosed as asthma or chronic obstructive pulmonary disease. Pathologically, LAM is characterized by the proliferation of atypical pulmonary interstitial smooth muscle and cyst formation. The immature-appearing smooth-muscle cells react with monoclonal antibody HMB45, which recognizes a 100-kDa glycoprotein (gp100) originally found in human melanoma cells. Caucasians are affected much more commonly than members of other racial groups. The disease accelerates during pregnancy and abates after oophorectomy. Common complaints at presentation are dyspnea, cough, and chest pain. Hemoptysis may be life threatening. Spontaneous

pneumothorax occurs in 50% of patients; it may be bilateral and necessitate pleurodesis. Meningioma and renal angiomyolipomas (hamartomas), characteristic findings in the genetic disorder tuberous sclerosis, are also common in patients with LAM. Chylothorax, chyloperitoneum (chylous ascites), chyluria, and chylopericardium are other complications. Pulmonary function testing usually reveals an obstructive or mixed obstructive-restrictive pattern, and gas exchange is often abnormal. HRCT shows thin-walled cysts surrounded by normal lung without zonal predominance. Progression is common, with a median survival of 8–10 years from diagnosis. Progesterone (10 mg/d) and luteinizing hormone–releasing hormone analogues have been used. Oophorectomy is no longer recommended and estrogen-containing drugs should be discontinued. Lung transplantation offers the only hope for cure despite reports of recurrent disease in the transplanted lung.

SYNDROMES OF ILD WITH DIFFUSE ALVEOLAR HEMORRHAGE

Injury to arterioles, venules, and the alveolar septal (alveolar wall or interstitial) capillaries can result in hemoptysis secondary to disruption of the alveolar-capillary basement membrane. This results in bleeding into the alveolar spaces, which characterizes DAH. Pulmonary capillaritis, characterized by a neutrophilic infiltration of the alveolar septae, may lead to necrosis of these structures, loss of capillary structural integrity, and the pouring of red blood cells into the alveolar space. Fibrinoid necrosis of the interstitium and red blood cells within the interstitial space are sometimes seen. Bland pulmonary hemorrhage (i.e., DAH without inflammation of the alveolar structures) may also occur.

The clinical onset is often abrupt, with cough, fever, and dyspnea. Severe respiratory distress requiring ventilatory support may be evident at initial presentation. Although hemoptysis is expected, it can be absent at the time of presentation in one-third of the cases. For patients without hemoptysis, new alveolar opacities, a falling hemoglobin level, and hemorrhagic BAL fluid point to the diagnosis. The chest radiograph is nonspecific and most commonly shows new patchy or diffuse alveolar opacities. Recurrent episodes of DAH may lead to pulmonary fibrosis, resulting in interstitial opacities on the chest radiograph. An elevated white blood cell count and falling hematocrit are frequent. Evidence for impaired renal function caused by focal segmental necrotizing glomerulonephritis, usually with crescent formation, may also be present.

Varying degrees of hypoxemia may occur and are often severe enough to require ventilatory support. The D_{LCO} may be increased, resulting from the increased hemoglobin within the alveoli compartment. Evaluation of either lung or renal tissue by immunofluorescent techniques indicates an absence of immune complexes (pauci-immune) in Wegener's granulomatosis, microscopic polyangiitis pauci-immune glomerulonephritis, and isolated pulmonary capillaritis. A granular pattern is found in the CTDs, particularly SLE, and a characteristic linear deposition is found in Goodpasture's syndrome. Granular deposition of IgA-containing immune complexes is present in Henoch-Schönlein purpura.

The mainstay of therapy for the DAH associated with systemic vasculitis, CTD, Goodpasture's syndrome, and isolated pulmonary capillaritis is IV methylprednisolone, 0.5–2.0 g daily in divided doses for up to 5 days, followed by a gradual tapering, and then maintenance on an oral preparation. Prompt initiation of therapy is important, particularly in the face of renal insufficiency, since early initiation of therapy has the best chance of preserving renal function. The decision to start other immunosuppressive therapy (cyclophosphamide or azathioprine) acutely depends on the severity of illness.

Goodpasture's Syndrome Pulmonary hemorrhage and glomerulonephritis are features in most patients with this disease. Autoantibodies to renal glomerular and lung alveolar basement membranes are present. This syndrome can present and recur as DAH without an associated glomerulonephritis. In such case, circulating anti-basement membrane antibody is often absent, and the only way to establish the diagnosis is by demonstrating linear immunofluorescence in lung tissue. The underlying histology may be bland hemorrhage or DAH associated with capillaritis. Plasmapheresis has been recommended as adjunctive treatment.

INHERITED DISORDERS ASSOCIATED WITH ILD

Pulmonary opacities and respiratory symptoms typical of ILD can develop in related family members and in several inherited diseases. These include the phakomatoses, tuberous sclerosis and neurofibromatosis (Chap. 374), and the lysosomal storage diseases, Niemann-Pick disease and Gaucher's disease (Chap. 355). The Hermansky-Pudlak syndrome is an autosomal recessive disorder in which granulomatous colitis and ILD may occur. It is characterized by oculocutaneous albinism, bleeding diathesis secondary to platelet dysfunction, and the accumulation of a chromolipid, lipofuscin material in cells of the reticuloendothelial system. A fibrotic pattern is found on lung biopsy, but the alveolar macrophages may contain cytoplasmic ceroid-like inclusions.

ILD WITH A GRANULOMATOUS RESPONSE IN LUNG TISSUE OR VASCULAR STRUCTURES

Inhalation of organic dusts, which cause hypersensitivity pneumonitis, or of inorganic dust, such as silica, which elicits a granulomatous inflammatory reaction leading to ILD, produces diseases of known etiology (Table 255-1) that are discussed in Chaps. 249 and 250. Sarcoidosis (Chap. 322) is prominent among granulomatous diseases of unknown cause in which ILD is an important feature.

Granulomatous Vasculitides (See also Chap. 319) The granulomatous vasculitides are characterized by pulmonary angiitis (i.e., inflammation and necrosis of blood vessels) with associated granuloma formation (i.e., infiltrates of lymphocytes, plasma cells, epithelioid cells, or histiocytes, with or without the presence of multinucleated giant cells, sometimes with tissue necrosis). The lungs are almost always involved, although any organ system may be affected. Wegener's granulomatosis and allergic angiitis and granulomatosis (Churg-Strauss syndrome) primarily affect the lung but are associated with a systemic vasculitis as well. The granulomatous vasculitides generally limited to the lung include necrotizing sarcoid granulomatosis and benign lymphocytic angiitis and granulomatosis. Granulomatous infection and pulmonary angiitis due to irritating embolic material (e.g., talc) are important known causes of pulmonary vasculitis.

LYMPHOCYTIC INFILTRATIVE DISORDERS

This group of disorders features lymphocyte and plasma cell infiltration of the lung parenchyma. The disorders either are benign or can behave as low-grade lymphomas. Included are angioimmunoblastic lymphadenopathy with dysproteinemia, a rare lymphoproliferative disorder characterized by diffuse lymphadenopathy, fever, hepatosplenomegaly, and hemolytic anemia, with ILD in some cases.

Lymphocytic Interstitial Pneumonitis This rare form of ILD occurs in adults, some of whom have an autoimmune disease or dysproteinemia. It has been reported in patients with Sjögren's syndrome and HIV infection.

Lymphomatoid Granulomatosis This multisystem disorder of unknown etiology is an angiocentric malignant (T cell) lymphoma characterized by a polymorphic lymphoid infiltrate, an angiitis, and granulomatosis. Although it may affect virtually any organ, it is most frequently characterized by pulmonary, skin, and central nervous system involvement.

BRONCHOCENTRIC GRANULOMATOSIS

Rather than a specific clinical entity, bronchocentric granulomatosis (BG) is a descriptive histologic term that describes an uncommon and nonspecific pathologic response to a variety of airway injuries. There is evidence that BG is caused by a hypersensitivity reaction to *Aspergillus* or other fungi in patients with asthma. About half of the patients described have chronic asthma with severe wheezing and peripheral blood eosinophilia. In patients with asthma, BG probably represents one pathologic manifestation of allergic bronchopulmonary aspergillosis or another allergic mycosis. In patients without asthma, BG has been associated with RA and a variety of infections, including tuberculosis,

echinococcosis, histoplasmosis, coccidioidomycosis, and nocardiosis. The chest roentgenogram reveals irregularly shaped nodular or mass lesions with ill-defined margins, which are usually unilateral and solitary, with upper-lobe predominance. Glucocorticoids are the treatment of choice, often with excellent outcome, although recurrences may occur as therapy is tapered or stopped.

GLOBAL CONSIDERATIONS

Limited epidemiologic data exists describing the prevalence or incidence of ILD in the general population. With a few exceptions, e.g., sarcoidosis, certain occupational and environmental exposures, there appear to be no significant differences in the prevalence or incidence of ILD among various populations. For sarcoidosis, there are important environmental, racial, and genetic differences (Chap. 322).

256 Deep Venous Thrombosis and Pulmonary Thromboembolism

Samuel Z. Goldhaber

EPIDEMIOLOGY

A quiet revolution has occurred in the field of venous thromboembolism (VTE), which encompasses deep venous thrombosis (DVT) and pulmonary embolism (PE). VTE is no longer an orphan disease. Its adverse public health impact has been acknowledged in the United States by the National Quality Forum, the Joint Commission for Accreditation of Hospitals, the National Comprehensive Cancer Network, and the Surgeon General's Office. Public service announcements have educated laypersons on the definition and medical consequences of DVT and PE, along with risk factors and warning signs. VTE-related deaths in the United States are estimated at 300,000 annually: 7% diagnosed with VTE and treated, 34% sudden fatal PE, and 59% as undetected PE. Approximately two-thirds of symptomatic VTE events are hospital acquired, and the remainder are community acquired. Residents of skilled nursing facilities are especially vulnerable. The most recent estimates of hospitalized patients at risk for VTE in the United States total 13.4 million (M) patients annually: 5.8 M surgical patients at moderate–high risk and 7.6 M medical patients with comorbidities such as heart failure, cancer, and stroke. These new data provide the rationale for changing the prophylaxis paradigm from voluntary to mandatory compliance with guidelines to prevent VTE among hospitalized patients.

VTE is also a major European health problem, with an estimated 370,000 per year PE-related deaths, when data in France, Germany, Spain, Italy, Sweden, and the United Kingdom are combined. The estimated direct cost for VTE-associated care in Europe exceeds 3 billion euros per year.

Though DVT and PE encompass one disease entity, VTE, there are important differences. DVT occurs about 3 times more often than PE. The major adverse outcome of DVT alone, without PE, is the development of *postphlebitic syndrome*, which occurs in more than half of patients with DVT. Postphlebitic syndrome is a late adverse effect of DVT that is caused by permanent damage to the venous valves of the leg, which become incompetent and permit abnormal exudation of interstitial fluid from the venous system. It may not become clinically manifest until several years after the initial DVT. There is no effective medical therapy for this condition, which impairs quality of life and disables. Most patients describe chronic ankle swelling and calf swelling and aching, especially after prolonged standing. In its most severe form, postphlebitic syndrome causes skin ulceration, especially in the medial malleolus of the leg. PE can be fatal or can cause chronic thromboembolic pulmonary hypertension, with breathlessness at rest or with mild exertion. Patients with PE are more likely to suffer recurrent VTE than patients with DVT alone.

Genetic and acquired factors contribute to the likelihood of VTE. The two most common autosomal dominant genetic mutations are the factor V Leiden and the prothrombin gene mutations (Chap. 59). However, only a minority of patients with VTE have identifiable predisposing genetic factors. The majority of patients with predisposing genetic factors will not develop clinical evidence of clotting. Acquired predispositions include long-haul air travel, obesity, cigarette smoking, oral contraceptives, pregnancy, postmenopausal hormone replacement, surgery, trauma, and medical conditions such as antiphospholipid antibody syndrome, cancer, systemic arterial hypertension, and chronic obstructive pulmonary disease. Thrombophilia contributes to the risk of venous thrombosis, often due to an inherited risk factor in combination with an acquired predisposition.

PATHOPHYSIOLOGY

Embolization When venous thrombi dislodge from their site of formation, they embolize to the pulmonary arterial circulation or, paradoxically, to the arterial circulation through a patent foramen ovale or atrial septal defect. About half of patients with pelvic vein thrombosis or proximal leg DVT develop PE, which is usually asymptomatic. Isolated calf vein thrombi pose a much lower risk of PE, but they are the most common source of paradoxical embolism. These tiny thrombi can cross a small patent foramen ovale or atrial septal defect, unlike larger, more proximal leg thrombi. With increased use of chronic indwelling central venous catheters for hyperalimentation and chemotherapy, as well as more frequent insertion of permanent pacemakers and internal cardiac defibrillators, upper extremity venous thrombosis is becoming a more common problem. These thrombi rarely embolize and cause PE.

Physiology The most common gas exchange abnormalities are hypoxemia (decreased arterial P_{O_2}) and an increased alveolar-arterial O_2 tension gradient, which represents the inefficiency of O_2 transfer across the lungs. Anatomic dead space increases because breathed gas does not enter gas exchange units of the lung. Physiologic dead space increases because ventilation to gas exchange units exceeds venous blood flow through the pulmonary capillaries.

Other pathophysiological abnormalities include:

1. *Increased pulmonary vascular resistance* due to vascular obstruction or platelet secretion of vasoconstricting neurohumoral agents such

as serotonin. Release of vasoactive mediators can produce ventilation-perfusion mismatching at sites remote from the embolus, thereby accounting for a potential discordance between a small PE and a large alveolar-arterial O_2 gradient.

2. *Impaired gas exchange* due to increased alveolar dead space from vascular obstruction, hypoxemia from alveolar hypoventilation relative to perfusion in the nonobstructed lung, right-to-left shunting, and impaired carbon monoxide transfer due to loss of gas exchange surface.
3. *Alveolar hyperventilation* due to reflex stimulation of irritant receptors
4. *Increased airway resistance* due to constriction of airways distal to the bronchi
5. *Decreased pulmonary compliance* due to lung edema, lung hemorrhage, or loss of surfactant

Right Ventricular (RV) Dysfunction Progressive right heart failure is the usual cause of death from PE. In the International Cooperative Pulmonary Embolism Registry (ICOPER), the presence of RV dysfunction on baseline echocardiography of PE patients who presented with a systolic blood pressure >90 mmHg was associated with a doubling of the 3-month mortality rate. As pulmonary vascular resistance increases, RV wall tension rises and causes further RV dilatation and dysfunction. RV contraction continues even after the left ventricle (LV) starts relaxing at end-systole. Consequently, the interventricular septum bulges into and compresses an intrinsically normal left ventricle. Diastolic LV impairment develops, attributable to septal displacement, and results in reduced LV distensibility and impaired LV filling during diastole. Increased RV wall tension also compresses the right coronary artery, diminishes subendocardial perfusion, limits myocardial oxygen supply, and may precipitate myocardial ischemia and RV infarction. Underfilling of the LV may lead to a fall in left ventricular cardiac output and systemic arterial pressure, thereby provoking myocardial ischemia due to compromised coronary artery perfusion. Eventually, circulatory collapse and death may ensue.

DIAGNOSIS

Clinical Evaluation The diagnosis is challenging because symptoms and signs are nonspecific. VTE mimics other illnesses, and PE is known as "The Great Masquerader."

For patients who have DVT, the most frequent history is a cramp in the lower calf that persists for several days and that becomes more uncomfortable as time progresses. For patients who have PE, the most frequent history is unexplained breathlessness.

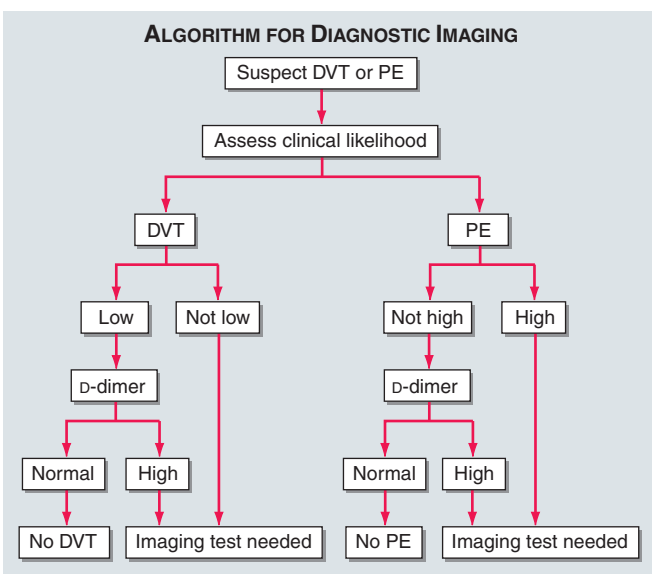

FIGURE 256-1 How to decide whether diagnostic imaging is needed. For assessment of clinical likelihood, see Table 256-1.

TABLE 256-1 CLINICAL DECISION RULES

Low Clinical Likelihood of DVT If the Point Score Is Zero or Less

Clinical Variable	Score
Active cancer	1
Paralysis, paresis, or recent cast	1
Bedridden for >3 days; major surgery <12 weeks	1
Tenderness along distribution of deep veins	1
Entire leg swelling	1
Unilateral calf swelling >3 cm	1
Pitting edema	1
Collateral superficial nonvaricose veins	1
Alternative diagnosis at least as likely as DVT	–2

High Clinical Likelihood of PE if the Point Score Exceeds 4

Clinical Variable	Score
Signs and symptoms of DVT	3.0
Alternative diagnosis less likely than PE	3.0
Heart rate >100/min	1.5
Immobilization >3 days; surgery within 4 weeks	1.5
Prior PE or DVT	1.5
Hemoptysis	1.0
Cancer	1.0

When evaluating patients with possible DVT, the initial task is to decide whether the clinical likelihood for DVT is low. When evaluating possible PE, the initial task is to decide whether the clinical likelihood is high. Patients with low likelihood of DVT or non-high (i.e., low/moderate) likelihood of PE can undergo initial diagnostic evaluation with D-dimer testing alone (see below) without obligatory imaging tests (Fig. 256-1).

Point score methods are useful for estimating the clinical likelihood of DVT and PE (Table 256-1).

Clinical Syndromes The differential diagnosis is critical because not all leg pain is due to DVT and not all dyspnea is due to PE (Table 256-2). Sudden, severe calf discomfort suggests a ruptured Baker's cyst. Fever and chills usually herald cellulitis rather than DVT, though DVT may be present concomitantly. Physical findings, if present at all, may simply consist of mild palpation discomfort in the lower calf. Massive DVT is much easier to recognize. The patient presents with severe thigh swelling and marked tenderness when palpating the inguinal area and common femoral vein. In extreme cases, patients will be unable to walk or may require a cane, crutches, or walker.

If the leg is diffusely edematous, DVT is unlikely. Much more common is an acute exacerbation of venous insufficiency due to postphlebitic syndrome. Upper extremity venous thrombosis may present with asymmetry in the supraclavicular fossa or in the circumference of the upper arms. A prominent superficial venous pattern may be evident on the anterior chest wall.

Patients with *massive PE* present with systemic arterial hypotension and usually have anatomically widespread thromboembolism. Those with *moderate to large PE* have RV hypokinesis on echocardiography but normal systemic arterial pressure. Patients with *small to moderate PE*

TABLE 256-2 DIFFERENTIAL DIAGNOSIS

DVT
Ruptured Baker's cyst
Cellulitis
Postphlebitic syndrome/venous insufficiency
PE
Pneumonia, asthma, chronic obstructive pulmonary disease
Congestive heart failure
Pericarditis
Pleurisy: "viral syndrome," costochondritis, musculoskeletal discomfort
Rib fracture, pneumothorax
Acute coronary syndrome
Anxiety

have both normal right heart function and normal systemic arterial pressure. They have an excellent prognosis with adequate anticoagulation.

The presence of *pulmonary infarction* usually indicates a small PE, but one that is exquisitely painful, because it lodges peripherally, near the innervation of pleural nerves. Pleuritic chest pain is more common with small, peripheral emboli. However, larger, more central PEs can occur concomitantly with peripheral pulmonary infarction.

Nonthrombotic PE may be easily overlooked. Possible etiologies include fat embolism after blunt trauma and long bone fractures, tumor embolism, bone marrow, or air embolism. Cement embolism and bony fragment embolism can occur after total hip or knee replacement. Intravenous drug users may inject themselves with a wide array of substances, such as hair, talc, or cotton. *Amniotic fluid embolism* occurs when fetal membranes leak or tear at the placental margin. Pulmonary edema in this syndrome is probably due to alveolar capillary leakage.

Dyspnea is the most frequent symptom of PE, and tachypnea is its most frequent sign. Whereas dyspnea, syncope, hypotension, or cyanosis indicates a massive PE, pleuritic pain, cough, or hemoptysis often suggests a small embolism located distally near the pleura. On physical examination, young and previously healthy individuals may appear anxious but otherwise seem deceptively well, even with an anatomically large PE. They may only have dyspnea with moderate exertion. They often lack "classic" signs such as tachycardia, low-grade fever, neck vein distension, or an accentuated pulmonic component of the second heart sound. Sometimes paradoxical bradycardia occurs.

Some patients have occult PE and an overt coexisting illness such as pneumonia or heart failure. In such circumstances, clinical improvement often fails to occur despite standard medical treatment of the concomitant illness. This situation can serve as a clinical clue to the possible coexistence of PE.

Nonimaging Diagnostic Modalities Nonimaging tests are best utilized in combination with clinical likelihood of DVT or PE (Fig. 256-1).

BLOOD TESTS The quantitative *plasma D-dimer enzyme-linked immunosorbent assay (ELISA)* rises in the presence of DVT or PE because of plasmin's breakdown of fibrin. Elevation of D-dimer indicates endogenous although often clinically ineffective thrombolysis. The sensitivity of the D-dimer is greater than 80% for DVT (including isolated calf DVT) and greater than 95% for PE. The D-dimer is less sensitive for DVT than PE because the DVT thrombus size is smaller. The D-dimer is a useful "rule out" test. It is normal (<500 ng/mL) in more than 95% of patients without PE. In patients with low clinical suspicion of DVT, it is normal in more than 90% without DVT.

The D-dimer assay is not specific. Levels increase in patients with myocardial infarction, pneumonia, sepsis, cancer, the postoperative state, and second or third trimester of pregnancy. Therefore, it rarely has a useful role among hospitalized patients because their D-dimers are frequently elevated due to some systemic illness.

Contrary to classic teaching, *arterial blood gases* lack diagnostic utility for PE, even though both the P_{O_2} and P_{CO_2} often decrease. Among patients suspected of PE, neither the room air arterial P_{O_2} nor calculation of the alveolar-arterial O_2 gradient can reliably differentiate or triage patients who actually have PE at angiography.

ELEVATED CARDIAC BIOMARKERS Serum troponin levels increase in RV microinfarction. Myocardial stretch often results in elevation of brain natriuretic peptide or NT-pro-brain natriuretic peptide. Elevated cardiac biomarkers predict an increase in major complications and mortality from PE.

ELECTROCARDIOGRAM The most cited abnormality, in addition to sinus tachycardia, is the S1Q3T3 sign: an S wave in lead I, Q wave in lead III, and inverted T wave in lead III (Chap. 221). This finding is relatively specific but insensitive. Perhaps the most frequent abnormality is T-wave inversion in leads V_1 to V_4.

TABLE 256-3 ULTRASONOGRAPHY OF THE DEEP LEG VEINS

Criteria for Establishing the Diagnosis of Acute DVT
Lack of vein compressibility (the principal criterion) Vein does not "wink" when gently compressed in cross-section Failure to appose the walls of the vein due to passive distension
Direct Visualization of Thrombus
Homogenous Low echogenicity
Abnormal Doppler Flow Dynamics
Normal response: calf compression augments Doppler flow signal and confirms vein patency proximal and distal to Doppler Abnormal response: flow blunted rather than augmented with calf compression

Noninvasive Imaging Modalities • ***VENOUS ULTRASONOGRAPHY***

Ultrasonography of the deep venous system (Table 256-3) relies upon loss of vein compressibility as the primary criterion for DVT. When a normal vein is imaged in cross-section, it readily collapses with gentle manual pressure from the ultrasound transducer. This creates the illusion of a "wink." With acute DVT, the vein loses its compressibility because of passive distension by acute thrombus. The diagnosis of acute DVT is even more secure when thrombus is directly visualized. It appears homogeneous and has low echogenicity (Fig. 256-2). The vein itself often appears mildly dilated, and collateral channels may be absent.

Venous flow dynamics can be examined with Doppler imaging. Normally, manual calf compression causes augmentation of the Doppler flow pattern. Loss of normal respiratory variation is caused by obstructing DVT or by any obstructive process within the pelvis. Because DVT and PE are so closely related and are both treated with anticoagulation (see below), confirmed DVT is usually an adequate surrogate for PE. In contrast, a normal venous ultrasound does not exclude PE. The majority of patients with PE have no imaging evidence of DVT, probably because the clot has already embolized to the lung or is in the pelvic veins, where ultrasonography is usually inadequate. In patients without DVT, the ultrasound examination may identify other reasons for leg discomfort such as a Baker's cyst (also known as a popliteal or synovial cyst) or a hematoma. For patients with a technically poor or nondiagnostic venous ultrasound, consider alternative imaging modalities for DVT such as CT or magnetic resonance imaging.

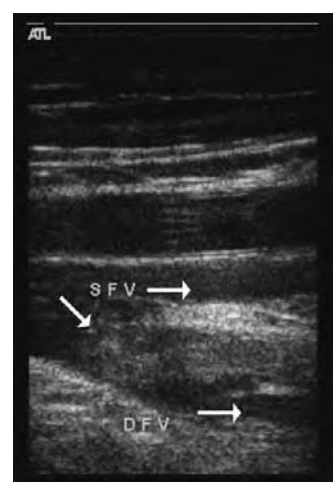

FIGURE 256-2 Acute DVT on venous ultrasound examination. The vein is not compressible and thrombus (*far left arrow*) is visualized directly in the deep venous system. SFV, superficial femoral vein (which is a deep vein, despite the terminology "superficial"); DFV, deep femoral vein (synonymous with profunda femoral vein). *(From the personal collection of Samuel Z. Goldhaber, MD; with permission.)*

CHEST ROENTGENOGRAPHY A normal or near-normal chest x-ray in a dyspneic patient often occurs in PE. Well-established abnormalities include focal oligemia (Westermark's sign), a peripheral wedged-shaped density above the diaphragm (Hampton's hump), or an enlarged right descending pulmonary artery (Palla's sign).

CHEST CT Computed tomography (CT) of the chest with intravenous contrast is the principal imaging test for the diagnosis of PE **(Fig. 256-3)**. Multidetector-row spiral CT acquires all chest images with ≤1 mm resolution during a short breath hold. This generation of CT scanners can image small peripheral emboli. Sixth-order branches can be visualized with resolution superior to conventional invasive contrast pulmonary angiography. The CT scan also obtains excellent images of the RV and LV and can be used for a risk stratification as well as a diagnostic tool. In patients with PE, RV enlargement on chest CT indicates a fivefold increased likelihood of death within the next 30 days compared with PE patients with normal RV size on chest CT. When imaging is continued below the chest to the knee, pelvic and proximal leg DVT can also be diagnosed by CT scanning. In patients without PE, the lung parenchymal images may establish alternative diagnoses not apparent on chest x-ray that explain the presenting symptoms and signs, such as pneumonia, emphysema, pulmonary fibrosis, pulmonary mass, or aortic pathology. Sometimes asymptomatic early stage lung cancer is diagnosed incidentally.

LUNG SCANNING Lung scanning is now a second-line diagnostic test for PE. It is mostly used for patients who cannot tolerate intravenous contrast. Small particulate aggregates of albumin labeled with a gamma-emitting radionuclide are injected intravenously and are trapped in the pulmonary capillary bed. The perfusion scan defect indicates absent or decreased blood flow, possibly due to PE. Ventilation scans, obtained with radiolabeled inhaled gases such as xenon or krypton, improve the specificity of the perfusion scan. Abnormal ventilation scans indicate abnormal nonventilated lung, thereby providing possible explanations for perfusion defects other than acute PE, such as asthma or chronic obstructive pulmonary disease. A high probability scan for PE is defined as having two or more segmental perfusion defects in the presence of normal ventilation.

The diagnosis of PE is very unlikely in patients with normal and near-normal scans but is about 90% certain in patients with high-probability scans. Unfortunately, most patients have nondiagnostic scans, and fewer than half of patients with angiographically confirmed PE have a high-probability scan. As many as 40% of patients with high clinical suspicion for PE and "low-probability" scans do, in fact, have PE at angiography.

FIGURE 256-3 Large bilateral proximal PE on chest CT following radical prostatectomy.

MAGNETIC RESONANCE (MR) (CONTRAST-ENHANCED) When ultrasound is equivocal, MR venography is an excellent imaging modality to diagnose DVT. MR utilizes gadolinium contrast agent, which, unlike iodinated contrast agents used in venography or CT angiography, is not nephrotoxic. MR imaging should be considered for suspected DVT or PE patients with renal insufficiency or contrast dye allergy. MR pulmonary angiography detects large proximal PE but is not reliable for smaller segmental and subsegmental PE.

ECHOCARDIOGRAPHY Echocardiography is *not* a reliable diagnostic imaging tool for acute PE because most patients with PE have normal echocardiograms. However, echocardiography is a very useful diagnostic tool for detecting conditions that might mimic PE, such as acute myocardial infarction, pericardial tamponade, or aortic dissection.

Transthoracic echocardiography rarely images thrombus directly. The best-known indirect sign of PE on transthoracic echocardiography is McConnell's sign, hypokinesis of the RV free wall with normal motion of the RV apex.

Transesophageal echocardiography should be considered when CT scanning facilities are not available or when a patient has renal failure or severe contrast allergy that precludes administration of contrast despite premedication with high dose steroids. This imaging modality can directly visualize large proximal PE.

Invasive Diagnostic Modalities • ***PULMONARY ANGIOGRAPHY*** Chest CT with contrast (see above) has virtually replaced invasive pulmonary angiography as a diagnostic test. Invasive catheter-based diagnostic testing is reserved for patients with technically unsatisfactory chest CTs or for those in whom an interventional procedure such as catheter-directed thrombolysis or embolectomy is planned. A definitive diagnosis of PE depends upon visualization of an intraluminal filling defect in more than one projection. Secondary signs of PE include abrupt occlusion ("cut-off") of vessels, segmental oligemia or avascularity, a prolonged arterial phase with slow filling, or tortuous, tapering peripheral vessels.

CONTRAST PHLEBOGRAPHY Venous ultrasonography has virtually replaced contrast phlebography as the diagnostic test for suspected DVT.

Integrated Diagnostic Approach An integrated diagnostic approach (Fig. 256-1) streamlines the workup of suspected DVT and PE **(Fig. 256-4)**.

Rx DEEP VENOUS THROMBOSIS

PRIMARY THERAPY VERSUS SECONDARY PREVENTION *Primary therapy* consists of clot dissolution with thrombolysis or removal of PE by embolectomy. Anticoagulation with heparin and warfarin or placement of an inferior vena caval filter constitutes *secondary prevention* of recurrent PE rather than primary therapy.

RISK STRATIFICATION Rapid and accurate risk stratification is critical in determining optimal treatment strategy. The presence of hemodynamic instability, RV dysfunction, or elevation of the troponin level due to RV microinfarction can identify high-risk patients. Detection of RV hypokinesis on echocardiography is the most widely used approach to risk stratification. However, RV enlargement on chest CT also predicts an increased mortality rate from PE. The combination of RV dysfunction plus elevated biomarkers such as troponin portends an especially ominous prognosis.

Primary therapy should be reserved for patients at high risk of an adverse clinical outcome. When RV function remains normal in a hemodynamically stable patient, a good clinical outcome is highly likely with anticoagulation alone **(Fig. 256-5)**.

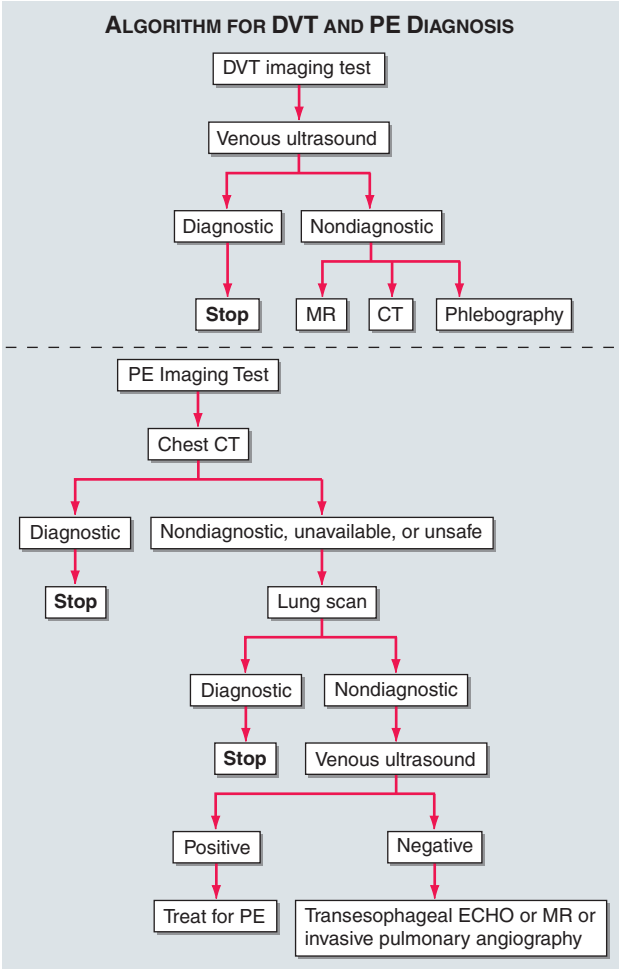

FIGURE 256-4 Imaging tests to diagnose DVT and PE.

MASSIVE PULMONARY EMBOLISM

ANTICOAGULATION Anticoagulation is the foundation for successful treatment of DVT and PE **(Table 256-4)**. Immediately effective anticoagulation is initiated with a parenteral drug: unfractionated heparin (UFH), low molecular weight heparin (LMWH), or fondaparinux. These parenteral drugs (see below) are continued as a transition or "bridge" to stable, long-term anticoagulation with a vitamin K antagonist (exclusively warfarin in the United States). The first dose of warfarin may be given as soon as several hours after the bridging anticoagulant if LMWH or fondaparinux are used. Otherwise, with UFH a therapeutic aPTT must first be documented. Warfarin requires 5–7 days to achieve a therapeutic effect. During that period, the parenteral and oral agents are overlapped. After 5–7 days of anticoagulation, residual thrombus begins to become endothelialized in the vein or pulmonary artery. However, anticoagulants do *not* directly dissolve thrombus that already exists.

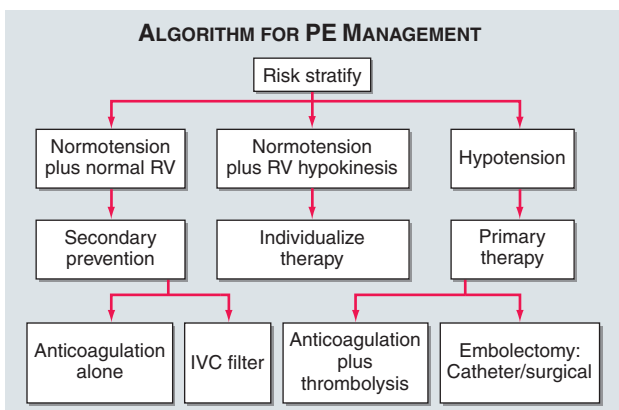

FIGURE 256-5 Acute management of pulmonary thromboembolism. RV, right ventricular; IVC, inferior vena cava.

TABLE 256-4 ANTICOAGULATION OF VTE

Immediate Parenteral Anticoagulation
Unfractionated heparin, bolus and continuous infusion, to achieve aPTT 2–3 times the upper limit of the laboratory normal, or Enoxaparin 1 mg/kg twice daily with normal renal function, or Tinzaparin 175 units/kg once daily with normal renal function, or Fondaparinux weight based once daily; adjust for impaired renal function
Warfarin Anticoagulation
Usual start dose is 5–10 mg. Titrate to INR, target 2.0–3.0. Continue parenteral anticoagulation for a minimum of 5 days and until 2 sequential INR values, at least 1 day apart, return in the target range.

Unfractionated Heparin Unfractionated heparin (UFH) anticoagulates by binding to and accelerating the activity of antithrombin III, thus preventing additional thrombus formation and permitting endogenous fibrinolytic mechanisms to lyse clot that has already formed. UFH is dosed to achieve a target activated partial thromboplastin time (aPTT) that is 2–3 times the upper limit of the laboratory normal. This is usually equivalent to an aPTT of 60–80 s. For UFH, a typical intravenous bolus is 5000–10,000 units followed by a continuous infusion of 1000–1500 units/h. Nomograms based upon a patient's weight may assist in adjusting the dose of heparin. The most popular nomogram utilizes an initial bolus of 80 units/kg, followed by an initial infusion rate of 18 units/kg per hour.

The major advantage of UFH is that it has a short half-life. Its anticoagulant effect abates after several hours. This is especially useful if the patient will undergo an invasive procedure such as surgical embolectomy.

The major disadvantage of UFH is that achieving the target aPTT can be difficult and may require repeated blood sampling and heparin dose adjustment every 4–6 h. Furthermore, by using UFH, patients are at risk of developing heparin-induced thrombocytopenia.

Low Molecular Weight Heparins These fragments of UFH exhibit less binding to plasma proteins and endothelial cells and consequently have greater bioavailability, a more predictable dose response, and a longer half-life than UFH. No monitoring or dose adjustment is needed unless the patient is markedly obese or has renal insufficiency.

Enoxaparin 1 mg/kg twice daily and *tinzaparin* 175 units/kg once daily have received U.S. Food and Drug Administration (FDA) approval for treatment of patients who present with DVT. The weight-adjusted doses must be adjusted downward in renal insufficiency because the kidneys excrete LMWH.

Fondaparinux Fondaparinux, an anti-Xa pentasaccharide, is administered by once-daily subcutaneous injection and has been approved by the FDA to treat DVT and PE. No laboratory monitoring is required. Patients weighing <50 kg receive 5 mg, 50–100 kg patients receive 7.5 mg, and patients weighing >100 kg receive 10 mg. The dose must be adjusted downward for patients with renal dysfunction because the drug is excreted by the kidneys.

Warfarin This vitamin K antagonist prevents carboxylation activation of coagulation factors II, VII, IX, and X. The full effect of warfarin requires at least 5 days, even if the prothrombin time, used for monitoring, becomes elevated more rapidly. If warfarin is initiated as monotherapy during an acute thrombotic illness, a paradoxical exacerbation of hypercoagulability can increase the likelihood of thrombosis rather than prevent it. Overlapping UFH, LMWH, or fondaparinux with warfarin for at least 5 days can counteract the early procoagulant effect of unopposed warfarin.

Dosing In an average-sized adult, warfarin is usually initiated in a dose of 5 mg. Doses of 7.5 or 10 mg can be used in obese or large-framed young patients who are otherwise healthy. Patients who are malnourished or who have received prolonged courses of antibiotics are probably deficient in vitamin K and should receive smaller initial doses of warfarin, such as 2.5 mg. The prothrombin time is standardized with the INR, which assesses the anticoagulant effect of warfarin (Chap. 59). The target INR is usually 2.5, with a range of 2.0–3.0.

The warfarin dose is titrated to achieve the target INR. Proper dosing is difficult because hundreds of drug-drug and drug-food interactions affect warfarin metabolism. Furthermore, variables such as increasing age and comorbidities such as systemic illness, malabsorption, and diarrhea reduce the warfarin-dosing requirement.

No reliable nomogram has been established to predict how individual patients will respond to warfarin. Therefore, dosing is adjusted according to an "educated guess." Centralized anticoagulation clinics have improved the efficacy and safety of warfarin dosing. Based upon a meta-analysis of trials comparing anticoagulation clinic care versus self-monitoring, patients benefit if they can self-monitor their INR with a home point-of-care fingerstick machine. The subgroup with the best results also learns to self-adjust warfarin doses.

Pharmacogenomics may provide the gateway to rational dosing of warfarin. A recent discovery is that five polymorphisms of the vitamin K receptor gene explain 25% of the variance in warfarin dosing. These polymorphisms can stratify patients into low, intermediate, and high-dose warfarin groups. An additional 10% of dosing variance can be explained by allelic variants of the cytochrome P-450 enzyme 2C9. These mutations decrease warfarin dosing because they impair the metabolism of the S-enantiomer of warfarin. In the future, if rapid turnaround of genetic testing becomes possible, warfarin could be dosed according to specific pharmacogenomic profiles.

Complications of Anticoagulants The most important adverse effect of anticoagulation is hemorrhage. For life-threatening or intracranial hemorrhage due to heparin or LMWH, protamine sulfate can be administered. There is no specific antidote for bleeding from fondaparinux.

Major bleeding from warfarin is traditionally managed with cryoprecipitate or fresh-frozen plasma (usually 2–4 units) to achieve rapid hemostasis. Recombinant human coagulation factor VIIa (rFVIIa), FDA-approved for bleeding in hemophiliacs, is widely used off-label to manage catastrophic bleeding from warfarin. The optimal dose appears to be 40 mcg/kg. The greatest risk of this therapy is rebound thromboembolism. For minor bleeding, or to manage an excessively high INR in the absence of bleeding, a small 2.5 mg dose of oral vitamin K may be administered.

Heparin-induced thrombocytopenia (HIT) and osteopenia are far less common with LMWH than with UFH. Thrombosis due to HIT should be managed with a direct thrombin inhibitor: argatroban for patients with renal insufficiency or lepirudin for patients with hepatic failure. In the setting of percutaneous coronary intervention, administer bivalirudin.

The most common nonbleeding side effect of warfarin is alopecia. A rare complication is warfarin-induced skin necrosis, which may be related to warfarin-induced reduction of protein C.

During pregnancy, warfarin should be avoided if possible because of warfarin embryopathy, which is most common with exposure during the 6th through 12th week of gestation. However, women can take warfarin postpartum and breast-feed safely. Warfarin can also be administered safely during the second trimester.

Duration of Hospital Stay Acute DVT patients with good family and social support, permanent residence, telephone, and no hearing or language impairment can often be managed as outpatients. They or a family member or a visiting nurse can administer a parenteral anticoagulant. Warfarin dosing can be titrated to the INR and adjusted on an outpatient basis.

Acute PE patients, who traditionally have required 5-7 day hospital stays for intravenous heparin as a "bridge" to warfarin, can be considered for abbreviated hospitalization if they have an excellent prognosis. The latter are characterized by clinical stability, absence of chest pain or shortness of breath, normal right ventricular size and function, and normal levels of cardiac biomarkers.

Duration of Anticoagulation Patients with PE following surgery or trauma ordinarily have a low rate of recurrence after 3–6 months of anticoagulation. For DVT isolated to an upper extremity or calf that has been provoked by surgery or trauma, 3 months of anticoagulation suffices. For provoked proximal leg DVT or PE, 6 months of anticoagulation is sufficient.

However, among patients with "idiopathic," unprovoked DVT or PE, the recurrence rate is surprisingly high after cessation of anticoagulation. VTE that occurs during long-haul air travel is considered unprovoked.

Current American College of Chest Physicians (ACCP) guidelines recommend anticoagulation for an indefinite duration with a target INR between 2.0 and 3.0 for patients with idiopathic VTE. However, I recommend that the intensity of anticoagulation be tailored to the patient's risk of recurrent VTE versus risk of bleeding. For a patient at high risk of recurrent VTE (for example, someone with multiple thrombophilic disorders) and a low risk of bleeding (for example, young age and no comorbidities), I recommend standard intensity anticoagulation. However, for a patient with a high bleeding risk (for example, older age and a prior history of gastrointestinal bleeding), I advise low-intensity anticoagulation (INR 1.5–2.0) after 6 months.

Several years ago, the presence of genetic mutations such as factor V Leiden or prothrombin gene mutation was thought to markedly increase the risk of recurrent VTE. Now, however, the clinical circumstances in which the DVT or PE occurs rather than underlying thrombophilia are considered much more important in deciding the risk of recurrence and the optimal duration of anticoagulation. However, patients with moderate or high levels of anticardiolipin antibodies probably warrant indefinite duration anticoagulation, even if the initial VTE was provoked by trauma or surgery.

INFERIOR VENA CAVAL (IVC) FILTERS The two principal indications for insertion of an IVC filter are (1) active bleeding that precludes anticoagulation, and (2) recurrent venous thrombosis despite intensive anticoagulation. Prevention of recurrent PE in patients with right heart failure who are not candidates for fibrinolysis or prophylaxis of extremely high-risk patients are "softer" indications for filter placement. The filter itself may fail by permitting the passage of small to medium-sized clots. Large thrombi may embolize to the pulmonary arteries via collateral veins that develop. A more common complication is caval thrombosis with marked bilateral leg swelling.

Paradoxically, by providing a nidus for clot formation, filters double the DVT rate over the ensuing 2 years following placement. Therefore, if clinically safe, patients receiving IVC filters should also receive concomitant anticoagulation.

Retrievable filters can now be placed for patients with an anticipated temporary bleeding disorder or for patients at temporary high risk of PE, such as individuals undergoing bariatric surgery with a prior history of perioperative PE. The filters can be retrieved up to several months following insertion, unless thrombus forms and is trapped within the filter. The retrievable filter becomes permanent if it remains in place or if, for technical reasons such as rapid endothelialization, it cannot be removed.

MAINTAINING ADEQUATE CIRCULATION For patients with massive PE and hypotension, the most common initial approach is administration of 500–1,000 ml of normal saline. However, fluids should be used with extreme caution. Excessive fluid administration exacerbates RV wall stress, causes more profound RV ischemia, and worsens LV compliance and filling by causing further interventricular septal shift toward the LV. Dopamine and dobutamine are first-line inotropic agents for treatment of PE-related shock. There should be a low threshold to initiate these pressors. However, a "trial and error" approach may be necessary with other agents such as norepinephrine, vasopressin, or phenylephrine.

FIBRINOLYSIS Successful fibrinolytic therapy rapidly reverses right heart failure and leads to a lower rate of death and recurrent PE. Thrombolysis usually (1) dissolves much of the anatomically obstructing pulmonary arterial thrombus; (2) prevents the continued release of serotonin and other neurohumoral factors that exacerbate pulmonary hypertension; and (3) dissolves much of the source of the thrombus in the pelvic or deep leg veins, thereby decreasing the likelihood of recurrent PE.

The preferred fibrinolytic regimen is 100 mg of recombinant tissue plasminogen activator (tPA) administered as a continuous peripheral intravenous infusion over 2 h. Patients appear to respond to fibrinolysis for up to 14 days after the PE has occurred.

Contraindications to fibrinolysis include intracranial disease, recent surgery, or trauma. The overall major bleeding rate is about 10%, including a 1–3% risk of intracranial hemorrhage. Careful screening of patients for contraindications to fibrinolytic therapy (Chap. 239) is the best way to minimize bleeding risk.

The only FDA-approved indication for PE fibrinolysis is massive PE. For patients with preserved systolic blood pressure and submassive PE, guidelines recommend individual patient risk assessment of the thrombotic burden versus bleeding risk. I concur with these guidelines. Younger patients with submassive PE but without comorbidities are generally excellent candidates for fibrinolysis. For older patients (>70 yrs) with risk of intracranial hemorrhage, a "watch and wait" approach is suitable, with frequent serial

evaluation of RV function by echocardiography; fibrinolysis should be considered in those with deterioration of RV function.

PULMONARY EMBOLECTOMY The risk of intracranial hemorrhage with fibrinolysis has prompted the renaissance of surgical embolectomy for acute PE. At Brigham and Women's Hospital, 47 patients with massive PE underwent emergency surgery in 53 months, with a 94% survival rate. This high survival rate may be attributed to improved surgical technique, rapid diagnosis and triage, and careful patient selection. A possible alternative to open surgical embolectomy is catheter embolectomy. New generation catheters are under development.

PULMONARY THROMBOENDARTERECTOMY Chronic thromboembolic pulmonary hypertension is caused by vascular obstruction at the capillary level, not direct thromboembolic occlusion. It used to be considered a rare complication (about 1 of 500) of acute PE. Now, however, it appears that chronic thromboembolic pulmonary hypertension is a more common development, occurring in approximately 4% of patients who develop acute PE. Therefore, PE patients should be followed to ensure that if they have initial pulmonary hypertension, it abates over time (usually 6 weeks).

Patients severely impaired with dyspnea due to chronic thromboembolic pulmonary hypertension should be considered for pulmonary thromboendarterectomy, which, if successful, can markedly reduce and at times even cure pulmonary hypertension (Chap. 244). The operation requires median sternotomy, cardiopulmonary bypass, deep hypothermia, and periods of hypothermic circulatory arrest. The fibrotic, thromboembolic material is grasped with a forceps and circumferentially dissected from the vessel wall. The mortality rate at experienced centers is approximately 5%. The two most common complications are (1) "pulmonary steal," where blood rushes from previously perfused areas to newly revascularized areas of the lung; and (2) reperfusion pulmonary edema.

EMOTIONAL SUPPORT Many patients with VTE will appear healthy and fit. They may be burdened with fear about the possible genetic implications of DVT or PE. They often feel overwhelmed when advised to continue lifelong anticoagulation. Many patients in whom anticoagulation is discontinued after 3–6 months of therapy feel vulnerable to a future recurrent VTE. They may be reluctant to discontinue warfarin. Support groups are useful. Responses to frequently asked questions by these patients have been posted on the following website: *http://web.mit.edu/karen/www/faq.html*.

PREVENTION OF POSTPHLEBITIC SYNDROME The only therapy to prevent postphlebitic syndrome is daily use of below-knee 30–40 mmHg vascular compression stockings. They halve the rate of developing postphlebitic syndrome. These vascular compression stockings should be prescribed as soon as DVT is diagnosed, and the stockings should be fitted carefully to maximize their benefit. When patients are in bed, the stockings need not be worn.

PREVENTION OF VTE

Prophylaxis is of paramount importance because VTE is difficult to detect and poses an excessive medical and economic burden. Mechanical and pharmacologic measures often succeed in preventing this complication (Table 256-5). Patients at high risk can receive a combination of mechanical and pharmacologic modalities. Graduated compression stockings and pneumatic compression devices may complement mini-dose unfractionated heparin (5000 units subcutaneously twice or preferably three times daily), low molecular weight heparin, a pentasaccharide (fondaparinux 2.5 mg daily), or warfarin administration. Computerized reminder systems can increase the use of preventive measures and at Brigham and Women's Hospital reduced the symptomatic VTE rate by more than 40%. Patients who have undergone total hip replacement, total knee replacement, or cancer surgery will benefit from extended pharmacologic prophylaxis for a total of 4–6 weeks.

TABLE 256-5 PREVENTION OF VENOUS THROMBOEMBOLISM

Condition	Prophylaxis Strategy
High-risk general surgery	Mini-UFH + GCS *or* LMWH + GCS
Thoracic surgery	Mini-UFH + IPC
Cancer surgery, including gynecologic cancer surgery	LMWH, consider 1 month of prophylaxis
Total hip replacement, total knee replacement, hip fracture surgery	LMWH, fondaparinux (a pentasaccharide) 2.5 mg sc, once daily *or* (except for total knee replacement) warfarin (target INR 2.5)
Neurosurgery	GCS + IPC
Neurosurgery for brain tumor	Mini-UFH *or* LMWH, + IPC, + predischarge venous ultrasonography
Benign gynecologic surgery	Mini-UFH + GCS
Medically ill patients	Mini-UFH *or* LMWH
Anticoagulation contraindicated	GCS + IPC
Long-haul air travel	Consider LMWH for very high risk patients

Note: Mini-UFH, minidose unfractionated heparin, 5000 units subcutaneously twice (less effective) or three times daily (more effective); GCS, graduated compression stockings, usually 10–18 mm Hg; LMWH, low-molecular-weight heparin, typically in the United States, enoxaparin, 40 mg once daily, or dalteparin, 2500 or 5000 units once daily; IPC, intermittent pneumatic compression devices.

257 Disorders of the Pleura and Mediastinum

Richard W. Light

DISORDERS OF THE PLEURA

PLEURAL EFFUSION

The pleural space lies between the lung and chest wall and normally contains a very thin layer of fluid, which serves as a coupling system. A pleural effusion is present when there is an excess quantity of fluid in the pleural space.

Etiology Pleural fluid accumulates when pleural fluid formation exceeds pleural fluid absorption. Normally, fluid enters the pleural space from the capillaries in the parietal pleura and is removed via the lymphatics situated in the parietal pleura. Fluid can also enter the pleural space from the interstitial spaces of the lung via the visceral pleura or from the peritoneal cavity via small holes in the diaphragm. The lymphatics have the capacity to absorb 20 times more fluid than is normally formed. Accordingly, a pleural effusion may develop when there is excess pleural fluid formation (from the interstitial spaces of the lung, the parietal pleura, or the peritoneal cavity) or when there is decreased fluid removal by the lymphatics.

Diagnostic Approach When a patient is found to have a pleural effusion, an effort should be made to determine the cause (Fig. 257-1). The first step is to determine whether the effusion is a transudate or an exudate. A *transudative pleural effusion* occurs when *systemic factors* that influence the formation and absorption of pleural fluid are altered. The leading causes of transudative pleural effusions in the United States are left ventricular failure and cirrhosis. An *exudative pleural effusion* occurs when *local factors* that influence the formation and absorption of pleural fluid are altered. The leading causes of exudative pleural effusions are bacterial pneumonia, malignancy, viral infection, and pulmonary embolism. The primary reason to make this differentiation is that additional diagnostic procedures are indicated with exudative effusions to define the cause of the local disease.

Transudative and exudative pleural effusions are distinguished by measuring the lactate dehydrogenase (LDH) and protein levels in the pleural fluid. Exudative pleural effusions meet at least one of the following criteria, whereas transudative pleural effusions meet none:

1. pleural fluid protein/serum protein >0.5
2. pleural fluid LDH/serum LDH >0.6
3. pleural fluid LDH more than two-thirds normal upper limit for serum

The above criteria misidentify ~25% of transudates as exudates. If one or more of the exudative criteria are met and the patient is clinically thought to have a condition producing a transudative effusion, the difference between the protein levels in the serum and the pleural fluid should be measured. If this gradient is greater than 31 g/L (3.1 g/dL), the exudative categorization by the above criteria can be ignored because almost all such patients have a transudative pleural effusion.

If a patient has an exudative pleural effusion, the following tests on the pleural fluid should be obtained: description of the fluid, glucose level, differential cell count, microbiologic studies, and cytology.

Effusion Due to Heart Failure The most common cause of pleural effusion is left ventricular failure. The effusion occurs because the increased amounts of fluid in the lung interstitial spaces exit in part across the visceral pleura. This overwhelms the capacity of the lymphatics in the parietal pleura to remove fluid. Isolated right-sided pleural effusions are more common than left-sided effusions in heart failure. A diagnostic thoracentesis should be performed if the effusions are not bilateral and comparable in size, if the patient is febrile, or if the patient has pleuritic chest pain, to verify that the patient has a transudative effusion. Otherwise the patient is best treated with diuretics. If the effusion persists despite diuretic therapy, a diagnostic thoracentesis should be performed. A pleural fluid N-terminal pro-brain natriuretic peptide (NT-proBNP) >1500 pg/mL is virtually diagnostic of an effusion secondary to congestive heart failure.

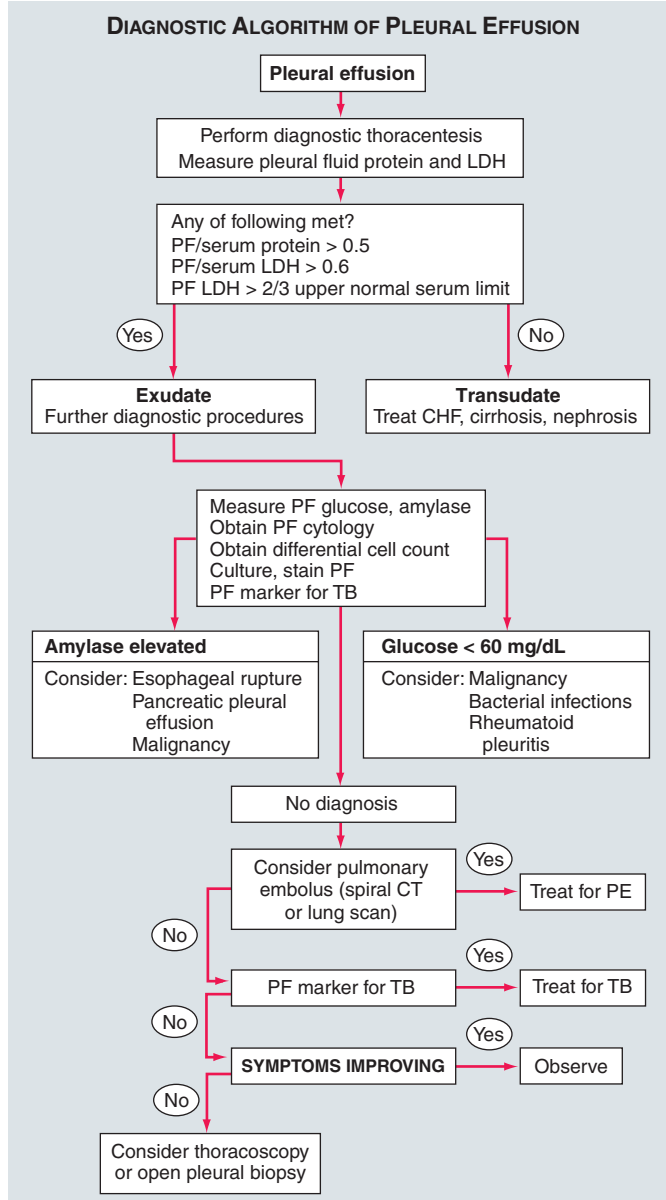

FIGURE 257-1 Approach to the diagnosis of pleural effusions. CHF, congestive heart failure; CT, computed tomography; LDH, lactate dehydrogenase; PE, pulmonary embolism; TB, tuberculosis; PF, pleural fluid.

Hepatic Hydrothorax Pleural effusions occur in ~5% of patients with cirrhosis and ascites. The predominant mechanism is the direct movement of peritoneal fluid through small openings in the diaphragm into the pleural space. The effusion is usually right-sided and frequently is large enough to produce severe dyspnea.

Parapneumonic Effusion Parapneumonic effusions are associated with bacterial pneumonia, lung abscess, or bronchiectasis and are probably the most common cause of exudative pleural effusion in the United States. *Empyema* refers to a grossly purulent effusion.

Patients with aerobic bacterial pneumonia and pleural effusion present with an acute febrile illness consisting of chest pain, sputum production, and leukocytosis. Patients with anaerobic infections present with a subacute illness with weight loss, a brisk leukocytosis, mild anemia, and a history of some factor that predisposes them to aspiration.

The possibility of a parapneumonic effusion should be considered whenever a patient with a bacterial pneumonia is initially evaluated. The presence of free pleural fluid can be demonstrated with a lateral decubitus radiograph, computed tomography (CT) of the chest, or ultrasound. If the free fluid separates the lung from the chest wall by >10 mm, a therapeutic thoracentesis should be performed. Factors indicating the likely need for a procedure more invasive than a thoracentesis (in increasing order of importance) include:

1. loculated pleural fluid
2. pleural fluid pH < 7.20
3. pleural fluid glucose < 3.3 mmol/L (<60 mg/dL)
4. positive Gram stain or culture of the pleural fluid
5. the presence of gross pus in the pleural space

If the fluid recurs after the initial therapeutic thoracentesis, and if any of the above characteristics are present, a repeat thoracentesis should be performed. If the fluid cannot be completely removed with the therapeutic thoracentesis, consideration should be given to inserting a chest tube and instilling a fibrinolytic (e.g., streptokinase, 250,000 units) or performing thoracoscopy with the breakdown of adhesions. Decortication should be considered when the above are ineffective.

Effusion Secondary to Malignancy Malignant pleural effusions secondary to metastatic disease are the second most common type of exudative pleural effusion. The three tumors that cause ~75% of all malignant pleural effusions are lung carcinoma, breast carcinoma, and lymphoma. Most patients complain of dyspnea, which is frequently out of proportion to the size of the effusion. The pleural fluid is an exudate, and its glucose level may be reduced if the tumor burden in the pleural space is high.

The diagnosis is usually made via cytology of the pleural fluid. If the initial cytologic examination is negative, then thoracoscopy is the best next procedure if malignancy is strongly suspected. At the time of thoracoscopy, a procedure such as pleural abrasion should be performed to effect a pleurodesis. If thoracoscopy is unavailable, then needle biopsy of the pleura should be performed.

Patients with a malignant pleural effusion are treated symptomatically for the most part, since the presence of the effusion indicates disseminated disease and most malignancies associated with pleural effusion are not curable with chemotherapy. The only symptom that can be attributed to the effusion itself is dyspnea. If the patient's lifestyle is compromised by dyspnea, and if the dyspnea is relieved with a therapeutic thoracentesis, then one of the following procedures should be considered: (1) insertion of a small indwelling catheter; or (2) tube thoracostomy with the instillation of a sclerosing agent such as doxycycline, 500 mg.

Mesothelioma Malignant mesotheliomas are primary tumors that arise from the mesothelial cells that line the pleural cavities; most are related to asbestos exposure. Patients with mesothelioma present with chest pain and shortness of breath. The chest radiograph reveals a pleural effusion, generalized pleural thickening, and a shrunken hemithorax. Thoracoscopy or open pleural biopsy is usually necessary to establish the diagnosis. Chest pain should be treated with opiates and shortness of breath with oxygen and/or opiates.

Effusion Secondary to Pulmonary Embolization The diagnosis most commonly overlooked in the differential diagnosis of a patient with an undiagnosed pleural effusion is pulmonary embolism. Dyspnea is the most common symptom. The pleural fluid is almost always an exudate. The diagnosis is established by spiral CT scan or pulmonary arteriography (Chap. 256). Treatment of the patient with a pleural effusion secondary to pulmonary embolism is the same as for any patient with pulmonary emboli. If the pleural effusion increases in size after anticoagulation, the patient probably has recurrent emboli or another complication such as a hemothorax or a pleural infection.

Tuberculous Pleuritis (See also Chap. 158) In many parts of the world, the most common cause of an exudative pleural effusion is tuberculosis (TB), but tuberculous effusions are relatively uncommon in the United States. Tuberculous pleural effusions are usually associated with primary TB and are thought to be due primarily to a hypersensitivity reaction to tuberculous protein in the pleural space. Patients with tuberculous pleuritis present with fever, weight loss, dyspnea, and/or pleuritic chest pain. The pleural fluid is an exudate with predominantly small lymphocytes. The diagnosis is established by demonstrating high levels of TB markers in the pleural fluid (adenosine deaminase > 40 IU/L, interferon γ > 140 pg/mL, or positive polymerase chain reaction (PCR) for tuberculous DNA). Alternatively, the diagnosis can be established by culture of the pleural fluid, needle biopsy of the pleura, or thoracoscopy. The recommended treatment of pleural and pulmonary TB is identical (Chap. 158).

Effusion Secondary to Viral Infection Viral infections are probably responsible for a sizable percentage of undiagnosed exudative pleural effusions. In many series, no diagnosis is established for ~20% of exudative effusions, and these effusions resolve spontaneously with no long-term residua. The importance of these effusions is that one should not be too aggressive in trying to establish a diagnosis for the undiagnosed effusion, particularly if the patient is improving clinically.

AIDS (See also Chap. 182) Pleural effusions are uncommon in such patients. The most common cause is Kaposi's sarcoma, followed by parapneumonic effusion. Other common causes are TB, cryptococcosis, and primary effusion lymphoma. Pleural effusions are very uncommon with *Pneumocystis carinii* infection.

Chylothorax A chylothorax occurs when the thoracic duct is disrupted and chyle accumulates in the pleural space. The most common cause of chylothorax is trauma, but it also may result from tumors in the mediastinum. Patients with chylothorax present with dyspnea, and a large pleural effusion is present on the chest radiograph. Thoracentesis reveals milky fluid, and biochemical analysis reveals a triglyceride level that exceeds 1.2 mmol/L (110 mg/dL). Patients with chylothorax and no obvious trauma should have a lymphangiogram and a mediastinal CT scan to assess the mediastinum for lymph nodes. The treatment of choice for most chylothoraces is insertion of a chest tube plus the administration of octreotide. If these modalities fail, a pleuroperitoneal shunt should be placed unless the patient has chylous ascites. Patients with chylothoraces should not undergo prolonged tube thoracostomy with chest tube drainage because this will lead to malnutrition and immunologic incompetence.

Hemothorax When a diagnostic thoracentesis reveals bloody pleural fluid, a hematocrit should be obtained on the pleural fluid. If the hematocrit is more than half of that in the peripheral blood, the patient is considered to have a hemothorax. Most hemothoraces are the result of trauma; other causes include rupture of a blood vessel or tumor. Most patients with hemothorax should be treated with tube thoracostomy, which allows continuous quantification of bleeding. If the bleeding emanates from a laceration of the pleura, apposition of the two pleural surfaces is likely to stop the bleeding. If the pleural hemorrhage exceeds 200 mL/h, consideration should be given to thoracoscopy or thoracotomy.

Miscellaneous Causes of Pleural Effusion There are many other causes of pleural effusion (Table 257-1). Key features of some of these conditions are as follows: If the pleural fluid amylase level is elevated, the diagnosis of esophageal rupture or pancreatic disease is likely. If the patient is febrile, has predominantly polymorphonuclear cells in the pleural fluid, and has no pulmonary parenchymal abnormalities, an intraabdominal abscess should be considered. The diagnosis of an asbestos pleural effusion is one of exclusion. Benign ovarian tumors can produce ascites and a pleural effusion (Meigs' syndrome), as can the ovarian hyperstimulation syndrome. Several drugs can cause pleural effusion; the associated fluid is usually eosinophilic. Pleural effusions commonly occur following coronary artery bypass surgery. Effusions occurring within the first

TABLE 257-1 DIFFERENTIAL DIAGNOSES OF PLEURAL EFFUSIONS

Transudative Pleural Effusions

1. Congestive heart failure
2. Cirrhosis
3. Pulmonary embolization
4. Nephrotic syndrome
5. Peritoneal dialysis
6. Superior vena cava obstruction
7. Myxedema
8. Urinothorax

Exudative Pleural Effusions

1. Neoplastic diseases
   a. Metastatic disease
   b. Mesothelioma
2. Infectious diseases
   a. Bacterial infections
   b. Tuberculosis
   c. Fungal infections
   d. Viral infections
   e. Parasitic infections
3. Pulmonary embolization
4. Gastrointestinal disease
   a. Esophageal perforation
   b. Pancreatic disease
   c. Intraabdominal abscesses
   d. Diaphragmatic hernia
   e. After abdominal surgery
   f. Endoscopic variceal sclerotherapy
   g. After liver transplant
5. Collagen-vascular diseases
   a. Rheumatoid pleuritis
   b. Systemic lupus erythematosus
   c. Drug-induced lupus
   d. Immunoblastic lymphadenopathy
   e. Sjögren's syndrome
   f. Wegener's granulomatosis
   g. Churg-Strauss syndrome
6. Post-coronary artery bypass surgery
7. Asbestos exposure
8. Sarcoidosis
9. Uremia
10. Meigs' syndrome
11. Yellow nail syndrome
12. Drug-induced pleural disease
    a. Nitrofurantoin
    b. Dantrolene
    c. Methysergide
    d. Bromocriptine
    e. Procarbazine
    f. Amiodarone
13. Trapped lung
14. Radiation therapy
15. Post-cardiac injury syndrome
16. Hemothorax
17. Iatrogenic injury
18. Ovarian hyperstimulation syndrome
19. Pericardial disease
20. Chylothorax

weeks are typically left-sided and bloody, with large numbers of eosinophils, and respond to one or two therapeutic thoracenteses. Effusions occurring after the first few weeks are typically left-sided and clear yellow, with predominantly small lymphocytes, and tend to recur. Other medical manipulations that induce pleural effusions include abdominal surgery; radiation therapy; liver, lung, or heart transplantation; or the intravascular insertion of central lines.

PNEUMOTHORAX

Pneumothorax is the presence of gas in the pleural space. A *spontaneous pneumothorax* is one that occurs without antecedent trauma to the thorax. A *primary spontaneous pneumothorax* occurs in the absence of underlying lung disease, while a *secondary pneumothorax* occurs in its presence. A *traumatic pneumothorax* results from penetrating or nonpenetrating chest injuries. A *tension pneumothorax* is a pneumothorax in which the pressure in the pleural space is positive throughout the respiratory cycle.

Primary Spontaneous Pneumothorax Primary spontaneous pneumothoraces are usually due to rupture of apical pleural blebs, small cystic spaces that lie within or immediately under the visceral pleura. Primary spontaneous pneumothoraces occur almost exclusively in smokers, which suggests that these patients have subclinical lung disease. Approximately one-half of patients with an initial primary spontaneous pneumothorax will have a recurrence. The initial recommended treatment for primary spontaneous pneumothorax is simple aspiration. If the lung does not expand with aspiration, or if the patient has a recurrent pneumothorax, thoracoscopy with stapling of blebs and pleural abrasion is indicated. Thoracoscopy or thoracotomy with pleural abrasion is almost 100% successful in preventing recurrences.

Secondary Pneumothorax Most secondary pneumothoraces are due to chronic obstructive pulmonary disease, but pneumothoraces have been reported with virtually every lung disease. Pneumothorax in patients with lung disease is more life-threatening than it is in normal individuals because of the lack of pulmonary reserve in these patients. Nearly all patients with secondary pneumothorax should be treated with tube thoracostomy. Most should also be treated with thoracoscopy or thoracotomy with the stapling of blebs and pleural abrasion. If the patient is not a good operative candidate or refuses surgery, then pleurodesis should be attempted by the intrapleural injection of a sclerosing agent such as doxycycline.

Traumatic Pneumothorax Traumatic pneumothoraces can result from both penetrating and nonpenetrating chest trauma. Traumatic pneumothoraces should be treated with tube thoracostomy unless they are very small. If a hemopneumothorax is present, one chest tube should be placed in the superior part of the hemithorax to evacuate the air, and another should be placed in the inferior part of the hemithorax to remove the blood. Iatrogenic pneumothorax is a type of traumatic pneumothorax that is becoming more common. The leading causes are transthoracic needle aspiration, thoracentesis, and the insertion of central intravenous catheters. Most can be managed with supplemental oxygen or aspiration, but if these are unsuccessful a tube thoracostomy should be performed.

Tension Pneumothorax This condition usually occurs during mechanical ventilation or resuscitative efforts. The positive pleural pressure is life-threatening both because ventilation is severely compromised and because the positive pressure is transmitted to the mediastinum, which results in decreased venous return to the heart and reduced cardiac output.

Difficulty in ventilation during resuscitation or high peak inspiratory pressures during mechanical ventilation strongly suggests the diagnosis. The diagnosis is made by physical examination showing an enlarged hemithorax with no breath sounds, hyperresonance to percussion, and shift of the mediastinum to the contralateral side. Tension pneumothorax must be treated as a medical emergency. If the tension in the pleural space is not relieved, the patient is likely to die from inadequate cardiac output or marked hypoxemia. A large-bore needle should be inserted into the pleural space through the second anterior intercostal space. If large amounts of gas escape from the needle after insertion, the diagnosis is confirmed. The needle should be left in place until a thoracostomy tube can be inserted.

DISORDERS OF THE MEDIASTINUM

The mediastinum is the region between the pleural sacs. It is separated into three compartments. The *anterior mediastinum* extends from the sternum anteriorly to the pericardium and brachiocephalic vessels posteriorly. It contains the thymus gland, the anterior mediastinal lymph nodes, and the internal mammary arteries and veins. The *middle mediastinum* lies between the anterior and posterior mediastina and contains the heart; the ascending and transverse arches of the aorta; the venae cavae; the brachiocephalic arteries and veins; the phrenic nerves; the trachea, main bronchi, and their contiguous lymph nodes; and the pulmonary arteries and veins. The *posterior mediastinum* is bounded by the pericardium and trachea anteriorly and the vertebral column posteriorly. It contains the descending thoracic aorta, esophagus, thoracic duct, azygos and hemiazygos veins, and the posterior group of mediastinal lymph nodes.

MEDIASTINAL MASSES

The first step in evaluating a mediastinal mass is to place it in one of the three mediastinal compartments, since each has different characteristic lesions. The most common lesions in the anterior mediastinum are thymomas, lymphomas, teratomatous neoplasms, and thyroid masses. The most common masses in the middle mediastinum are vascular masses, lymph node enlargement from metastases or granulomatous disease, and pleuropericardial and bronchogenic cysts. In the posterior mediastinum, neurogenic tumors, meningoceles, meningomyeloceles, gastroenteric cysts, and esophageal diverticula are commonly found.

CT scanning is the most valuable imaging technique for evaluating mediastinal masses and is the only imaging technique that should be

done in most instances. Barium studies of the gastrointestinal tract are indicated in many patients with posterior mediastinal lesions, since hernias, diverticula, and achalasia are readily diagnosed in this manner. An ^{131}I scan can efficiently establish the diagnosis of intrathoracic goiter.

A definite diagnosis can be obtained with mediastinoscopy or anterior mediastinotomy in many patients with masses in the anterior or middle mediastinal compartments. A diagnosis can be established without thoracotomy via percutaneous fine-needle aspiration biopsy or endoscopic transesophageal or endobronchial ultrasound-guided biopsy of mediastinal masses in most cases. Alternative ways to establish the diagnosis are video-assisted thoracoscopy, mediastinoscopy, or mediastinotomy. In many cases the diagnosis can be established and the mediastinal mass removed with video-assisted thoracoscopy.

ACUTE MEDIASTINITIS

Most cases of acute mediastinitis either are due to esophageal perforation or occur after median sternotomy for cardiac surgery. Patients with esophageal rupture are acutely ill with chest pain and dyspnea due to the mediastinal infection. The esophageal rupture can occur spontaneously or as a complication of esophagoscopy or the insertion of a Blakemore tube. Appropriate treatment is exploration of the mediastinum with primary repair of the esophageal tear and drainage of the pleural space and the mediastinum.

The incidence of mediastinitis following median sternotomy is 0.4–5.0%. Patients most commonly present with wound drainage. Other presentations include sepsis or a widened mediastinum. The diagnosis is usually established with mediastinal needle aspiration. Treatment includes immediate drainage, debridement, and parenteral antibiotic therapy, but the mortality still exceeds 20%.

CHRONIC MEDIASTINITIS

The spectrum of chronic mediastinitis ranges from granulomatous inflammation of the lymph nodes in the mediastinum to fibrosing mediastinitis. Most cases are due to TB or histoplasmosis, but sarcoidosis, silicosis, and other fungal diseases are at times causative. Patients with granulomatous mediastinitis are usually asymptomatic. Those with fibrosing mediastinitis usually have signs of compression of some mediastinal structure such as the superior vena cava or large airways, phrenic or recurrent laryngeal nerve paralysis, or obstruction of the pulmonary artery or proximal pulmonary veins. Other than antituberculous therapy for tuberculous mediastinitis, no medical or surgical therapy has been demonstrated to be effective for mediastinal fibrosis.

PNEUMOMEDIASTINUM

In this condition, there is gas in the interstices of the mediastinum. The three main causes are: (1) alveolar rupture with dissection of air into the mediastinum; (2) perforation or rupture of the esophagus, trachea, or main bronchi; and (3) dissection of air from the neck or the abdomen into the mediastinum. Typically, there is severe substernal chest pain with or without radiation into the neck and arms. The physical examination usually reveals subcutaneous emphysema in the suprasternal notch and *Hamman's sign*, which is a crunching or clicking noise synchronous with the heartbeat and best heard in the left lateral decubitus position. The diagnosis is confirmed with the chest radiograph. Usually no treatment is required, but the mediastinal air will be absorbed faster if the patient inspires high concentrations of oxygen. If mediastinal structures are compressed, the compression can be relieved with needle aspiration.

258 Disorders of Ventilation

Eliot A. Phillipson

HYPOVENTILATION

DEFINITION AND ETIOLOGY

Alveolar hypoventilation exists by definition when arterial P_{CO_2} (Pa_{CO_2}) increases above the normal range of 37–43 mmHg, but in clinically important hypoventilation syndromes Pa_{CO_2} is generally in the range of 50–80 mmHg. Hypoventilation disorders can be acute or chronic. This chapter deals with chronic hypoventilation syndromes. **The acute disorders, which represent life-threatening emergencies, are discussed in Chap. 262.**

Chronic hypoventilation can result from numerous disease entities **(Table 258-1)**, but in all cases the underlying mechanism involves a defect in either the metabolic respiratory control system, the respiratory neuromuscular system, or the ventilatory apparatus. Disorders associated with impaired respiratory drive, defects in the respiratory neuromuscular system, some chest wall disorders such as obesity, and upper airway obstruction produce an increase in Pa_{CO_2}, despite normal lungs, because of a reduction in overall minute volume of ventilation and hence in alveolar ventilation. In contrast, most disorders of the chest wall and disorders of the lower airways and lungs may produce an increase in Pa_{CO_2}, despite a normal or even increased minute volume of ventilation, because of severe ventilation-perfusion mismatching that results in net alveolar hypoventilation.

Several hypoventilation syndromes involve combined disturbances in two elements of the respiratory system. For example, patients with chronic obstructive pulmonary disease may hypoventilate not simply because of impaired ventilatory mechanics but also because of a reduced central respiratory drive, which can be inherent or secondary to a coexisting metabolic alkalosis (related to diuretic and steroid therapy).

PHYSIOLOGIC AND CLINICAL FEATURES

Regardless of cause, the hallmark of all alveolar hypoventilation syndromes is an increase in alveolar P_{CO_2} ($P_{A_{CO_2}}$) and therefore in Pa_{CO_2} **(Fig. 258-1)**. The resulting respiratory acidosis eventually leads to a compensatory increase in plasma HCO_3^- concentration and a decrease in Cl^- concentration. The increase in $P_{A_{CO_2}}$ produces an obligatory decrease in $P_{A_{O_2}}$, resulting in hypoxemia. If severe, the hypoxemia manifests clinically as cyanosis and can stimulate erythropoiesis and induce secondary polycythemia. The combination of chronic hypoxemia and hypercapnia may also induce pulmonary vasoconstriction, leading eventually to pulmonary hypertension, right ventricular hypertrophy, and congestive heart failure. The disturbances in arterial blood gases are typically magnified during sleep because of a further reduction in central respiratory drive. The resulting increased nocturnal hypercapnia may cause cerebral vasodilation leading to morning headache; sleep quality may also be severely impaired, resulting in morning fatigue, daytime somnolence, mental confusion, and intellectual impairment. Other clinical features associated with hypoventilation syndromes are related to the specific underlying disease (Table 258-1).

TABLE 258-1 CHRONIC HYPOVENTILATION SYNDROMES

Mechanism	Site of Defect	Disorder
Impaired respiratory drive	Peripheral and central chemoreceptors	Carotid body dysfunction, trauma Prolonged hypoxia Metabolic alkalosis
	Brainstem respiratory neurons	Bulbar poliomyelitis, encephalitis Brainstem infarction, hemorrhage, trauma Brainstem demyelination, degeneration Chronic drug administration Hypothyroidism Primary alveolar hypoventilation syndrome
Defective respiratory neuromuscular system	Spinal cord and peripheral nerves	High cervical trauma Poliomyelitis Motor neuron disease Peripheral neuropathy
	Respiratory muscles	Myasthenia gravis Muscular dystrophy Chronic myopathy

DIAGNOSIS

Investigation of the patient with chronic hypoventilation involves several laboratory tests that will usually localize the disorder to either the metabolic respiratory control system, the neuromuscular system, or the ventilatory apparatus (Fig. 258-2). Defects in the control system impair responses to chemical stimuli, including ventilatory, occlusion pressure, and diaphragmatic electromyographic (EMG) responses. During sleep, hypoventilation is usually more marked, and central apneas and hypopneas are common. However, because the behavioral respiratory control system (which is anatomically distinct from the metabolic control system), the neuromuscular system, and the ventilatory apparatus are intact, such patients can usually hyperventilate voluntarily, generate normal inspiratory and expiratory muscle pressures (PI_{max}, PE_{max}, respectively) against an occluded airway, generate normal lung volumes and flow rates on routine spirometry, and have normal respiratory system resistance and compliance and a normal alveolar-arterial P_{O_2}[(A–a)P_{O_2}] difference.

Patients with defects in the respiratory neuromuscular system also have impaired responses to chemical stimuli but in addition are unable to hyperventilate voluntarily or to generate normal static respiratory muscle pressures, lung volumes, and flow rates. However, at least in the early stages of the disease, the resistance and compliance of the respiratory system and the alveolar-arterial oxygen difference are normal.

Site of defect	Responses to CO_2, hypoxia: Ventil.	P.1	EMGdi	Sleep studies	Voluntary hyperventil.	PI_{max} PE_{max}	Volume flow rates	Resistance, compliance	(A–a) Po_2
Metabolic control system (chemoreceptors, brainstem integrating neurons)	↓	↓	↓	↑ Hypoventil, central apneas	N	N	N	N	N
Respiratory neuromuscular system (brainstem motoneurons, spinal cord, respiratory nerves, and muscles)	↓	↓	↓	↑ Hypoventil, central apneas	↓	↓	↓	N	N
Ventilatory apparatus (chest wall, lungs, airways)	↓	N	N	Variable	↓	N	Abnormal	Abnormal	↑

FIGURE 258-2 Pattern of laboratory test results in alveolar hypoventilation syndromes, based on the site of defect. Ventil, ventilation; P.1, mouth pressure generated after 0.1 s of inspiration against an occluded airway; EMGdi, diaphragmatic EMG; PI_{max}, PE_{max}, maximum inspiratory or expiratory pressure that can be generated against an occluded airway; (A–a)P_{O_2}, alveolar-arterial P_{O_2} difference; N, normal. Defects in the metabolic control system impair central respiratory drive in response to chemical stimuli (CO_2 or hypoxia); therefore responses of EMGdi, P.1, and minute volume of ventilation are reduced and hypoventilation during sleep is aggravated. In contrast, tests of voluntary respiratory control, muscle strength, lung mechanics, and gas exchange [(A–a)P_{O_2}] are normal. Defects in the respiratory neuromuscular system impair muscle strength; therefore all tests dependent on muscular activity (voluntary or in response to metabolic stimuli) are abnormal, but lung resistance, lung compliance, and gas exchange are normal. Defects in the ventilatory apparatus usually impair gas exchange. Because resistance and compliance are also impaired, all tests dependent on ventilation (whether voluntary or in response to chemical stimuli) are abnormal; in contrast, tests of muscle activity or strength that do not involve airflow (i.e., P.1, EMGdi, PI_{max}, PE_{max}) are normal. *(After Phillipson and Duffin.)*

In contrast to patients with disorders of the respiratory control or neuromuscular systems, patients with disorders of the chest wall, lungs, and airways typically demonstrate abnormalities of respiratory system resistance and compliance and have a widened $(A–a)P_{O_2}$. Because of the impaired mechanics of breathing, routine spirometric tests are abnormal, as is the ventilatory response to chemical stimuli. However, because the neuromuscular system is intact, tests that are independent of resistance and compliance are usually normal, including tests of respiratory muscle strength and respiratory control that do not involve airflow.

℞ HYPOVENTILATION

The management of chronic hypoventilation must be individualized to the patient's particular disorder, circumstances, and needs and should include measures directed toward the underlying disease. Coexistent metabolic alkalosis should be corrected, including elevations of HCO_3^- that are inappropriately high for the degree of chronic hypercapnia. Administration of supplemental oxygen is effective in attenuating hypoxemia, polycythemia, and pulmonary hypertension but can aggravate CO_2 retention and the associated neurologic symptoms. For this reason, supplemental oxygen must be prescribed judiciously and the results monitored carefully. Pharmacologic agents that stimulate respiration, such as progesterone and methylxanthines, are of benefit in some patients, but results are generally disappointing.

Most patients with chronic hypoventilation related to impairment of respiratory drive or neuromuscular disease eventually require mechanical ventilatory assistance for effective management. When hypoventilation is severe, treatment may be required on a 24-h basis, but in most patients ventilatory assistance only during sleep produces dramatic improvement in clinical features and daytime arterial blood gases. In patients with reduced respiratory drive but intact respiratory lower motor neurons, phrenic nerves, and respiratory muscles, diaphragmatic pacing through an implanted phrenic electrode can be very effective. However, for patients with defects in the respiratory nerves and muscles, electrophrenic pacing is contraindicated. Such patients can usually be managed effectively with either intermittent negative-pressure ventilation in a cuirass or intermittent positive-pressure ventilation delivered through a tracheostomy or nose mask. For patients who require ventilatory assistance only during sleep, positive-pressure ventilation through a nose mask is the preferred method because it obviates a tracheostomy and avoids the problem of upper airway occlusion that can arise in a negative-pressure ventilator. Hypoventilation related to restrictive disorders of the chest wall (Table 258-1) can also be managed effectively with nocturnal intermittent positive-pressure ventilation through a nose mask or tracheostomy.

HYPOVENTILATION SYNDROMES

PRIMARY ALVEOLAR HYPOVENTILATION

Primary alveolar hypoventilation (PAH) is a disorder of unknown cause characterized by chronic hypercapnia and hypoxemia in the absence of identifiable neuromuscular disease or mechanical ventilatory impairment. The disorder is thought to arise from a defect in the metabolic respiratory control system, but few neuropathologic studies have been reported in such patients. Studies in animals suggest an important role for genetic factors in the pathogenesis of hypoventilation, and familial cases in humans have been described. Isolated PAH is relatively rare, and although it occurs in all age groups, the majority of reported cases in adults have been in males ages 20–50 years. The disorder typically develops insidiously and often first comes to attention when severe respiratory depression follows administration of standard doses of sedatives or anesthetics. As the degree of hypoventilation increases, patients typically develop lethargy, fatigue, daytime somnolence, disturbed sleep, and morning headaches; eventually cyanosis, polycythemia, pulmonary hypertension, and congestive heart failure occur (Fig. 258-1). Despite severe arterial blood gas derangements, dyspnea is uncommon, presumably because of impaired chemoreception and ventilatory drive. If left untreated, PAH is usually progressive over a period of months to years and ultimately fatal.

The key diagnostic finding in PAH is a chronic respiratory acidosis in the absence of respiratory muscle weakness or impaired ventilatory mechanics (Fig. 258-2). Because patients can hyperventilate voluntarily and reduce Pa_{CO_2} to normal or even hypocapnic levels, hypercapnia may not be demonstrable in a single arterial blood sample, but the presence of an elevated plasma HCO_3^- level should draw attention to the underlying chronic disturbance. Despite normal ventilatory mechanics and respiratory muscle strength, ventilatory responses to chemical stimuli are reduced or absent (Fig. 258-2), and breath-holding time may be markedly prolonged without any sensation of dyspnea.

Patients with PAH maintain rhythmic respiration when awake, although the level of ventilation is below normal. However, during sleep, when breathing is critically dependent on the metabolic control system, there is typically a further deterioration in ventilation, with frequent episodes of central hypopnea or apnea.

PAH must be distinguished from other central hypoventilation syndromes that are secondary to underlying neurologic disease of the brainstem or chemoreceptors (Table 258-1). This distinction requires a careful neurologic investigation for evidence of brainstem or autonomic disturbances. Unrecognized respiratory neuromuscular disorders, particularly those that produce diaphragmatic weakness, are often misdiagnosed as PAH. However, such disorders can usually be suspected on clinical grounds (see below) and can be confirmed by the finding of reduced voluntary hyperventilation, as well as $P_{I_{max}}$ and $P_{E_{max}}$.

Patients with PAH must be cautioned against the use of sedative medications, which may readily induce acute respiratory failure. Some patients respond favorably to respiratory stimulant medications and to supplemental oxygen. However, the majority eventually require mechanical ventilatory assistance. Excellent long-term benefits can be achieved with diaphragmatic pacing by electrophrenic stimulation or with negative- or positive-pressure mechanical ventilation. The administration of such treatment only during sleep is sufficient in most patients.

RESPIRATORY NEUROMUSCULAR DISORDERS

Several primary disorders of the spinal cord, peripheral respiratory nerves, and respiratory muscles produce a chronic hypoventilation syndrome (Table 258-1). Hypoventilation usually develops gradually over a period of months to years and often first comes to attention when a relatively trivial increase in mechanical ventilatory load (such as mild airways obstruction) produces severe respiratory failure. In some of the disorders (such as motor neuron disease, myasthenia gravis, and muscular dystrophy), involvement of the respiratory nerves or muscles is usually a later feature of a more widespread disease. In other disorders, respiratory involvement can be an early or even isolated feature, and hence the underlying problem is often not suspected. Included in this category are the postpolio syndrome (a form of chronic respiratory insufficiency that develops 20–30 years following recovery from poliomyelitis), the myopathy associated with adult acid maltase deficiency, and idiopathic diaphragmatic paralysis.

Generally, respiratory neuromuscular disorders do not result in chronic hypoventilation unless there is significant weakness of the diaphragm. Distinguishing features of bilateral diaphragmatic weakness include orthopnea, paradoxical movement of the abdomen in the supine posture, and paradoxical diaphragmatic movement under fluoroscopy. However, the absence of these features does not exclude diaphragmatic weakness. Important laboratory features are a fall in forced vital capacity in the supine, compared to the upright, posture; a rapid deterioration of ventilation during a maximum voluntary ventilation maneuver; and reduced $P_{I_{max}}$ and $P_{E_{max}}$ (Fig. 258-2). More sophisticated investigations reveal reduced or absent transdiaphragmatic pressures, calculated from simultaneous measurement of esophageal and gastric pressures; reduced diaphragmatic EMG responses (recorded from an esophageal electrode) to transcutaneous phrenic nerve stimulation; and marked hypopnea and arterial oxygen desaturation during rapid eye movement sleep, when there is normally a physiologic inhibition of all nondiaphragmatic respiratory muscles and breathing becomes critically dependent on diaphragmatic activity.

The management of chronic alveolar hypoventilation due to respiratory neuromuscular disease involves treatment of the underlying disorder, where feasible, and mechanical ventilatory assistance as described for the PAH syndrome. However, electrophrenic diaphragmatic pacing is contraindicated in these disorders, except for high cervical spinal cord lesions in which the phrenic lower motor neurons and nerves are intact.

OBESITY-HYPOVENTILATION SYNDROME

Massive obesity represents a mechanical load to the respiratory system because the added weight on the rib cage and abdomen serves to reduce the compliance of the chest wall. As a result, the functional residual capacity (i.e., end-expiratory lung volume) is reduced, particularly in the recumbent posture. An important consequence of breathing at a low lung volume is that some airways, particularly those in the lung bases, may be closed throughout part or even all of each tidal breath, resulting in underventilation of the lung bases and widening of the $(A–a)P_{O_2}$. Nevertheless, in the majority of obese individuals, central respiratory drive is increased sufficiently to maintain a normal Pa_{CO_2}. However, a small proportion of obese patients develop chronic hypercapnia, hypoxemia, and eventually polycythemia, pulmonary hypertension, and right-sided heart failure. Studies in mice demonstrate that genetically obese mice lacking circulating leptin also develop chronic hypoventilation that can be reversed by leptin infusions. In humans with obesity-hypoventilation syndrome, serum leptin levels are elevated, suggesting that leptin resistance may play a role in the pathogenesis of the disorder.

In many patients, obstructive sleep apnea (Chap. 259) is a prominent feature, and even in those patients without sleep apnea, sleep-induced hypoventilation is an important element of the disorder and contributes to its progression. Most patients demonstrate a decrease in central respiratory drive, which may be inherent or acquired, and many have mild to moderate degrees of airflow obstruction, usually related to smoking. Based on these considerations, several therapeutic measures can be of considerable benefit, including weight loss, cessation of smoking, elimination of obstructive sleep apnea, and enhancement of respiratory drive by medications such as progesterone.

HYPERVENTILATION AND ITS SYNDROMES

DEFINITION AND ETIOLOGY

Alveolar hyperventilation exists when Pa_{CO_2} decreases below the normal range of 37–43 mmHg. *Hyperventilation* is not synonymous with *hyperpnea*, which refers to an increased minute volume of ventilation without reference to Pa_{CO_2}. Although hyperventilation is frequently associated with dyspnea, patients who are hyperventilating do not necessarily complain of shortness of breath; and conversely, patients with dyspnea need not be hyperventilating.

Numerous disease entities can be associated with alveolar hyperventilation (Table 258-2), but in all cases the underlying mechanism involves an increase in respiratory drive that is mediated through either the behavioral or the metabolic respiratory control systems (Fig. 258-3). Thus, hypoxemia drives ventilation by stimulating the peripheral chemoreceptors, and several pulmonary disorders and congestive heart failure drive ventilation by stimulating afferent vagal receptors in the lungs and airways. Low cardiac output and hypotension stimulate the peripheral chemoreceptors and inhibit the baroreceptors, both of which increase ventilation. Metabolic acidosis, a potent respiratory stimulant, excites both the peripheral and central chemoreceptors and increases the sensitivity of the peripheral chemoreceptors to coexistent hypoxemia. Hepatic failure can also produce hyperventilation, presumably as a result of metabolic stimuli acting on the peripheral and central chemoreceptors.

Several neurologic and psychological disorders are thought to drive ventilation through the behavioral respiratory control system. Included in this category are psychogenic or anxiety hyperventilation and severe cerebrovascular insufficiency, which may interfere with the inhibitory influence normally exerted by cortical structures on the brainstem respiratory neurons. Rarely, disorders of the midbrain and hypothalamus induce hyperventilation, and it is conceivable that fever and sepsis also cause hyperventilation through effects on these structures. Several drugs cause hyperventilation by stimulating the central or peripheral chemoreceptors or by direct action on the brainstem respiratory neurons. Chronic hyperventilation is a normal feature of pregnancy and results from the effects of progesterone and other hormones acting on the respiratory neurons.

PHYSIOLOGIC AND CLINICAL FEATURES

Because hyperventilation is associated with increased respiratory drive, muscle effort, and minute volume of ventilation, the most frequent symptom associated with hyperventilation is dyspnea. However, there is considerable discrepancy between the degree of hyperventilation, as measured by Pa_{CO_2}, and the degree of associated dyspnea. From a physiologic standpoint, hyperventilation is beneficial in patients who are hypoxemic, because the alveolar hypocapnia is associated with an increase in alveolar and arterial P_{O_2}. Conversely, hyperventilation can also be detrimental. In particular, the alkalemia associated with hypocapnia may produce neurologic symptoms, including dizziness, visual impairment, syncope, and seizure activity (secondary to cerebral vasoconstriction); paresthesia, carpopedal spasm, and tetany (secondary to decreased free serum calcium); and muscle weakness (secondary to hypophosphatemia). It may also be associated with panic attacks, and severe alkalemia can induce cardiac arrhythmias and evidence of myocardial ischemia. Patients with a primary respiratory alkalosis are also prone to periodic breathing and central sleep apnea (Chap. 259).

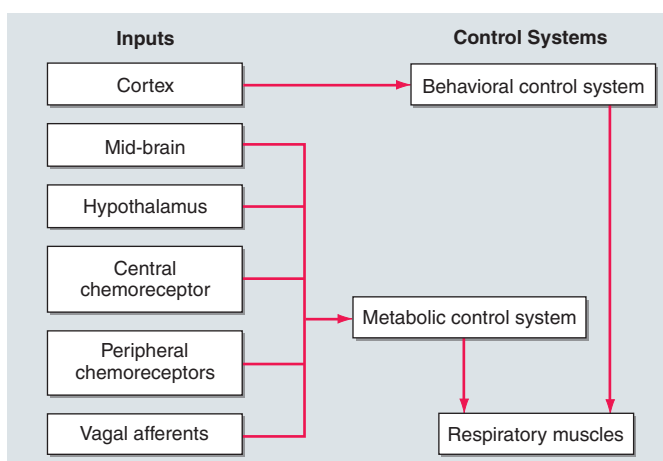

FIGURE 258-3 Schematic diagram of the mechanisms involved in alveolar hyperventilation. *[From EA Phillipson, AS Slutsky, in JF Murray, JA Nadel (eds), Textbook of Respiratory Medicine, 3d ed. Philadelphia, Saunders, 2000.]*

DIAGNOSIS

In most patients with a hyperventilation syndrome, the cause is readily apparent on the basis of history, physical examination, and knowledge of coexisting medical disorders (Table 258-2). In patients in whom the cause is not clinically apparent, investigation begins with arterial blood gas analysis, which establishes the presence of alveolar hyperventilation (decreased Pa_{CO_2}) and its severity. Equally important is the arterial pH, which generally allows the disorder to be classified as either a primary respiratory alkalosis (elevated pH) or a primary metabolic acidosis (decreased pH). Also of importance is the Pa_{O_2} and calculation of the $(A–a)P_{O_2}$, since a widened alveolar-arterial oxygen difference suggests a pulmonary disorder as the underlying cause. The finding of a reduced plasma HCO_3^- level establishes the chronic nature of the disorder and points toward an organic cause. Measurements of ventilation and arterial or transcutaneous P_{CO_2} during sleep are very useful in suspected psychogenic hyperventilation, since such patients do not maintain the hyperventilation during sleep.

The disorders that most frequently give rise to unexplained hyperventilation are pulmonary vascular disease (particularly chronic or recurrent thromboembolism) and psychogenic or anxiety hyperventilation. Hyperventilation due to pulmonary vascular disease is associated with exertional dyspnea, a widened $(A–a)P_{O_2}$ and maintenance of hyperventilation during exercise. In contrast, patients with psychogenic hyperventilation typically complain of dyspnea at rest, but not during mild exercise, and of the need to sigh frequently. They are also more likely to complain of dizziness, sweating, palpitations, and paresthesia. During mild to moderate exercise, their hyperventilation tends to disappear and $(A–a)P_{O_2}$ is normal, but heart rate and cardiac output may be increased relative to metabolic rate.

℞ HYPERVENTILATION

Mild alveolar hyperventilation is usually of relatively minor clinical consequence and therefore is generally managed by appropriate treatment of the underlying cause. In the few patients in whom alkalemia is thought to be inducing significant cerebral vasoconstriction, paresthesia, tetany, or cardiac disturbances, acute inhalation of a low concentration of CO_2 can be very beneficial. For patients with disabling psychogenic hyperventilation, careful explanation of the basis of their symptoms can be reassuring and is often sufficient. Others have benefited from β-adrenergic antagonists or an exercise program. Specific treatment for anxiety may also be indicated.

259 Sleep Apnea

Neil J. Douglas

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea/hypopnea syndrome (OSAHS) is one of the most important medical conditions identified in the last 50 years. It is a major cause of morbidity, a significant cause of mortality throughout the world, and the most common medical cause of daytime sleepiness. Central sleep apnea is a less common clinical problem. **Other sleep disorders are discussed in Chap. 28.**

DEFINITION

OSAHS may be defined as the coexistence of unexplained excessive daytime sleepiness with at least five obstructed breathing events (apnea or hypopnea) per hour of sleep (Table 259-1). This event threshold may need to be refined upward in the elderly. *Apneas* are defined in adults as breathing pauses lasting ≥10 s and hypopneas as ≥10 s events where there is continued breathing but the ventilation is reduced by at least 50% from the previous baseline during sleep. As a syndrome, OSAHS is the association of a clinical picture with specific abnormalities on testing; asymptomatic individuals with abnormal breathing during sleep should not be labeled as having OSAHS.

MECHANISM OF OBSTRUCTION

Apneas and hypopneas are caused by the airway being sucked closed on inspiration during sleep. This occurs as the upper-airway dilating muscles—like all striated muscles—normally relax during sleep. In patients with OSAHS, the dilating muscles can no longer successfully oppose negative pressure within the airway during inspiration. The primary defect is not in the upper-airway muscles, which function normally in OSAHS patients when awake. These patients have narrow upper airways already during wakefulness, but when they are awake their airway dilating muscles have higher than normal activity, which ensures airway patency. However, when they are asleep, muscle tone falls and the airway narrows; snoring may commence before the airway occludes, and apnea results. Apneas and hypopneas terminate when the subject arouses, i.e., wakens briefly, from sleep. This arousal is sometimes too subtle to be seen on the electroencephalogram but may be detected by cardiac acceleration, blood pressure elevation, or sympathetic tone increase. The arousal results in return of upper-airway dilating muscle tone, and thus airway patency is resumed.

The factors predisposing to OSAHS by narrowing the pharynx include obesity—around 50% have a body mass index (BMI) >30 kg/m^2 in western populations—and shortening of the mandible and/or maxilla. This change in jaw shape may be subtle and can be familial. Hypothyroidism and acromegaly predispose to OSAHS by narrowing the

upper airway with tissue infiltration. Other predisposing factors for OSAHS include male gender and middle age (40–65 years), myotonic dystrophy, Ehlers Danlos syndrome, and perhaps also smoking.

EPIDEMIOLOGY

Broadly, the frequency of OSAHS is in the range of 1–4% of the middle-aged male population; it is around half as common in women. The syndrome also occurs in childhood–usually associated with tonsil or adenoid enlargement–and in the elderly, although the frequency is slightly lower in old age. Irregular breathing during sleep *without* daytime sleepiness is much more common, occurring in perhaps one-fourth of the middle-aged male population. However, as these individuals are asymptomatic, they do not have OSAHS and there is no evidence at present that these events are harmful.

CLINICAL FEATURES

Randomized controlled treatment trials have shown that OSAHS causes daytime sleepiness; impaired vigilance, cognitive performance, and driving; depression; disturbed sleep; and hypertension. Daytime sleepiness may range from mild to irresistible, and the sleep attacks can be indistinguishable from those in narcolepsy (Chap. 28). The sleepiness may result in inability to work effectively and may damage interpersonal relationships and prevent socializing. The somnolence is dangerous when driving, with a three- to sixfold risk in accidents on the road or when operating machinery. Experiments with normal subjects repeatedly aroused from sleep indicate that the sleepiness results, at least in part, from the repetitive sleep disruption associated with the breathing abnormality. The possible contribution from the recurrent hypoxemia requires further evaluation.

Other symptoms include difficulty concentrating, unrefreshing nocturnal sleep, nocturnal choking, nocturia, and decreased libido. Partners report nightly loud snoring in all postures, which may be punctuated by the silence of apneas. Partners often give a markedly different assessment of the extent of sleepiness.

Cardiovascular and Cerebrovascular Events OSAHS raises 24-h mean blood pressure. The increase is greater in those with recurrent nocturnal hypoxemia, is at least 4–5 mmHg, and may be as great as 10 mmHg in those with >20% arterial oxygen desaturations per hour of sleep. This rise probably results from a combination of surges in blood pressure accompanying each arousal from sleep that end each apnea or hypopnea and from the associated 24-h increases in sympathetic tone.

Epidemiologic data in normal populations indicate that this rise in blood pressure would increase the risk of myocardial infarction by around 20% and stroke by about 40%. While there are no long-term randomized controlled trials to indicate whether this is true in OSAHS patients—and such studies would not be ethically defensible—observational studies suggest an increase in the risk of myocardial infarction and stroke in untreated OSAHS. Furthermore, epidemiologic studies suggest, but do not prove, increased vascular risk in normal subjects with raised apneas and hypopneas during sleep. Patients with recent stroke have a high frequency of apneas and hypopneas during sleep. These seem largely to be a consequence, not a cause, of the stroke and to decline over the weeks after the vascular event. There is no evidence that treating the apneas and hypopneas improves stroke outcome.

There has been debate for decades whether OSAHS is an adult form of sudden infant death syndrome. Although earlier studies showed no increase in sudden nocturnal deaths in OSAHS, a recent large study reported excess nocturnal deaths in subjects previously shown to have apneas and hypopneas during sleep.

Diabetes Mellitus The association of OSAHS with diabetes mellitus is not just due to obesity being common in both conditions. Recent data suggest that increased apneas and hypopneas during sleep are associated with insulin resistance independent of obesity. In addition, uncontrolled trials suggest that OSAHS can aggravate diabetes and that treatment of OSAHS in patients who also have diabetes decreases their insulin requirements.

Liver Hepatic dysfunction has also been associated with irregular breathing during sleep. Non-alcohol drinking subjects with apneas and hypopneas during sleep were found to have raised liver enzymes and more steatosis and fibrosis on liver biopsy, independent of body weight.

Anesthetic Risk Patients with OSAHS are at increased risk perioperatively as their upper airway may obstruct during the recovery period or as a consequence of sedation. Patients whose anesthesiologists have difficulty intubating are much more likely to have irregular breathing during sleep. Anesthesiologists should thus take sleep histories on patients preoperatively and take the appropriate precautions with those who might have OSAHS. This should include referring patients suspected of having OSAHS for investigation, and some elective operations may need to be postponed until the OSAHS is treated.

Differential Diagnosis (See also Chap. 28) Causes of sleepiness which may need to be distinguished include (Table 259-1):

- *Insufficient sleep:* this can usually be diagnosed by history.
- *Shift work:* this is a major cause of sleepiness, especially in those over 40 years old on either rotating shift or night shift work patterns.
- *Psychological/psychiatric causes:* depression is a major cause of sleepiness.
- *Drugs:* both stimulant and sedative drugs can produce sleepiness.
- *Narcolepsy:* around 50 times less common than OSAHS, narcolepsy is usually evident from childhood or teens and is associated with cataplexy.
- *Idiopathic hypersomnolence:* this is an ill-defined condition typified by long sleep duration and sleepiness.
- *Phase alteration syndromes:* both the phase delay and the less-common phase advancement syndromes are characterized by sleepiness at the characteristic time of day.

Who to Refer for Diagnosis Anyone whose troublesome sleepiness is not readily explained and rectified by considering the above differential diagnosis should be referred to a sleep specialist. The guideline I use for patients with troublesome sleepiness includes those with an Epworth Sleepiness Score >11 (Table 259-2), and those for whom sleepiness during work or driving poses problems. However, the Epworth Score is not a perfect measure for detecting troublesome sleepiness, as many whose life is troubled by frequently fighting sleepiness but who never doze will correctly score themselves as having a low Epworth Score. The patient and his/her partner often give divergent scores for the patient's sleepiness, and in such cases the higher of the two scores should be used.

TABLE 259-2 EPWORTH SLEEPINESS SCORE

How often are you likely to doze off or fall asleep in the following situations, in contrast to feeling just tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the *most appropriate number* for each situation:

0 = would *never* doze
1 = *slight* chance of dozing
2 = *moderate* chance of dozing
3 = *high* chance of dozing

Diagnosis OSAHS is a condition requiring lifelong treatment, and the diagnosis needs to be made or excluded with certainty, when possible, by a specialist. This will hinge on obtaining a good sleep history from the patient and partner, including asking both to complete sleep questionnaires, including the Epworth Sleepiness Score (Table 259-2). Physical examination must include assessment of obesity, jaw structure, the upper airway, blood pressure, and possible predisposing causes, including hypothyroidism and acromegaly (see above).

In those with appropriate clinical features, the diagnostic test must demonstrate recurrent breathing pauses during sleep. This may be a full polysomnographic examination with recording of multiple respiratory and neurophysiologic signals during sleep (Chap. 28). Increasingly, and especially outside the United States, most diagnostic tests are "limited studies"—recording respiratory and oxygenation patterns overnight without neurophysiologic recording. Such approaches in expert hands produce good patient outcomes and are cost-effective. It is sensible to use such limited sleep studies as the first-line diagnostic test and then allow positively diagnosed patients to proceed to treatment. However, a reasonable approach at present is for patients with troublesome sleepiness but negative limited studies to then have polysomnography to exclude or confirm OSAHS.

℞ OBSTRUCTIVE SLEEP APNEA

WHOM TO TREAT There is evidence obtained from robust randomized controlled trials (RCT) that treatment improves symptoms, sleepiness, driving, cognition, mood, quality of life, and blood pressure in patients who have an Epworth score of >11, troublesome sleepiness while driving or working, and >15 apneas + hypopneas per hour of sleep. For those with similar degrees of sleepiness and 5–15 events per hour of sleep, RCTs indicate improvements in symptoms, including subjective sleepiness, with less strong evidence indicating gains in cognition and quality of life. There is no evidence of blood pressure improvements in this group, nor is there is evidence that treating nonsleepy subjects improves their symptoms, function, or blood pressure. Thus, treatment cannot be advocated for this large group.

HOW TO TREAT All patients diagnosed with OSAHS should have the condition and its significance explained to them and to their partner. This should be accompanied by provision of written and/or web-based information and a discussion of the implications of the local regulations for driving. Rectifiable predispositions should be discussed; this often includes weight loss and sometimes reduction of alcohol consumption to reduce caloric intake and because alcohol acutely decreases upper-airway dilating muscle tone, thus predisposing to obstructed breathing. Sedative drugs, which also affect airway tone, should be carefully withdrawn.

Continuous Positive Airway Pressure (CPAP) CPAP therapy works by blowing the airway open during sleep, usually with pressures of 5–20 cmHg. CPAP has been shown in randomized placebo-controlled trials to improve breathing during sleep, sleep quality, sleepiness, blood pressure, vigilance, cognition, and driving ability, as well as mood and quality of life in patients with OSAHS. However, this is obtrusive therapy, and care must be taken to explain the need for the treatment to the patient and his/her partner, and to support all patients on CPAP intensively, providing access to telephone support and regular follow-up. Initiation should include finding the most comfortable mask from the ranges of several manufacturers and trying the system for at least 30 min during the daytime to prepare for the overnight trial. An overnight monitored trial of CPAP is used to identify the pressure required to keep the patient's airway patent. The development of pressure-varying CPAP machines may make the in-lab CPAP night trial unnecessary, but treatment must be initiated in a supportive environment. Thereafter, patients can be treated with fixed-pressure CPAP machines set at the determined pressure or by a self-adjusting, intelligent CPAP device. The main side effect of CPAP is airway drying, which can be countered using an integral heated humidifier. CPAP use, like that of all therapies, is imperfect, but around 94% of patients with severe OSAHS are still using their therapy after 5 years on objective monitoring.

Mandibular Repositioning Splint (MRS) Also called oral devices, MRSs work by holding the lower jaw and the tongue forward, thereby widening the pharyngeal airway. MRSs have been shown in RCTs to improve OSAHS patients' breathing during sleep, daytime somnolence, and blood pressure. As there are many devices of differing design with unknown relative efficacy, these results cannot be generalized to all MRSs. Self-reports of the use of devices long-term suggest high dropout rates.

Surgery Four forms of surgery have a role in OSAHS, although it must always be remembered that these patients have a raised perioperative risk. Bariatric surgery can be curative in the morbidly obese. Tonsillectomy can be highly effective in children but rarely in adults. Tracheostomy is curative but rarely used because of the associated morbidity; nevertheless, it should not be overlooked in extremely advanced cases. Jaw advancement surgery—particularly maxillo-mandibular osteotomy—is effective in those with retrognathia (posterior displacement of the mandible) and should be particularly considered in young and thin patients. There is no robust evidence that pharyngeal surgery, including uvulopalatopharyngoplasty (whether by scalpel, laser, or thermal techniques) helps OSAHS.

Drugs Unfortunately, no drugs are clinically useful in the prevention or reduction of apneas and hypopneas. A marginal improvement in sleepiness in patients who remain sleepy despite CPAP can be produced by modafinil, but the clinical value is debatable and the financial cost significant.

CHOICE OF TREATMENT CPAP and MRS are the two most widely used and best evidence-based therapies. Direct comparisons in RCTs indicate better outcomes with CPAP in terms of apneas and hypopneas, nocturnal oxygenation, symptoms, quality of life, mood, and vigilance. Adherence to CPAP is generally better than to an MRS, and there is evidence that CPAP improves driving, whereas there are no such data on MRSs, Thus, CPAP is the current treatment of choice. However, MRSs are evidence-based second-line therapy in those who fail CPAP. In younger, thinner patients, maxillo-mandibular advancement should be considered.

HEALTH RESOURCES Untreated OSAHS patients are heavy users of health care and dangerous drivers; they also work beneath their potential. Treatment of OSAHS with CPAP is cost-effective in terms of reducing health care costs of associated illness and associated accidents.

CENTRAL SLEEP APNEA

Central sleep apneas (CSAs) are respiratory pauses caused by lack of respiratory effort. These occur occasionally in normal subjects, particularly at sleep onset and in REM sleep, and are transiently increased following ascent to altitude. Recurrent CSA is most commonly found in the presence of cardiac failure or neurologic disease, especially stroke. Spontaneous central sleep syndrome is rare and can be classified on the basis of the arterial P_{CO_2}.

Hypercapnic CSA occurs in conjunction with diminished ventilatory drive in Ondine's curse (central alveolar hypoventilation). Patients with normocapnic spontaneous CSA have a normal or low arterial P_{CO_2} when awake, with brisk ventilatory responses to hypercapnia. This combination results in unstable ventilatory control, with subjects breathing close to or below their apneic threshold for P_{CO_2} during sleep; this apneic tendency is compounded by cycles of arousal-induced hyperventilation, inducing further hypocapnia.

CLINICAL FEATURES

Patients may present with sleep maintenance insomnia, which is relatively unusual in OSAHS. Daytime sleepiness may occur.

INVESTIGATION

Many apneas previously labeled central because of absent thoracoabdominal movement are actually obstructive, identification of movement being particularly difficult in the very obese. CSA can only be identified with certainty if either esophageal pressure or respiratory muscle electromyography is recorded and shown to be absent during the events.

℞ CENTRAL SLEEP APNEA

Patients with underlying cardiac failure should have their failure treated appropriately. CPAP may improve outcome but is difficult to initiate and has not been shown to improve survival. Patients with spontaneous normocapnic CSA may

be successfully treated with acetazolamide. In a minority of patients, CPAP is effective, perhaps because in some patients with OSAHS, pharyngeal collapse initiates reflex inhibition of respiration, and these episodes are prevented by CPAP. Oxygen and nocturnal nasal positive/pressure ventilation may also be tried.

260 Lung Transplantation

Elbert P. Trulock

Lung transplantation is a therapeutic consideration for patients with most nonmalignant end-stage lung diseases. After an initial period of rapid growth from 1990 through 1995, activity has increased slowly to ~1700 transplants per year worldwide. The demand for transplantation exceeds the supply of donor organs, and the waiting time is often lengthy. Recognizing the window of opportunity for transplantation in the clinical course of various lung diseases is crucial because deaths while awaiting transplantation are not unusual. However, in appropriately selected recipients, transplantation prolongs survival and improves quality of life, but it is also associated with significant morbidity and mortality.

INDICATIONS

The indications for lung transplantation span the gamut of lung diseases (Table 260-1). The distribution reflects the prevalence and natural history of the diseases, and the most common indications are chronic obstructive pulmonary disease (COPD), idiopathic pulmonary fibrosis (IPF), cystic fibrosis (CF), α_1-antitrypsin deficiency emphysema, and primary pulmonary hypertension (PPH). "Others" in Table 260-1 comprise many less prevalent lung diseases.

RECIPIENT SELECTION

Transplantation should be considered when other therapeutic options have been exhausted and when the patient's prognosis will be improved by the procedure. Survival rates after transplantation can be compared with predictive indices for the underlying disease, but each patient's clinical course must be integrated into the assessment, too. In any case, projected survival after transplantation should exceed life expectancy without the procedure. Quality of life is the primary motive for transplantation for many patients, and the prospect of an improved quality-adjusted survival is often attractive, even if the survival advantage itself might be marginal.

Disease-specific guidelines for referring patients for transplantation are summarized in Table 260-2, and these are intended to identify patients who may benefit from transplantation. Candidates for lung transplantation are thoroughly screened for any comorbidity that might adversely affect the outcome. Suitable candidates should have clinically and physiologically severe lung disease, but otherwise they must be in reasonably good health. The upper age limit is ~65 years at most centers.

Typical exclusions include HIV infection, chronic hepatitis B antigenemia or chronic active hepatitis C infection, uncured malignancy, active cigarette smoking, drug or alcohol dependency or abuse, uncontrolled or untreatable pulmonary or extrapulmonary infection, irreversible physical deconditioning, chronic noncompliance with medical care, and significant disease of any vital organ other than the lungs. Other problems that might increase the risk of complications or might be aggravated by the posttransplantation medical regimen constitute relative contraindications. Some typical issues are ventilator-dependent respiratory failure, previous thoracic surgical procedures, osteoporosis, systemic hypertension, diabetes mellitus, obesity or cachexia, and psychosocial problems. Chronic infection with antibiotic-resistant *Pseudomonas* species, some *Burkholderia* species, *Aspergillus* species, or nontuberculous mycobacteria is a unique concern in some patients with CF or other diseases that have a component of bronchiectasis or chronic bronchitis. The potential impact of these and many other factors has to be judged in clinical context to determine an individual candidate's suitability for transplantation.

WAITING LIST AND ORGAN ALLOCATION

Organ allocation policies are influenced by ethical, medical, geographical, and political factors, and systems vary from country to country. Re-

TABLE 260-1 INDICATIONS FOR ADULT LUNG TRANSPLANTATION (1995–2004)

Diagnosis	Single Lung Transplantation (*n* = 6731)		Bilateral Lung Transplantation (*n* = 6276)		Total (*n* = 13,007)	
Chronic obstructive pulmonary disease	3541	52.6%	1462	23.3%	5003	38.5%
Idiopathic pulmonary fibrosis	1618	24.0%	639	10.0%	2257	17.4%
Cystic fibrosis	151	2.2%	2002	31.9%	2153	16.6%
α_1-Antitrypsin deficiency emphysema	554	8.2%	571	9.1%	1125	8.6%
Primary pulmonary hypertension	79	1.2%	436	6.9%	515	4.0%
Sarcoidosis	157	2.3%	166	2.6%	323	2.5%
Bronchiectasis	45	0.7%	309	4.9%	354	2.7%
Eisenmenger's syndrome	13	0.2%	118	1.9%	131	1.0%
Lymphoangioleiomyomatosis	55	0.8%	83	1.3%	138	1.0%
Retransplantation	129	1.9%	104	1.7%	233	1.8%
Others	389	5.8%	386	6.2%	775	6.0%

TABLE 260-2 DISEASE-SPECIFIC GUIDELINES FOR SELECTING CANDIDATES FOR LUNG TRANSPLANTATION

COPD and α_1-antitrypsin deficiency emphysema
FEV_1 < 25% of predicted normal value (post-bronchodilator)
$Pa_{CO_2} \geq 55$ mmHg
Pulmonary arterial hypertension (mean pulmonary artery pressure > 25 mmHg)
Cystic fibrosis/bronchiectasis
FEV_1 < 30% of predicted normal value
Pa_{CO_2} > 50 mmHg
Pa_{O_2} < 50 mmHg (on room air)
Pulmonary arterial hypertension
Adverse clinical course in spite of optimal medical management
Increasing hospitalizations
Recurrent, massive hemoptysis
Rapidly declining FEV_1
Idiopathic pulmonary fibrosis
VC or TLC < 60–70% of predicted normal value
DL_{CO} < 50–60% of predicted normal value
Pulmonary arterial hypertension
Hypoxemia (Pa_{O_2} < 60 mmHg or Sp_{O_2} < 90%) at rest or with activity (on room air)
Progressive disease in spite of drug therapy
Primary pulmonary hypertension
New York Heart Association functional class III or IV in spite of optimal drug therapy
Unfavorable hemodynamic profile
Right atrial pressure > 15 mmHg
Mean pulmonary artery pressure > 55 mmHg
Cardiac index < 2 (L/min)/m^2

Abbreviations: VC, vital capacity; TLC, total lung capacity; FEV_1, forced expiratory volume in 1 s; DL_{CO}, diffusing capacity for carbon monoxide; Pa_{O_2} and Pa_{CO_2}, partial pressure of oxygen and carbon dioxide, respectively, in arterial blood; Sp_{O_2}, oxygen saturation by pulse oximetry.

Source: Modified from International Guidelines for the Selection of Lung Transplant Candidates: Am J Respir Crit Care Med 158:335, 1998.

gardless of the system, potential recipients are placed on a waiting list and must be matched for blood group compatibility and, with some latitude, for lung size with an acceptable donor. In the United States a priority algorithm for allocating donor lungs was implemented in May 2005. Priority is determined by a lung allocation score that weighs both the patient's risk of death on the waiting list and the likelihood of survival after transplantation. Both the type and the severity of lung disease affect the allocation score; relevant parameters must be updated periodically but can be submitted whenever the patient's condition changes. However, this priority system does not diminish the importance of timely referral.

The impact of the priority allocation scheme on key outcome measures has not been analyzed yet; however, this information will be forthcoming and may lead to further refinement of the allocation system. Under the previous seniority system, the median time to transplantation was 1104 days for patients who initially registered on the national waiting list in 1998. Approximately 10% of the patients on the waiting list died before transplantation, but the death rate while waiting was much higher for patients with IPF, PPH, or CF than for those with COPD or α_1-antitrypsin deficiency emphysema.

TRANSPLANT PROCEDURE

Bilateral transplantation is mandatory for bronchiectasis because the risk of spillover infection from a remaining native lung precludes single lung transplantation. Heart-lung transplantation is obligatory for Eisenmenger's syndrome with complex anomalies that cannot be readily repaired in conjunction with lung transplantation and for concomitant end-stage lung and heart disease. However, cardiac replacement is not necessary for cor pulmonale because right ventricular function will recover when pulmonary vascular afterload is normalized by lung transplantation.

Either bilateral or single lung transplantation is an acceptable alternative for other diseases unless there is a special consideration. Bilateral transplantation provides more reserve lung function as a buffer against complications, and it has been increasingly utilized for many indications. In recipients with COPD and α_1-antitrypsin deficiency emphysema, survival has been significantly better after bilateral transplantation, but there has not been a significant difference in survival between the two procedures for other diseases.

Living donor lobar transplantation has a limited role in adult lung transplantation. It has been performed predominantly in teenagers or young adults with CF. A right lower lobe is obtained from one living donor and a left lower lobe from another, and these lobes are implanted to replace the right and left lungs, respectively, in the recipient. Since a lobe must replace a whole lung, donor-recipient size considerations are crucial. The results have been comparable to those with transplantation from cadaveric donors. The usual morbidities associated with a lobectomy have been encountered in the donors, but no death has yet been reported. Because of ethical concerns, this approach is usually restricted to patients who are unlikely to survive the wait for a cadaveric donor.

POSTTRANSPLANTATION MANAGEMENT

Induction therapy with an antilymphocyte globulin or an interleukin 2 receptor antagonist is utilized by some centers, and a three-drug maintenance immunosuppressive regimen that includes a calcineurin inhibitor (cyclosporine or tacrolimus), a purine synthesis antagonist (azathioprine or mycophenolate mofetil), and prednisone is customary. Subsequently, other drugs such as sirolimus may be substituted in the maintenance regimen for various reasons. Prophylaxis for *Pneumocystis jiroveci* pneumonia is standard, and prophylaxis against cytomegalovirus (CMV) infection is prescribed in many protocols. The dose of cyclosporine or tacrolimus is adjusted by blood-level monitoring. Both are metabolized by the hepatic cytochrome P450 system, and interactions with medications that affect this pathway can significantly alter the clearance and blood levels of these key immunosuppressants.

Routine management is designed to monitor the allograft, to regulate immunosuppressive therapy, and to detect problems or complications expeditiously. The techniques include periodic contact with a transplant nurse coordinator, appointments with a physician, chest radiographs, blood tests, spirometry, and bronchoscopy. Lung function rapidly improves and then stabilizes by 3–6 months after transplantation. Subsequently, the coefficient of variation in spirometric measurements is small, and a sustained decline of 10–15% or more signals a potentially significant problem.

OUTCOMES

Survival Major registries publish survival (Table 260-3) and other outcomes annually, and these reports are accessible via the Internet (*www.ishlt.org; www.ustransplant.org*).

The main sources of perioperative mortality include technical complications of the operation, primary graft dysfunction, and infections.

TABLE 260-3 RECIPIENT SURVIVAL, BY PRETRANSPLANTATION DIAGNOSIS (1994–2003)

Diagnosis	*n*	Survival Rate, %				
		3 Months	1 Year	3 Years	5 Years	10 Years
Chronic obstructive pulmonary disease	4888	90	81	63	48	19
α_1-Antitrypsin deficiency emphysema	1127	86	76	60	51	31
Cystic fibrosis	1934	88	81	65	54	32
Idiopathic pulmonary fibrosis	2058	81	69	54	42	15
Primary pulmonary hypertension	553	73	65	56	46	26

Source: Data from Trulock et al.

Acute rejection and CMV infection are common problems in the first year, but neither is usually fatal. Beyond the first year, chronic rejection and non-CMV infections cause the majority of deaths.

Function Regardless of the disease, successful transplantation impressively restores cardiopulmonary function. After bilateral transplantation standard pulmonary function tests are typically normal; after single lung transplantation the remaining diseased lung typically contributes a mild abnormality. Formal exercise testing usually demonstrates some impairment in maximum work rate and maximum oxygen uptake, but few recipients report any limitation to activity.

Quality of Life Both overall and health-related quality of life are enhanced. With multidimensional profiles, improvements extend across most domains and are sustained longitudinally unless chronic rejection or some other complication develops. Other problems that detract from quality of life include renal dysfunction and drug side effects.

Cost The cost of transplantation depends on the health care system, other health care policies, and economic factors that vary from country to country. In the 1990s transplant hospitalization costs in the range of $160,000 were reported from two centers in the United States. At one of these centers, the average charge for posttransplantation care was ~$132,000 in the first year and $54,000 in subsequent years. The distribution of costs after lung transplantation was estimated by a center in the United Kingdom: 57% for routine care including medications, clinic appointments, and tests; 17% for rejection episodes; and 26% for infectious complications.

Complications Lung transplantation can be complicated by a variety of problems. Aside from those that are unique to transplantation, side effects and toxicities of the immunosuppressive medications can cause new medical problems or aggravate preexisting conditions (Table 260-4).

TABLE 260-4 MAJOR POTENTIAL COMPLICATIONS OF LUNG TRANSPLANTATION AND POSTTRANSPLANTATION IMMUNOSUPPRESSION

Category	Complication
Allograft	Acute graft dysfunction; anastomotic dehiscence or stenosis; ischemic airway injury with bronchostenosis or bronchomalacia; rejection; infections
Thoracic	Phrenic nerve injury—diaphragmatic dysfunction; recurrent laryngeal nerve injury—vocal cord dysfunction; cervical ganglia injury—Horner's syndrome; chylothorax; pneumothorax; pleural effusion
Cardiovascular	Air embolism; postoperative pericarditis; venous thromboembolism; supraventricular dysrhythmias; systemic hypertension
Gastrointestinal	Esophagitis (especially *Candida* species or CMV); gastroparesis; gastroesophageal reflux; *C. difficile* toxin diarrhea or pseudomembranous colitis
Hepatobiliary	Hepatitis (especially CMV or drug-induced)
Renal	Calcineurin inhibitor nephropathy; hemolytic-uremic syndrome (thrombotic microangiopathy)
Neurologic	Tremors; seizures; reversible posterior leukoencephalopathy; headaches
Musculoskeletal	Steroid myopathy; rhabdomyolysis (cyclosporine + HMG-CoA reductase inhibitor treatment); osteoporosis; avascular necrosis
Metabolic	Obesity; diabetes mellitus; hyperlipidemia; idiopathic hyperammonemia
Hematologic	Anemia; leukopenia; thrombocytopenia; thrombotic microangiopathy
Oncologic	Lymphoproliferative disease and lymphoma; skin cancers; other malignancies

Graft Dysfunction Primary graft dysfunction is an acute lung injury that is a manifestation of insults that are inherent in the transplantation process, and it has been referred to as *reperfusion edema*, *reimplantation response*, and *ischemia-reperfusion injury*. The principal clinical features are diffuse pulmonary infiltrates and hypoxemia within 72 h of transplantation, but the severity is variable. Pulmonary venous obstruction and hyperacute rejection can produce a similar pattern, and cardiogenic pulmonary edema and pneumonia must be excluded, too. The treatment is the conventional, supportive paradigm for acute lung injury, but inhaled nitric oxide and extracorporeal membrane oxygenation have been used successfully in severe cases. Most recipients recover, but severe primary graft dysfunction is a leading cause of early morbidity and mortality.

Airway Complications The bronchial blood supply to the donor lung is disrupted, and bronchial revascularization is not widely practiced. Consequently, when the lung is implanted in the recipient, the bronchus is dependent on retrograde bronchial blood flow through the pulmonary circulation and is vulnerable to ischemia.

The prevalence of major airway complications—dehiscence, stenosis, and bronchomalacia—has ranged from 4–20%, but the associated mortality has been very low. Bronchoscopic debridement or dilatation is sufficient in many cases, but stent placement is often necessary if a stricture or bronchomalacia evolves.

Acute Rejection This is an immunologic response to alloantigen recognition, and it is characterized by arteriolar and bronchiolar lymphocytic inflammation. With current immunosuppressive regimens, ~50% recipients have at least one episode of acute rejection in the first year. Acute rejection can be clinically silent, or it can be manifested by nonspecific symptoms or signs that may include cough, low-grade fever, dyspnea, hypoxemia, inspiratory crackles, interstitial infiltrates, and declining lung function; however, clinical impression is not reliable. The diagnosis should be confirmed by transbronchial biopsy, and a standardized pathologic classification scheme for rejection is used to grade the biopsies. Treatment usually includes a short course of high-dose steroid therapy and adjustment of the maintenance immunosuppressive regimen, but more intensive therapy may be necessary for persistent or recurrent episodes.

Chronic Rejection This complication is the main impediment to better medium-term survival rates, and it is the source of substantial morbidity because of its impact on lung function and quality of life. The pathogenesis is still a conundrum, but both alloimmune inflammatory and nonalloimmune fibroproliferative mechanisms are probably important.

Clinically, chronic rejection is a form of graft dysfunction that is synonymous with bronchiolitis obliterans syndrome (BOS). BOS is characterized physiologically by airflow limitation and pathologically by bronchiolitis obliterans. Transbronchial biopsies are relatively insensitive for detecting bronchiolitis obliterans, and the diagnosis of BOS is usually based on a sustained decrement (≥20%) in the FEV_1. A smaller decline in FEV_1 (≥10%) or a decrease in the $FEF_{25–75\%}$ may presage BOS.

The prevalence of BOS approaches 50% by 5 years after transplantation. Both antecedent acute rejection and lymphocytic bronchiolitis are risk factors for subsequent BOS, and CMV pneumonitis has been implicated inconsistently. BOS is usually treated with augmented immunosuppression. While immunosuppressive therapy may stabilize lung function, the overall results of treatment have been disappointing, probably because the fibroproliferative process is already well established. Retransplantation may be an option in ambulatory recipients without other complications, but in many cases the risk is prohibitive.

Infection The lung allograft is especially susceptible to infection, and infection has been one of the leading causes of death. In addition to a blunted immune response from the immunosuppressive drugs, other normal defenses are breached; the cough reflex is diminished, and mucociliary clearance is impaired in the transplanted lung. The spectrum of infections includes both opportunistic and nonopportunistic pathogens.

Bacterial bronchitis or pneumonia can occur at any time but are almost universal in the postoperative period. Later, episodes of bronchitis are quite common, especially in recipients with BOS, and

Pseudomonas aeruginosa or methicillin-resistant *Staphylococcus aureus* is often the culprit.

CMV is the most frequent viral infection. Although gastroenteritis, colitis, and hepatitis can occur, CMV viremia and CMV pneumonia are the main illnesses. Most episodes occur in the first 6 months, and treatment with ganciclovir is effective unless resistance develops with repeated exposure. Other community-acquired viruses such as influenza, parainfluenza, and respiratory syncytial virus also contribute to respiratory complications. *Aspergillus* species have been the most problematic fungal infection.

Other Complications Other potential complications are summarized in Table 260-4, and many of these are related to side effects or toxicities of the immunosuppressive drugs. Management of most of these general medical problems is guided by standard practices for the condition, but the complex milieu of transplantation dictates close collaboration and good communication among health care providers.

SECTION 1 RESPIRATORY CRITICAL CARE

261 Principles of Critical Care Medicine

John P. Kress, Jesse B. Hall

The care of critically ill patients requires a thorough understanding of pathophysiology and is centered initially around resuscitation of patients at extremes of physiologic deterioration. This resuscitation is often fast-paced and may occur in early stages without a detailed awareness of patients' chronic medical problems. While physiologic stabilization is taking place, intensivists attempt to gather important background medical information to supplement the real-time assessment of the patients' current physiologic conditions. Numerous tools are available to assist intensivists in the accurate assessment of pathophysiology and to support incipient organ failures, thus offering a window of opportunity for diagnosing and treating underlying disease(s) in a stabilized patient. Indeed, the use of invasive interventions such as mechanical ventilation and renal replacement therapy as well as diagnostic tools such as central venous catheters are commonplace in the intensive care unit. An appreciation of the risks and benefits of such aggressive and often invasive interventions is vital to assure an optimal patient outcome. Notwithstanding, intensivists must recognize when patients' chances for recovery are remote or impossible and work to counsel and comfort dying patients and their significant others. Critical care physicians must often redirect the goals of care from resuscitation and cure to comfort when the resolution of an underlying illness is not possible.

ASSESSMENT OF SEVERITY OF ILLNESS

Categorization of a patient's illness into grades of severity occurs frequently in the intensive care unit (ICU). There are numerous severity-of-illness scoring systems that have been developed and validated over the past two decades. While these scoring systems have been validated as tools to accurately assess populations of critically ill patients, their utility in predicting individual patient outcomes is not clear.

Severity-of-illness scoring systems are important for defining populations of critically ill patients. This allows effective comparison of groups of patients enrolled in clinical trials. To be assured that a purported benefit of a therapy is real, investigators must be assured that different groups involved in a clinical trial have similar illness severities. Severity-of-illness scores are also useful in guiding hospital administrative policies. Allocation of resources, such as nursing and ancillary care, can be directed by such scoring systems. Severity-of-illness scoring systems can also assist in the assessment of quality of ICU care over time. Scoring system validations are based on the premise that increasing age, presence of chronic medical illnesses, and increasingly severe derangements from normal physiology are each associated with increased mortality. All currently existing severity-of-illness scoring systems are derived from patients who have been already admitted to the ICU. There are no established scoring systems available that allege to direct clinicians' decision-making regarding what constitute criteria for admission to an ICU.

Currently, the most commonly utilized scoring systems are the APACHE (acute physiology and chronic health evaluation) system, the MPM (mortality probability model), and the SAPS (simplified acute physiology score) system. These were all designed to predict outcomes in critical illness and use severity-of-illness scoring systems with common variables. These include age; vital signs; assessments of respiratory, renal, and neurologic function; and an evaluation of chronic medical illnesses.

APACHE II SCORING SYSTEM

The APACHE II system is the most commonly used severity-of-illness scoring system in North America. Age, type of ICU admission (after elective surgery vs. nonsurgical or after emergency surgery), a chronic health problem score, and 12 physiologic variables (the most severely abnormal of each in the first 24 h of ICU admission) are used to derive a score. The predicted hospital mortality is derived from a formula that takes into account the APACHE II score, the need for emergency surgery, and a weighted, disease-specific diagnostic category (Table 261-1). The relationship between APACHE II score and mortality is illustrated in Fig. 261-1. More recently, the APACHE III scoring system has been released. This scoring system is similar to APACHE II, in that it is based upon age, physiologic abnormalities, and chronic medical comorbidities. The database from which this score was derived is larger.

THE SAPS AND MPM SCORING SYSTEM

The SAPS II score, used more frequently in Europe, was derived in a manner similar to the APACHE scores. This score is not disease specific but rather incorporates three underlying disease variables (AIDS, metastatic cancer, and hematologic malignancy). The MPM can be used to calculate a direct probability of death in patients admitted to the ICU.

Severity-of-illness scoring systems suffer from the problem of inability to predict survival in individual patients. Accordingly, the use of these scoring systems to direct therapy and clinical decision-making cannot be recommended at present. Rather, these tools should be used as important data to complement clinical bedside decision-making.

SHOCK (See also Chap. 264)

INITIAL EVALUATION

Shock is a common condition necessitating admission to the ICU or occurring in the course of critical care. Shock is defined by the presence of multisystem end-organ hypoperfusion. Clinical indicators include reduced mean arterial pressure (MAP), tachycardia, tachypnea, cool skin and extremities, acute altered mental status, and oliguria. Hypotension is usually, though not always, present. The end result of multiorgan hypoperfusion is tissue hypoxia, often clinically manifested by lactic acidosis. Since the MAP is the product of the cardiac output (CO) and the systemic vascular resistance (SVR), reductions in blood pressure can be caused by decreased CO and/or decreased SVR. Accordingly, the initial evaluation of a hypotensive patient should evaluate the adequacy of the CO. This should be part of the earliest assessment of the patient by the clinician at the bedside once shock is contemplated (Fig. 261-2). Clinical evidence of *diminished* CO includes a narrow pulse pressure—a marker that correlates with stroke volume—and cool extremities with delayed capillary refill. Signs of *increased* CO include a widened pulse pressure (particularly with a reduced diastolic pressure), warm extremities with bounding pulses, and rapid capillary refill. If a hypotensive patient has clinical signs of increased CO, one can infer that the reduced blood pressure is a result of decreased SVR.

In hypotensive patients with clinical signs of a reduced CO, an assessment of intravascular and cardiac volume status is appropriate. A hypotensive patient with decreased intravascular and cardiac volume status may have a history suggesting hemorrhage or other volume

Rectal temperature, °C	≥41	39.0–40.9		38.5–38.9	36.0–38.4	34.0–35.9	32.0–33.9	30.0–31.9	≤29.9
Mean blood pressure, mmHg	≥160	130–159	110–129		70–109		50–69		≤49
Heart rate	≥180	140–179	110–139		70–109		55–69	40–54	≤39
Respiratory rate	≥50	35–49		25–34	12–24	10–11	6–9		≤5
Arterial pH	≥7.70	7.60–7.69		7.50–7.59	7.33–7.49		7.25–7.32	7.15–7.24	<7.15
Oxygenation									
If $FI_{O_2} > 0.5$, use $(A - a)\ D_{O_2}$	≥500	350–499	200–349		<200				
If $FI_{O_2} \leq 0.5$, use Pa_{O_2}					>70	61–70		55–60	<55
Serum sodium, meq/L	≥180	160–179	155–159	150–154	130–149		120–129	111–119	≤110
Serum potassium, meq/L	≥7.0	6.0–6.9		5.5–5.9	3.5–5.4	3.0–3.4	2.5–2.9		<2.5
Serum creatinine, mg/dL	≥3.5	2.0–3.4	1.5–1.9		0.6–1.4		<0.6		
Hematocrit	≥60		50–59.9	46–49.9	30–45.9		20–29.9		<20
WBC count, 10^3/mL	≥40		20–39.9	15–19.9	3–14.9		1–2.9		<1

Glasgow Coma Score[b,c]

Eye Opening	Verbal (Nonintubated)	Verbal (Intubated)	Motor Activity
4—Spontaneous	5—Oriented and talks	5—Seems able to talk	6—Verbal command
3—Verbal stimuli	4—Disoriented and talks	3—Questionable ability to talk	5—Localizes to pain
2—Painful stimuli	3—Inappropriate words	1—Generally unresponsive	4—Withdraws to pain
1—No response	2—Incomprehensible sounds		3—Decorticate
	1—No response		2—Decerebrate
			1—No response

Points Assigned to Age and Chronic Disease as Part of the APACHE II Score

Age, Years	Score
<45	0
45–54	2
55–64	3
65–74	5
≥75	6

Chronic Health (History of Chronic Conditions)[d]	Score
None	0
If patient is admitted after elective surgery	2
If patient is admitted after emergency surgery or for reason other than after elective surgery	5

[a]APACHE II score is the sum of the acute physiology score (vital signs, oxygenation, laboratory values), Glasgow coma score, age, and chronic health points. Worst values during first 24 h in the ICU should be used.
[b]Glasgow coma score (GCS) = eye-opening score + verbal (intubated or nonintubated) score + motor score.
[c]For GCS component of acute physiology score, subtract GCS from 15 to obtain points assigned.
[d]Chronic health conditions: liver, cirrhosis with portal hypertension or encephalopathy; cardiovascular, class IV angina (at rest or with minimal self-care activities); pulmonary, chronic hypoxemia or hypercapnia, polycythemia, ventilator dependent; kidney, chronic peritoneal or hemodialysis; immune, immunocompromised host.
Note: $(A - a)\ D_{O_2}$, alveolar-arterial oxygen difference; WBC, white blood (cell) count.

losses (e.g., vomiting, diarrhea, polyuria). The jugular venous pressure (JVP) is often reduced in such a patient, while the change in pulse pressure as a function of respiration is increased. A hypotensive patient with increased intravascular volume status and cardiac dysfunction may have S_3 and/or S_4 gallops on cardiac examination, increased JVP, extremity edema, and crackles on lung auscultation. The chest x-ray may show cardiomegaly, widening of the vascular pedicle, Kerley B lines, and pulmonary edema. Chest pain and electrocardiographic changes consistent with ischemia may also be noted (Chap. 266).

In hypotensive patients with clinical evidence of increased CO, a search for causes of decreased SVR is appropriate. The most common cause of high cardiac output hypotension is sepsis (Chap. 265). Other causes of high CO hypotension include liver failure, severe pancreatitis, burns and other trauma that elicit the systemic inflammatory response syndrome (SIRS), anaphylaxis, thyrotoxicosis, and peripheral arteriovenous shunts.

In summary, the three most common categories of shock are hypovolemic, cardiogenic, and high CO with decreased SVR (high-output hypotension). Certainly these categories may overlap and occur simultaneously (e.g., hypovolemic and septic shock, septic and cardiogenic shock).

The initial assessment of a patient in shock as outlined above should take only a few minutes. It is important that aggressive, early resuscitation be instituted based on the initial assessment, particularly since early resuscitation of septic and cardiogenic shock may improve survival (see below). If the initial bedside assessment yields equivocal or confounding data, more objective assessments such as echocardiography and/or invasive vascular monitoring may be useful. The goal of early resuscitation is to reestablish adequate tissue perfusion to prevent or minimize end-organ injury.

MECHANICAL VENTILATORY SUPPORT

(See also Chap. 263) During the initial resuscitation of patients in shock, principles of advanced cardiac life support should be followed. Since patients in shock may be obtunded and unable to protect the airway, an early assessment of the patient's airway is mandatory during resuscitation from shock. Early intubation and mechanical ventilation are often required. Reasons for institution of endotracheal intubation and mechanical ventilation include acute hypoxemic respiratory failure as well as ventilatory failure, which frequently accompany shock. Acute hypoxemic respiratory failure may occur in patients with cardiogenic shock and pulmonary edema (Chap. 266) as well as in those in septic shock with pneumonia or acute respiratory distress syndrome (ARDS) (Chap. 265). Ventilatory failure often occurs as a result of an increased load on the respiratory system. This load may present

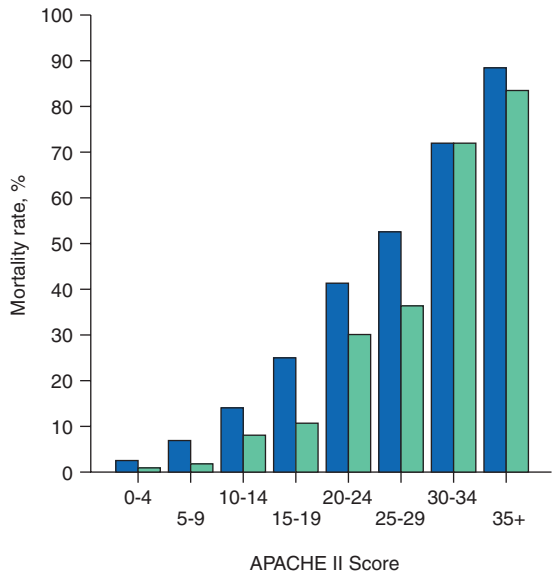

FIGURE 261-1 APACHE II survival curve. Blue, nonoperative; green, postoperative.

in the form of acute metabolic acidosis (often lactic acidosis) or decreased compliance of the lungs ("stiff" lungs) as a result of pulmonary edema. Inadequate perfusion to respiratory muscles in the setting of shock may be another reason for early intubation and mechanical ventilation. Normally, the respiratory muscles receive a very small percentage of the CO. However, in patients who are in shock with respiratory distress for the reasons listed above, the percentage of CO dedicated to respiratory muscles may increase tenfold or more. Lactic acid production from inefficient respiratory muscle activity presents an additional ventilatory load.

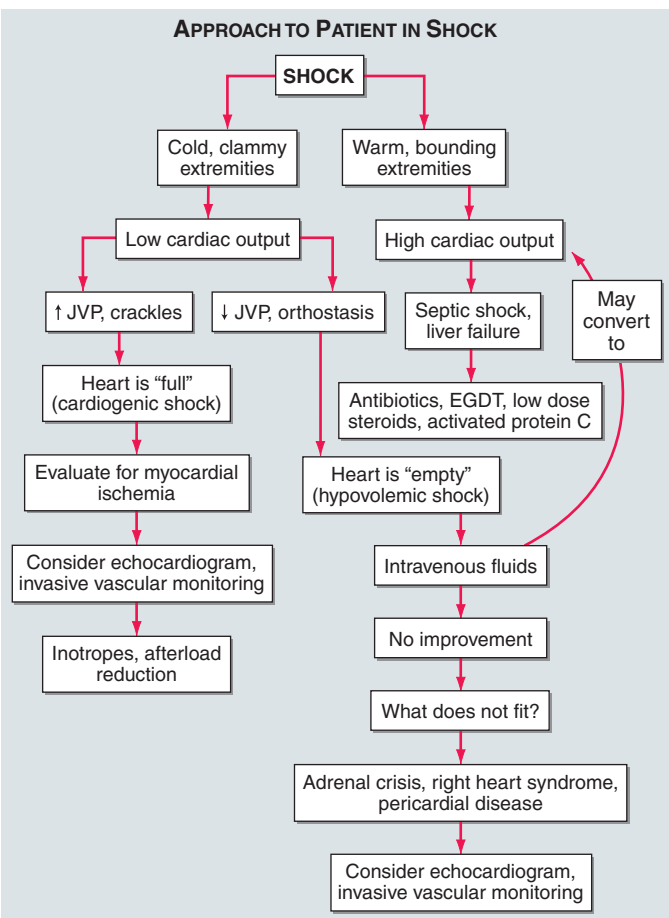

FIGURE 261-2 Approach to patient in shock. JVP, jugular venous pulse; EGDT, early goal-directed therapy.

Mechanical ventilation may relieve the patient of the work of breathing and allow redistribution of a limited CO to other vital organs, often with an improvement in lactic acidosis. Patients demonstrate signs of respiratory muscle fatigue with a number of clinical signs including inability to speak full sentences, accessory respiratory muscle use, paradoxical abdominal muscle activity, extreme tachypnea (> 40 breaths/min), and decreasing respiratory rate despite an increasing drive to breathe. When patients with shock are treated with mechanical ventilation, a major goal of ventilator settings is to assume all or the majority of work of breathing, facilitating a state of minimal respiratory muscle work. With the institution of mechanical ventilation for shock, further worsening of MAP is frequently seen. The reasons for this include impedance of venous return with positive-pressure ventilation, reduced endogenous catecholamine secretion once the stress associated with respiratory failure is abated, and drugs used to facilitate endotracheal intubation (e.g., barbiturates, benzodiazepines, opiates), all of which may result in hypotension. Accordingly, hypotension should be anticipated after endotracheal intubation and positive-pressure ventilation. Many of these patients have a component of hypovolemia, which may respond to IV volume administration. Fig. 261-2 summarizes the diagnosis and treatment of different types of shock. **For further discussion of individual forms of shock, see Chaps. 264, 265, and 266.**

RESPIRATORY FAILURE

Respiratory failure is one of the most common reasons patients are admitted to the ICU. In some ICU settings, ≥75% of patients require mechanical ventilation during their ICU stay. Respiratory failure can be categorized mechanistically, based on pathophysiologic derangements in respiratory function. Accordingly, four different types of respiratory failure can be described, based upon these pathophysiologic derangements.

Type I, or Acute Hypoxemic, Respiratory Failure This occurs when alveolar flooding and subsequent intrapulmonary shunt physiology occurs. Alveolar flooding may be a consequence of pulmonary edema, pneumonia, or alveolar hemorrhage. Pulmonary edema can be further categorized as occurring due to elevated intravascular pressures seen in heart failure and intravascular volume overload, or acute lung injury ("low-pressure pulmonary edema"; Chap. 266). ARDS (Chap. 262) represents an extreme degree of lung injury. This syndrome is defined by diffuse bilateral airspace edema seen by chest radiography, the absence of left atrial hypertension, and profound shunt physiology (Fig. 262-2), in a clinical setting in which this syndrome is known to occur. This includes sepsis, gastric aspiration, pneumonia, near drowning, multiple blood transfusions, and pancreatitis. The mortality rate of patients with ARDS was traditionally very high (50–70%), though recent changes in ventilator management strategy have led to reports of mortality in the low 30% range (see below).

For many years, physicians have suspected that mechanical ventilation of patients with acute lung injury and ARDS may propagate lung injury. Cyclical collapse and reopening of alveoli may be partly responsible for this. As seen in Fig. 261-3, the pressure-volume relationship of the lung in ARDS is not linear. Alveoli may collapse at very low lung volumes. Animal studies have suggested that stretching and overdistention of injured alveoli during mechanical ventilation can further injure the lung. Concern over this alveolar overdistention, termed *ventilator induced "volutrauma,"* led to a multicenter, randomized, prospective trial to compare traditional ventilator strategies for acute lung injury and ARDS (large tidal volume—12 mL/kg ideal body weight) to a low tidal volume (6 mL/kg ideal body weight). This study showed a dramatic reduction in mortality in the low tidal volume group (large tidal volume—39.8% mortality versus low tidal volume—31% mortality) and confirmed that ventilator management could impact outcomes in these patients. In addition, a "fluid conservative" man-

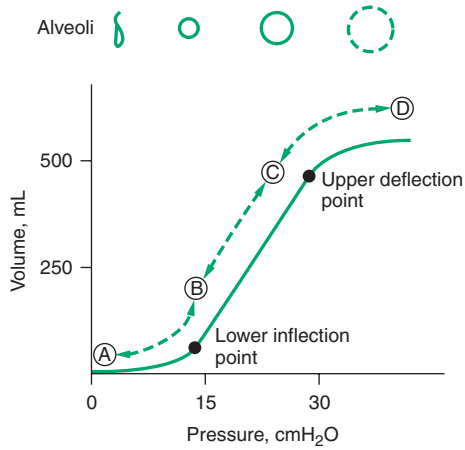

FIGURE 261-3 Pressure-volume relationship of the lungs of a patient with ARDS. At the lower inflection point, collapsed alveoli begin to open, and the lung compliance changes. At the upper deflection point, alveoli become overdistended. The shape and size of alveoli are illustrated at the top.

agement strategy [maintaining a relatively low central venous pressure (CVP) or pulmonary capillary wedge pressure (PCWP)] is associated with the need for fewer days of mechanical ventilation when compared to a "fluid liberal" management strategy (maintaining a relatively high CVP or PCWP) in acute lung injury and ARDS.

Type II Respiratory Failure This type of respiratory failure occurs as a result of alveolar hypoventilation and results in the inability to eliminate carbon dioxide effectively. Mechanisms by which this occurs are categorized by impaired central nervous system (CNS) drive to breathe, impaired strength with failure of neuromuscular function in the respiratory system, and increased load(s) on the respiratory system. Reasons for diminished CNS drive to breathe include drug overdose, brainstem injury, sleep-disordered breathing, and hypothyroidism. Reduced strength can be due to impaired neuromuscular transmission (e.g., myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis, phrenic nerve injury) or respiratory muscle weakness (e.g., myopathy, electrolyte derangements, fatigue).

The overall load on the respiratory system can be classified into increased resistive loads (e.g., bronchospasm), loads due to reduced lung compliance [e.g., alveolar edema, atelectasis, intrinsic positive end-expiratory pressure (autoPEEP)—see below], loads due to reduced chest wall compliance (e.g., pneumothorax, pleural effusion, abdominal distention), and loads due to increased minute ventilation requirements (e.g., pulmonary embolus with increased dead space fraction, sepsis).

The mainstays of therapy for type II respiratory failure are treatments directed at reversing the underlying cause(s) of ventilatory failure. Noninvasive positive-pressure ventilation using a mechanical ventilator with a tight-fitting face or nasal mask that avoids endotracheal intubation can often stabilize these patients. This approach has been shown to be beneficial in treating patients with exacerbations of chronic obstructive pulmonary disease. Noninvasive ventilation has been tested less extensively in other types of type II respiratory failure, but may be attempted nonetheless, in the absence of contraindications (hemodynamic instability, inability to protect airway, respiratory arrest).

Type III Respiratory Failure This form of respiratory failure occurs as a result of lung atelectasis. Because atelectasis occurs so commonly in the perioperative period, this is also called perioperative respiratory failure. After general anesthesia, decreases in functional residual capacity lead to collapse of dependent lung units. Such atelectasis can be treated by frequent changes in position, chest physiotherapy, upright positioning, and aggressive control of incisional and/or abdominal pain. Noninvasive positive-pressure ventilation may also be used to reverse regional atelectasis.

Type IV Respiratory Failure This form occurs due to hypoperfusion of respiratory muscles in patients in shock. Normally, respiratory muscles consume <5% of the total CO and O_2 delivery. Patients in shock often suffer respiratory distress due to pulmonary edema (e.g., patients in cardiogenic shock), lactic acidosis, and anemia. In this setting, up to 40% of the CO may be distributed to the respiratory muscles. Intubation and mechanical ventilation can allow redistribution of the CO away from the respiratory muscles and back to vital organs while the shock is treated.

CARE OF THE MECHANICALLY VENTILATED PATIENT (See also Chap. 263)

While a thorough understanding of the pathophysiology of respiratory failure is essential in order to optimize patient care, recognition of a patient's readiness to be liberated from mechanical ventilation is similarly important. Several studies have shown that subjecting patients to daily spontaneous breathing trials can identify those ready for extubation. Accordingly, all intubated, mechanically ventilated patients should undergo a daily screening of respiratory function. If oxygenation is stable (i.e., $Pa_{O_2}/FI_{O_2} > 200$ and PEEP ≤ 5 cmH_2O), cough and airway reflexes are intact, and no vasopressor agents or sedatives are being administered, the patient has passed the screening test and should undergo a spontaneous breathing trial. This trial consists of a period of breathing through the endotracheal tube without ventilator support [both continuous positive airway pressure (CPAP) of 5 cmH_2O and an open T-piece breathing system can be used] for 30–120 min. The spontaneous breathing trial is declared a failure and stopped if *any* of the following occur: (1) respiratory rate > 35/min for >5 min, (2) O_2 saturation < 90%, (3) heart rate > 140/min or a 20% increase or decrease from baseline, (4) systolic blood pressure < 90 mmHg or >180 mmHg, (5) increased anxiety or diaphoresis. If, at the end of the spontaneous breathing trial, the ratio of the respiratory rate and tidal volume in liters (f/V_T) is <105, the patient can be extubated. Such protocol-driven approaches to patient care can have an important impact on the duration of mechanical ventilation and length of stay in the ICU. In spite of such a careful approach to liberation from mechanical ventilation, up to 10% of patients will develop respiratory distress after extubation and may require resumption of mechanical ventilation. Many of these patients will require re-intubation. A recent study suggested that the use of noninvasive ventilation in patients who fail extubation may be associated with worse outcomes compared to immediate re-intubation.

Mechanically ventilated patients frequently require sedatives and analgesics. Most patients undergoing mechanical ventilation experience pain, which can be elicited by the presence of the endotracheal tube and endotracheal suctioning. Accordingly, early and aggressive attention to pain control is extremely important. Opiates are the mainstay of therapy for pain control in mechanically ventilated patients. After assuring adequate pain control, additional indications for sedation for mechanically ventilated patients include anxiolysis; treatment of subjective dyspnea; psychosis; facilitation of nursing care; reduction of autonomic hyperactivity, which may precipitate myocardial ischemia; and reducing total O_2 consumption (V_{O_2}).

Neuromuscular blocking agents are occasionally needed to facilitate mechanical ventilation in patients with profound dyssynchrony with the ventilator despite optimal sedation. The use of neuromuscular blocking agents may result in prolonged weakness—a myopathy known as the *postparalytic syndrome*. As such, these agents are typically used as a last resort, when aggressive sedation fails to achieve patient-ventilator synchrony. Because neuromuscular blocking agents result in pharmacologic paralysis without altering mental status, sedative-induced amnesia is mandatory when these agents are administered.

Amnesia can be reliably achieved with benzodiazepines such as lorazepam or midazolam, as well as the IV anesthetic agent propofol. Outside of the setting of pharmacologic paralysis, there are few data supporting the idea that amnesia is mandatory in all patients who require intubation and mechanical ventilation. Since many of these patients have

impaired hepatic and renal function, sedatives and opiates may accumulate in critically ill patients when they are given for prolonged periods of time. A protocol-driven approach to sedation of mechanically ventilated patients with daily interruption of sedative infusions has been shown to prevent excessive drug accumulation and shorten the durations of mechanical ventilation and length of stay in the ICU.

MULTIORGAN SYSTEM FAILURE

The syndrome of multiorgan system failure is a common problem associated with critical illness. This syndrome is defined by the simultaneous presence of physiologic dysfunction and/or failure of two or more organs. Typically, this occurs in the setting of severe sepsis, shock of any kind, as well as severe inflammatory conditions such as pancreatitis, and trauma. That multiorgan system failure occurs commonly in the ICU is a testament to our current ability to stabilize and support single organ failure. The ability to support single organ failure aggressively (e.g., mechanical ventilation for respiratory failure, renal replacement therapy for acute renal failure) has impacted early mortality in critical illness greatly. As such, it is uncommon for critically ill patients to die in the initial stages of resuscitation. Instead, many patients succumb to critical illness later in the ICU stay, after the initial presenting problem has been stabilized.

While there is debate regarding specific definitions of organ failure, several general principles governing the syndrome of multiorgan system failure apply. First, organ failure, no matter how defined, must persist beyond 24 h. Second, mortality risk increases as patients accrue additional organ failures. Third, prognosis is worsened by increased duration of organ failure. These observations remain true across various critical care settings (e.g., medical versus surgical). SIRS is a common basis for multiorgan system failure. Though infection is a common cause of SIRS, "sterile" triggers such as pancreatitis, trauma, and burns are often invoked to explain multiorgan system failure.

MONITORING IN THE ICU

Because respiratory failure occurs commonly in critically ill patients, monitoring of the respiratory and cardiovascular systems is undertaken frequently in the ICU. Evaluation of respiratory gas exchange is routine in critical illness. The "gold standard" remains arterial blood-gas analysis, where pH, partial pressures of O_2 and CO_2, and O_2 saturation are measured directly. With arterial blood-gas analysis, the two main functions of the lung—oxygenation of arterial blood and elimination of CO_2—can be directly assessed. Importantly, the blood pH, which has a profound effect on the drive to breathe, can be assessed only by sampling of arterial blood. Though sampling of arterial blood is generally safe, it may be painful and cannot provide continuous information for clinicians routinely. Given these limitations, noninvasive monitoring of respiratory function is often employed in the critical care setting.

PULSE OXIMETRY

This is the most commonly utilized noninvasive monitor of respiratory function. This technique takes advantage of differences in the absorptive properties of oxygenated and deoxygenated hemoglobin. At wavelengths of 660 nm, oxyhemoglobin reflects light more effectively than deoxyhemoglobin, whereas the reverse is true in the infrared spectrum (940 nm). A pulse oximeter passes both wavelengths of light through a perfused digit such as a finger, and the relative intensity of light transmission at these two wavelengths is recorded. This allows the derivation of the relative percent of oxyhemoglobin. Since arterial pulsations produce phasic changes in the intensity of transmitted light, the pulse oximeter is designed to detect only light of alternating intensity. This allows distinction of arterial and venous blood O_2 saturations.

Respiratory System Mechanics These can be measured in patients during mechanical ventilation (Chap. 263). When volume-controlled modes of mechanical ventilation are used, accompanying airway pressures can be easily measured. The peak airway pressure is determined by two variables—the airways resistance and respiratory system compliance. At the end of inspiration, inspiratory flow can be stopped transiently. This end-inspiratory pause (*plateau pressure*) is a static measurement, impacted only by respiratory system compliance, not airways resistance. Therefore, during volume-controlled ventilation, the difference between the peak (airways resistance + respiratory system compliance) and plateau (respiratory system compliance only) airway pressures provides a quantitative assessment of airways resistance. Accordingly, during volume-controlled ventilation, patients with increases in airways resistance typically have increased peak airway pressures as well as abnormally high gradients between peak and plateau airway pressures (typically >15 cmH_2O). The compliance of the respiratory system is defined by the change in pressure of the respiratory system per unit change in volume.

The respiratory system can be divided further into two components—the lungs and the chest wall. Normally, the respiratory system compliance is ~100 mL per cmH_2O. Pathophysiologic processes such as pleural effusions, pneumothorax, or increased abdominal girth from ascites or obesity all reduce chest wall compliance. Lung compliance may be reduced by pneumonia, pulmonary edema from any cause, or autoPEEP. Accordingly, patients with abnormalities in compliance of the respiratory system (lungs and/or chest wall) typically have elevated peak *and* plateau airway pressures but a normal gradient between peak and plateau airway pressures. AutoPEEP occurs when there is insufficient time for emptying of alveoli prior to the next inspiratory cycle. Since the alveoli have not decompressed completely, alveolar pressure remains positive at end-exhalation (functional residual capacity). This phenomenon occurs most commonly due to critical narrowing of distal airways in disease processes such as asthma and chronic obstructive pulmonary disease. AutoPEEP with resulting alveolar overdistention may result in diminished lung compliance, reflected by abnormally increased plateau airway pressures. Modern mechanical ventilators allow breath-to-breath display of pressure and flow, which may allow detection of problems such as patient-ventilator dyssynchrony, airflow obstruction, and autoPEEP (Fig. 261-4).

CIRCULATORY STATUS

Monitors to characterize the circulation status of critically ill patients are used commonly in the ICU. One of the most frequently used is the pulmonary artery catheter, also known as the right heart catheter or Swan-Ganz catheter. This catheter was originally designed as a tool to

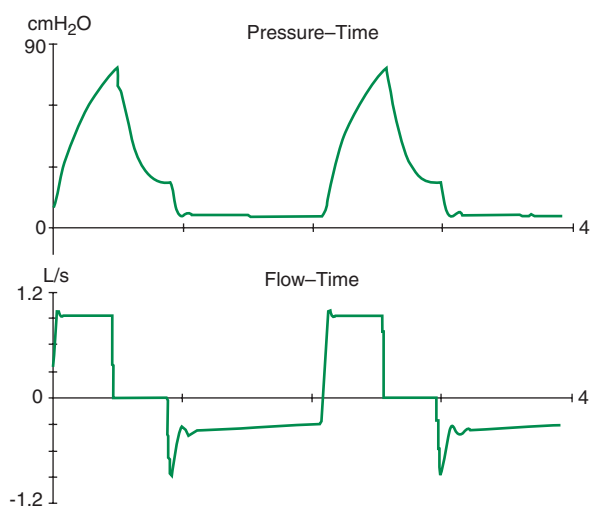

FIGURE 261-4 Increased airway resistance with autoPEEP. The top waveform (airway pressure vs. time) shows a large difference between the peak airway pressure (80 cmH_2O) and the plateau airway pressure (20 cmH_2O). The bottom waveform (flow vs. time) demonstrates airflow throughout expiration (reflected by the flow tracing on the negative portion of the abscissa) that persists up to the next inspiratory effort.

guide therapy in acute myocardial infarction but is currently used in the ICU for evaluation and treatment of a variety of other conditions such as ARDS, septic shock, congestive heart failure, and acute renal failure. This device has never been validated as a tool associated with reduction in morbidity and mortality. Indeed, in spite of numerous prospective studies, there has been no report of mortality or morbidity benefit associated with the use of the pulmonary artery catheter in any setting.

Pulmonary artery catheters are invasive monitors and may be associated with a number of complications. Since the catheter is inserted via a central vein, all of the complications associated with central venous catheterization are present. These include central venous catheter–related infections, pneumothorax, arterial puncture with or without cannulation, bleeding, air embolism, venous thrombosis, and catheter embolism. The insertion of the pulmonary artery catheter also carries a number of risks, including dysrhythmias, heart block, cardiac perforation, and balloon fragmentation. After the catheter is placed, pulmonary infarction, pulmonary artery rupture, and pulmonic valve insufficiency may occur. Fortunately, most of these complications are quite rare. Indeed, misinterpretation of data derived from central venous and pulmonary artery catheters may be the most common "complication" seen with these monitors. Pressure measurements in various cardiac chambers require careful zeroing of the pressure transducer relative to atmospheric pressure. In addition, the transducer must also be at the same level as the cardiac chamber whose pressure is being measured. If the transducer is either higher or lower by several centimeters, the value recorded may be quite inaccurate.

Atrial pressure measurements should be made at end-expiration when there is no movement of air in or out of the thorax. It is during this period, with the lungs at functional residual capacity (cessation of gas flow), that gas flow in or out of the chest cannot complicate measurements of the atrial pressure. Many critically ill patients with respiratory distress may never come to a point where airflow in and out of the thorax ceases, instead breathing with continuous inspiratory and expiratory movements. In such patients, atrial pressure may be difficult to measure accurately. Failure to recognize this limitation may lead to reliance on inaccurate data obtained from the central venous or pulmonary artery catheter. Indeed, studies have shown that many clinicians are unable to obtain and interpret data from such catheters accurately. Accordingly, it appears that the routine use of pulmonary artery catheterization is not indicated as a monitor to characterize the circulatory status in most critically ill patients.

Oxygen delivery (Q_{O_2}) is a function of CO and the content of O_2 in the arterial blood (Ca_{O_2}). The Ca_{O_2} is determined by the hemoglobin concentration, the arterial hemoglobin saturation, and dissolved O_2 not bound to hemoglobin. For normal adults:

$$\begin{aligned} Q_{O_2} &= 50\ \text{dL/min} \times [1.39 \times 15\ \text{g/dL (hemoglobin concentration)} \times 1.0 \\ &\quad \text{(hemoglobin \% saturation)} + 0.0031 \times 100\ (Pa_{O_2})] \\ &= 50\ \text{dL/min (CO)} \times 21.16\ \text{mL } O_2 \text{ per dL blood } (Ca_{O_2}) \\ &= 1058\ \text{mL } O_2 \text{ per min} \end{aligned}$$

It is apparent that the vast majority of O_2 delivered to tissues is bound to hemoglobin and that the dissolved O_2 (Pa_{O_2}) contributes very little to O_2 content in arterial blood or O_2 delivery. Normally, the content of O_2 in mixed venous blood ($C\bar{v}_{O_2}$) is 15.95 mL O_2 per dL blood, since the mixed venous blood is 75% saturated. Therefore, the normal tissue extraction ratio for O_2 is $Ca_{O_2} - C\bar{v}_{O_2}/Ca_{O_2}$ (21.16 – 15.95/21.16) or ~25%. A pulmonary artery catheter allows measurements of O_2 delivery and O_2 extraction ratio.

The mixed venous O_2 saturation allows assessment of global tissue perfusion. A reduced mixed venous O_2 saturation may be caused by inadequate cardiac output, reduced hemoglobin concentration, and/or reduced arterial O_2 saturation. An abnormally high O_2 consumption (V_{O_2}) may also lead to a reduced mixed venous O_2 saturation if O_2 delivery is not concomitantly increased. Abnormally increased V_{O_2} by peripheral tissues may be caused by a multitude of problems such as fever, agitation, shivering, or thyrotoxicosis.

PREVENTION OF COMPLICATIONS OF CRITICAL ILLNESS

Sepsis in the Critical Care Unit (See also Chap. 265) Sepsis is a significant problem in the care of critically ill patients. It is the leading cause of death in noncoronary ICUs in the United States. Current estimates suggest that >750,000 patients are affected with this condition each year, and these numbers are expected to increase as the population continues to age and a greater percentage of persons vulnerable to infection seek medical care.

Many therapeutic interventions in the ICU are invasive and predispose patients to infectious complications. These interventions include endotracheal intubation, indwelling vascular catheters, nasally placed enteral feeding tubes, transurethral bladder catheters, and other catheters placed into sterile body cavities (e.g., tube thoracostomy, percutaneous intraabdominal drainage catheters). The longer such devices remain in place, the more prone to these infections patients become. For example, ventilator-associated pneumonia correlates strongly with the duration of intubation and mechanical ventilation. Therefore, an important aspect of preventive care is the timely removal of invasive devices as soon as they as no longer needed. Multidrug resistant organisms are commonplace in the ICU.

An important aspect of critical care is infection control in the ICU. Simple measures such as frequent handwashing are effective but underutilized strategies. Protective isolation of patients with colonization or infection by drug-resistant organisms is another frequently used strategy in the critical care setting. Antibiotic-coated vascular catheters or endotracheal tubes with specialized suction ports above the cuff to decrease pooling and aspiration of oral secretions are other strategies that may be used, with varying degrees of effectiveness reported. Surveillance programs monitoring adherence to infection control practices such as those described here may reduce the incidence of nosocomial infections.

Deep Venous Thromboses (DVTs) All ICU patients are at high risk for this complication given their predilection toward immobility. Therefore, all ICU patients should receive some form of prophylaxis against DVT. The most commonly employed forms of prophylaxis are subcutaneous low-dose heparin injections and sequential compression devices for the lower extremities. Observational studies report an alarming incidence of the occurrence of DVTs despite the use of these standard prophylactic regimens. Heparin prophylaxis may result in heparin-induced thrombocytopenia (HIT)—another relatively common nosocomial complication in critically ill patients.

Low-molecular-weight heparins such as enoxaparin are more effective than unfractionated heparin for DVT prophylaxis in high-risk patients, such as those undergoing orthopedic surgery, and they have a lower incidence of HIT. Fondaparinux, a selective factor Xa inhibitor, is even more effective than enoxaparin in high-risk orthopedic patients.

Stress Ulcers Prophylaxis against stress ulcers is frequently administered in most ICUs. Typically, histamine-2 antagonists are administered. Currently available data suggest that high-risk patients, such as those with coagulopathy, shock, or respiratory failure requiring mechanical ventilation, benefit from such prophylactic treatment.

Nutrition and Glycemic Control These are important issues in critically ill patients that may be associated with respiratory failure, impaired wound healing, and dysfunctional immune response. Early enteral feeding is reasonable, though no data are available to suggest that this improves patient outcome *per se*. Certainly, enteral feeding, if possible, is preferred over parenteral nutrition, which is associated with numerous complications including hyperglycemia, fatty liver, cholestasis, and sepsis. In addition to this, enteral feeding may prevent bacterial translocation across the gut mucosa. Intensive insulin therapy to normalize glucose levels is associated with improved survival in surgical ICU patients.

ICU-Acquired Weakness This occurs frequently in patients who survive critical illness. It is particularly common in those with SIRS and/or sepsis. Neuropathies and myopathies both have been described,

most commonly after ~1 week in the ICU. The mechanisms behind ICU-acquired weakness syndromes are poorly understood. Intensive insulin therapy may reduce polyneuropathy of critical illness. Apart from this, no preventative measures against this complication of critical illness have been described.

Anemia This is a common problem in critically ill patients. Studies have shown that the vast majority of ICU patients are anemic. Furthermore, most suffer from anemia of chronic inflammation. Phlebotomy contributes significantly to anemia in ICU patients. Studies have demonstrated that erythropoietin levels are inappropriately reduced in most ICU patients and that exogenous erythropoietin administration may reduce transfusion requirements in the ICU. The hemoglobin level that merits transfusion in critically ill patients has been a long-standing area of controversy. A large, multicenter study involving patients in many different ICU settings challenged the conventional notion that a hemoglobin level of 100 g/L (10 g/dL) is needed in critically ill patients. Red blood cell transfusion is associated with impairment of immune function and increased risk of infections, as well as acute lung injury and volume overload—all of which may explain the findings in this study. A conservative transfusion strategy should be the rule in managing critically ill patients who are not actively hemorrhaging.

Acute Renal Failure (See also Chap. 273) This occurs in a significant percentage of critically ill patients. The most common underlying etiology is acute tubular necrosis, usually precipitated by hypoperfusion and/or nephrotoxic agents. Currently, there are no pharmacologic agents available for prevention of renal injury in critical illness. A recent study showed convincingly that low-dose dopamine is *not* effective in protecting the kidneys from acute injury.

NEUROLOGIC DYSFUNCTION IN CRITICALLY ILL PATIENTS

Neurologic dysfunction is common in critically ill patients.

Delirium (See also Chap. 26 and Chap. 268) This state is defined by: (1) an acute onset of changes or fluctuations in the course of mental status, (2) inattention, (3) disorganized thinking, and (4) an altered level of consciousness (i.e., other than alert). Delirium has been reported to occur in >80% of a cohort of patients admitted to the ICU. A rapid test—the Confusion Assessment Method (CAM)—to assess critically ill patients for delirium is available and has been validated. This assessment asks patients to answer simple questions and perform simple tasks and can be completed by the bedside nurse in ~2 min. The differential diagnosis of delirium in the ICU patient is broad and includes infectious etiologies (including sepsis), medications (particularly sedatives and analgesics), drug withdrawal, metabolic/electrolyte derangements, intracranial pathology (e.g., stroke, intracranial hemorrhage), seizures, hypoxia, hypertensive crisis, shock, and vitamin deficiencies (particularly thiamine).

Anoxic Cerebral Injury (See also Chap. 269) This condition is common after cardiac arrest and often results in severe and permanent brain injury in patients whose cardiac arrest is resuscitated. Active cooling of patients after cardiac arrest has been shown to improve neurologic outcomes. As such, patients who present to the ICU after circulatory arrest from ventricular fibrillation or pulseless ventricular tachycardia should be actively cooled with cooling blankets and ice packs if necessary to achieve a core body temperature of 32–34°C.

Stroke (See also Chap. 364) This is a common cause of neurologic critical illness. Hypertension must be managed carefully, since abrupt reductions in blood pressure may be associated with further brain ischemia and injury. Acute ischemic stroke treated with tissue plasminogen activator (tPA) shows improved neurologic outcome when treatment is given within 3 h of onset of symptoms. Mortality is not improved when tPA is compared to placebo, despite improved neurologic outcome. Cerebral hemorrhage is significantly higher in patients given tPA. A treatment benefit is not seen when tPA therapy is given beyond 3 h. Heparin has not been shown to demonstrate improved outcomes convincingly in patients with acute ischemic stroke.

Subarachnoid Hemorrhage (See also Chap. 364) This may occur secondary to aneurysm rupture and is often complicated by cerebral vasospasm, rebleeding, and hydrocephalus. Vasospasm can be detected by either transcranial Doppler assessment or cerebral angiography; it is typically treated with the calcium channel blocker nimodipine, aggressive IV fluid administration, and therapy aimed at increasing the blood pressure, typically with vasoactive drugs such as phenylephrine. The IV fluids and vasoactive drugs (hypertensive hypervolemic therapy) are used to overcome the cerebral vasospasm. Early surgical clipping of aneurysms is advocated by most authorities to prevent complications related to rebleeding. Hydrocephalus, typically heralded by a decreased level of consciousness, may require ventriculostomy drainage.

Status Epilepticus (See also Chap. 363) Recurrent or relentless seizure activity is a medical emergency. Cessation of seizure activity is required to prevent irreversible neurologic injury. Lorazepam is the most effective benzodiazepine for treating status epilepticus and is the treatment of choice for controlling seizures acutely. Phenytoin or fosphenytoin should be given concomitantly since lorazepam has a short half-life. Other drugs such as gabapentin, carbamazepine, and phenobarbital should be reserved for patients with contraindications to phenytoin (e.g., allergy or pregnancy) or ongoing seizures despite phenytoin.

Brain Death (See also Chap. 269) Though critically ill patients usually die from irreversible cessation of circulatory and respiratory function, a diagnosis of death may also be established by irreversible cessation of all functions of the entire brain, including the brainstem, even if circulatory and respiratory function remains intact by artificial life support. Patients must demonstrate absence of cerebral function (unresponsive to all external stimuli) and brainstem functions [e.g., unreactive pupils, absent ocular movement to head turning or ice water irrigation of ear canals, positive apnea test (no drive to breathe)]. Absence of brain function must have an established cause and be permanent without possibility of recovery (e.g., must confirm the absence of sedative effect, hypothermia, hypoxemia, neuromuscular paralysis, or severe hypotension). If there is uncertainty about the cause of coma, studies of cerebral blood flow and electroencephalography should be performed.

WITHHOLDING AND WITHDRAWING CARE (See also Chap. 11)

The withholding and withdrawing of care occurs commonly in the ICU setting. The Task Force on Ethics of the Society of Critical Care Medicine reported that it is ethically sound to withhold or withdraw care if a patient or surrogate makes such a request or if the goals of therapy are not achievable according to the physician. Since all medical treatments are justified by their expected benefits, the loss of such an expectation justifies the act of withdrawing or withholding such a treatment. As such, the act of withdrawing care is fundamentally similar to the act of withholding care. An underlying stipulation derived from this Task Force report is that the informed patient should have his or her wishes respected with regard to life-sustaining therapy. Implicit in this stipulation is the need to ensure that patients are thoroughly and accurately informed regarding the plausibility and expected results of various therapies.

The act of informing patients and/or surrogate decision makers is the responsibility of the physician and other health care providers. In the event a patient or surrogate desires therapy deemed futile by the treating physician, the latter is not obligated ethically to provide such treatment. Rather, arrangements may be made to transfer the patient's care to another care provider. Critical care providers should meet regularly with patients and/or surrogates to discuss prognosis when the withholding or withdrawal of care is being considered. After a consensus amongst caregivers has been reached regarding withholding or withdrawal of care, this should be relayed to the patient and/or surro-

gate decision maker. If a decision to withhold or withdraw life-sustaining care for a patient has been reached, aggressive attention to analgesia and anxiolysis is needed. Opiates and benzodiazepines are typically used to achieve these goals.

262 Acute Respiratory Distress Syndrome

Bruce D. Levy, Steven D. Shapiro

Acute respiratory distress syndrome (ARDS) is a clinical syndrome of severe dyspnea of rapid onset, hypoxemia, and diffuse pulmonary infiltrates leading to respiratory failure. ARDS is caused by diffuse lung injury from many underlying medical and surgical disorders. The lung injury may be direct, as occurs in toxic inhalation, or indirect, as occurs in sepsis (Table 262-1). The clinical features of ARDS are listed in Table 262-2. Acute lung injury (ALI) is a less severe disorder but has the potential to evolve into ARDS (Table 262-2). The arterial (a) P_{O_2} (in mmHg)/FI_{O_2} (inspiratory O_2 fraction) <200 mmHg is characteristic of ARDS, while a Pa_{O_2}/FI_{O_2} between 200 and 300 identifies patients with ALI who are likely to benefit from aggressive therapy.

The annual incidences of ALI and ARDS are estimated to be up to 80/100,000 and 60/100,000, respectively. Approximately 10% of all intensive care unit (ICU) admissions suffer from acute respiratory failure, with ~20% of these patients meeting criteria for ALI or ARDS.

ETIOLOGY

While many medical and surgical illnesses have been associated with the development of ALI and ARDS, most cases (>80%) are caused by a relatively small number of clinical disorders, namely, severe sepsis syndrome and/or bacterial pneumonia (~40–50%), trauma, multiple transfusions, aspiration of gastric contents, and drug overdose. Among patients with trauma, pulmonary contusion, multiple bone fractures, and chest wall trauma/flail chest are the most frequently reported surgical conditions in ARDS, whereas head trauma, near-drowning, toxic inhalation, and burns are rare causes. The risks of developing ARDS are increased in patients suffering from more than one predisposing medical or surgical condition; e.g., the risk for ARDS increases from 25% in patients with severe trauma to 56% in patients with trauma and sepsis.

TABLE 262-1 CLINICAL DISORDERS COMMONLY ASSOCIATED WITH ARDS

Direct Lung Injury	Indirect Lung Injury
Pneumonia	Sepsis
Aspiration of gastric contents	Severe trauma
Pulmonary contusion	Multiple bone fractures
Near-drowning	Flail chest
Toxic inhalation injury	Head trauma
	Burns
	Multiple transfusions
	Drug overdose
	Pancreatitis
	Post-cardiopulmonary bypass

TABLE 262-2 DIAGNOSTIC CRITERIA FOR ALI AND ARDS

Oxygenation	Onset	Chest Radiograph	Absence of Left Atrial Hypertension
ALI: Pa_{O_2}/FI_{O_2} ≤ 300 mmHg ARDS: Pa_{O_2}/FI_{O_2} ≤ 200 mmHg	Acute	Bilateral alveolar or interstitial infiltrates	PCWP ≤ 18 mmHg *or* no clinical evidence of increased left atrial pressure

Note: ALI, acute lung injury; ARDS, acute respiratory distress syndrome; Pa_{O_2}, arterial partial pressure of O_2; FI_{O_2}, inspired O_2 percentage; PCWP, pulmonary capillary wedge pressure.

Several other clinical variables have been associated with the development of ARDS. These include older age, chronic alcohol abuse, metabolic acidosis, and severity of critical illness. Trauma patients with an acute physiology and chronic health evaluation (APACHE) II score ≥16 (Chap. 261) have a 2.5-fold increase in the risk of developing ARDS, and those with a score >20 have an incidence of ARDS that is more than threefold greater than those with APACHE II scores ≤9.

CLINICAL COURSE AND PATHOPHYSIOLOGY

The natural history of ARDS is marked by three phases—exudative, proliferative, and fibrotic—each with characteristic clinical and pathologic features (Fig. 262-1).

Exudative Phase (Fig. 262-2) In this phase, alveolar capillary endothelial cells and type I pneumocytes (alveolar epithelial cells) are in-

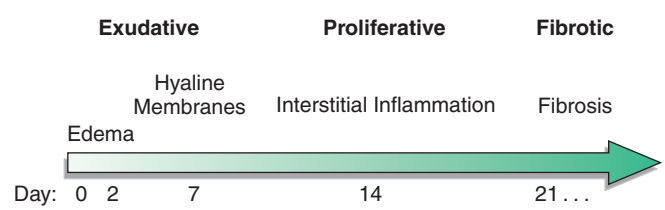

FIGURE 262-1 Diagram illustrating the time course for the development and resolution of ARDS. The exudative phase is notable for early alveolar edema and neutrophil-rich leukocytic infiltration of the lungs with subsequent formation of hyaline membranes from diffuse alveolar damage. Within 7 days, a proliferative phase ensues with prominent interstitial inflammation and early fibrotic changes. Approximately 3 weeks after the initial pulmonary injury, most patients recover. However, some patients enter the fibrotic phase, with substantial fibrosis and bullae formation.

FIGURE 262-2 A representative anteroposterior (AP) chest x-ray in the exudative phase of ARDS that shows diffuse interstitial and alveolar infiltrates, which can be difficult to distinguish from left ventricular failure.

jured, leading to the loss of the normally tight alveolar barrier to fluid and macromolecules. Edema fluid that is rich in protein accumulates in the interstitial and alveolar spaces. Significant concentrations of cytokines (e.g., interleukin 1, interleukin 8, and tumor necrosis factor α) and lipid mediators (e.g., leukotriene B_4) are present in the lung in this acute phase. In response to proinflammatory mediators, leukocytes (especially neutrophils) traffic into the pulmonary interstitium and alveoli. In addition, condensed plasma proteins aggregate in the air spaces with cellular debris and dysfunctional pulmonary surfactant to form hyaline membrane whorls. Pulmonary vascular injury also occurs early in ARDS, with vascular obliteration by microthrombi and fibrocellular proliferation (Fig. 262-3).

Alveolar edema predominantly involves *dependent* portions of the lung, leading to diminished aeration and atelectasis. Collapse of large sections of dependent lung markedly decreases lung compliance. Consequently, intrapulmonary shunting and hypoxemia develop and the work of breathing rises, leading to dyspnea. The pathophysiologic alterations in alveolar spaces are exacerbated by microvascular occlusion, which leads to reductions in pulmonary arterial blood flow to ventilated portions of the lung, increasing the dead space, and pulmonary hypertension. Thus, in addition to severe hypoxemia, hypercapnia secondary to an increase in pulmonary dead space is also prominent in early ARDS.

The exudative phase encompasses the first 7 days of illness after exposure to a precipitating ARDS risk factor, with the patient experiencing the onset of respiratory symptoms. Although usually present within 12–36 h after the initial insult, symptoms can be delayed by 5–7 days. Dyspnea develops with a sensation of rapid shallow breathing and an inability to get enough air. Tachypnea and increased work of breathing frequently result in respiratory fatigue and ultimately in respiratory failure. Laboratory values are generally nonspecific and primarily indicative of underlying clinical disorders. The chest radiograph usually reveals alveolar and interstitial opacities involving at least three-quarters of the lung fields (Fig. 262-2). While characteristic for ARDS or ALI, these radiographic findings are not specific and can be indistinguishable from cardiogenic pulmonary edema (Chap. 266). Unlike the latter, however, the chest x-ray in ARDS rarely shows cardiomegaly, pleural effusions, or pulmonary vascular redistribution. Chest computed tomography (CT) scanning in ARDS reveals extensive heterogeneity of lung involvement (Fig. 262-4).

Because the early features of ARDS and ALI are nonspecific, alternative diagnoses must be considered. In the differential diagnosis of ARDS, the most common disorders are cardiogenic pulmonary edema, diffuse pneumonia, and alveolar hemorrhage. Less frequent diagnoses to consider include acute interstitial lung diseases [e.g., acute interstitial pneumonitis (Chap. 255)], acute immunologic injury [e.g., hypersensitivity pneumonitis (Chap. 249)], toxin injury (e.g., radiation pneumonitis), and neurogenic pulmonary edema.

Proliferative Phase This phase of ARDS usually lasts from day 7 to day 21. Most patients recover rapidly and are liberated from mechanical ventilation during this phase. Despite this improvement, many still experience dyspnea, tachypnea, and hypoxemia. Some patients develop progressive lung injury and early changes of pulmonary fibrosis during the proliferative phase. Histologically, the first signs of resolution are often evident in this phase with the initiation of lung repair, organization of alveolar exudates, and a shift from a neutrophil to a lymphocyte-predominant pulmonary infiltrate. As part of the reparative process, there is a proliferation of type II pneumocytes along alveolar basement membranes. These specialized epithelial cells synthesize new pulmonary surfactant and differentiate into type I pneumocytes. The presence of alveolar type III procollagen peptide, a marker of pulmonary fibrosis, is associated with a protracted clinical course and increased mortality from ARDS.

Fibrotic Phase While many patients with ARDS recover lung function 3–4 weeks after the initial pulmonary injury, some will enter a fibrotic phase that may require long-term support on mechanical ventilators and/or supplemental oxygen. Histologically, the alveolar edema and inflammatory exudates of earlier phases are now converted to extensive alveolar duct and interstitial fibrosis. Acinar architecture is markedly disrupted, leading to emphysema-like changes with large bullae. Intimal fibroproliferation in the pulmonary microcirculation leads to progressive vascular occlusion and pulmonary hypertension. The physiologic consequences include an increased risk of pneumothorax, reductions in lung compliance, and increased pulmonary dead space. Patients in this late phase experience a substantial burden of excess morbidity. Lung biopsy evidence for pulmonary fibrosis in any phase of ARDS is associated with increased mortality.

℞ ACUTE RESPIRATORY DISTRESS

GENERAL PRINCIPLES Recent reductions in ARDS/ALI mortality are largely the result of general advances in the care of critically ill patients (Chap. 261). Thus, caring for these patients requires close attention to: (1) the recognition and treatment of the underlying medical and surgical disorders (e.g., sepsis, aspiration, trauma); (2) minimizing procedures and their complications; (3) prophylaxis against venous thromboembolism, gastrointestinal bleeding, and central venous catheter infections; (4) the prompt recognition of nosocomial infections; and (5) provision of adequate nutrition.

MANAGEMENT OF MECHANICAL VENTILATION (See also Chap. 263) Patients meeting clinical criteria for ARDS frequently fatigue from increased work of breathing and progressive hypoxemia, requiring mechanical ventilation for support.

Ventilator-Induced Lung Injury Despite its life-saving potential, mechanical ventilation can aggravate lung injury. Experimental models have demonstrated that ventilator-induced lung injury appears to require two processes: repeated alveolar overdistention and recurrent alveolar collapse. Clearly evident by chest CT (Fig. 262-4), ARDS is a heterogeneous disorder, principally involving dependent portions of the lung with relative sparing of other regions. Because of their differing compliance, attempts to fully inflate the consolidated lung may lead to overdistention and injury to the more "normal" areas of lung. Ventilator-induced injury can be demonstrated in experimental models of ALI, with high tidal volume ventilation resulting in additional, synergistic alveolar damage. These findings led to the hypothesis that ventilating patients suffering from ALI or ARDS with lower tidal volumes would protect against ventilator-induced lung injury and improve clinical outcomes.

A large-scale, randomized controlled trial sponsored by the National Institutes of Health and conducted by the ARDS Network compared low tid-

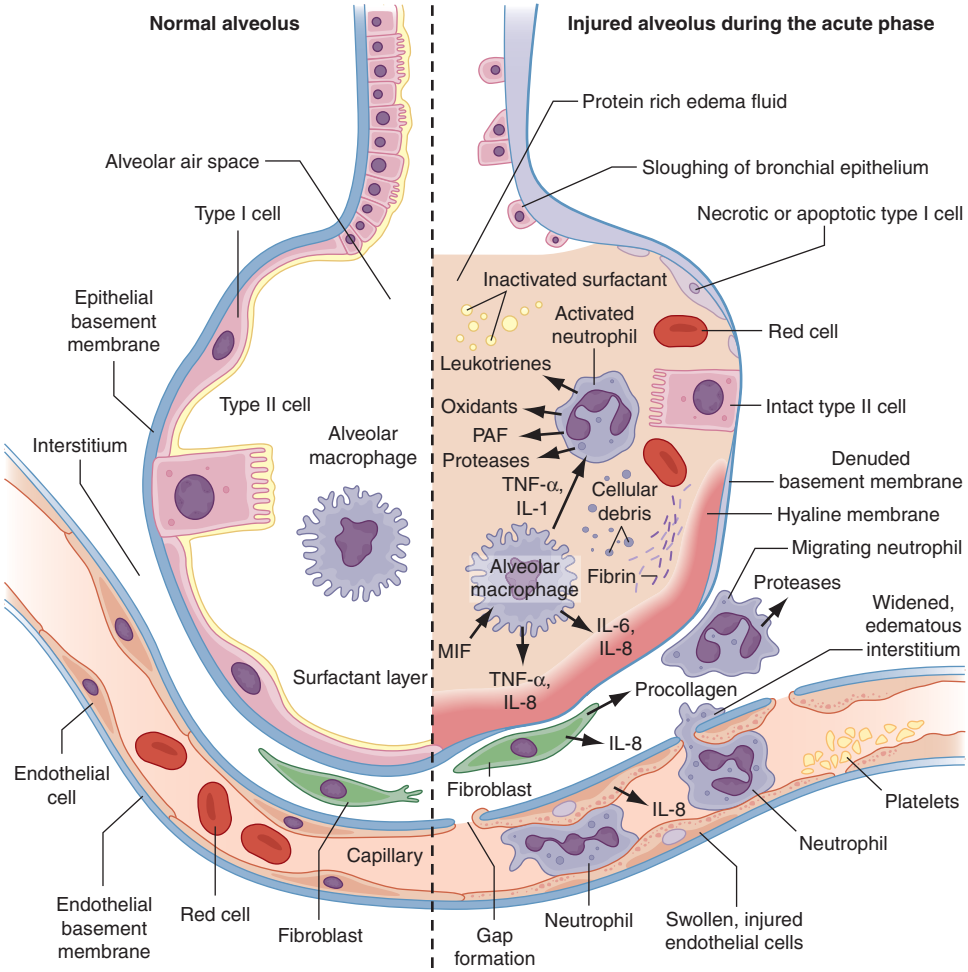

FIGURE 262-3 The normal alveolus (left-hand side) and the injured alveolus in the acute phase of acute lung injury and the acute respiratory distress syndrome (right-hand side). In the acute phase of the syndrome (right-hand side), there is sloughing of both the bronchial and alveolar epithelial cells, with the formation of protein-rich hyaline membranes on the denuded basement membrane. Neutrophils are shown adhering to the injured capillary endothelium and marginating through the interstitium into the air space, which is filled with protein-rich edema fluid. In the air space, an alveolar macrophage is secreting cytokines, interleukin 1, 6, 8, and 10 (IL-1, 6, 8, and 10) and tumor necrosis factor α (TNF-α), which act locally to stimulate chemotaxis and activate neutrophils. Macrophages also secrete other cytokines, including interleukin 1, 6, and 10. Interleukin 1 can also stimulate the production of extracellular matrix by fibroblasts. Neutrophils can release oxidants, proteases, leukotrienes, and other proinflammatory molecules, such as platelet-activating factor (PAF). A number of anti-inflammatory mediators are also present in the alveolar milieu, including interleukin 1–receptor antagonist, soluble tumor necrosis factor receptor, autoantibodies against interleukin 8, and cytokines such as interleukin 10 and 11 (not shown). The influx of protein-rich edema fluid into the alveolus has led to the inactivation of surfactant. MIF denotes macrophage inhibitory factor. *(From Ware and Matthay, with permission.)*

al volume (6 mL/kg predicted body weight) ventilation to conventional tidal volume (12 mL/kg predicted body weight) ventilation. Mortality was significantly lower in the low tidal volume patients (31%) compared to the conventional tidal volume patients (40%). This improvement in survival represents the most substantial benefit in ARDS mortality demonstrated for *any* therapeutic intervention in ARDS to date.

Prevention of Alveolar Collapse In ARDS, the presence of alveolar and interstitial fluid and the loss of surfactant can lead to a marked reduction of lung compliance. Without an increase in end-expiratory pressure, significant alveolar collapse can occur at end-expiration, impairing oxygenation. In most clinical settings, positive end-expiratory pressure (PEEP) is empirically set to minimize $F_{I_{O_2}}$ and maximize Pa_{O_2}. On most modern mechanical ventilators, it is possible to construct a static pressure–volume curve for the respiratory system. The lower inflection point on the curve represents alveolar opening (or "recruitment"). The pressure at this point, usually 12–15 mmHg in ARDS, is a theoretical "optimal PEEP" for alveolar recruitment. Titration of the PEEP to the lower inflection point on the static pressure–volume curve has been hypothesized to keep the lung open, improving oxygenation and protecting against lung injury. ARDS Network investigators compared low-to-high PEEP (8.3–13.2 cmH_2O) in over 500 patients with ARDS ventilated at low tidal volumes (6 mL/kg PBW). No significant differences in mortality, ventilator-free days, or ICU stay were observed. Until more data become available on the clinical utility of high PEEP, it is advisable to set PEEP to minimize $F_{I_{O_2}}$ and optimize Pa_{O_2} (Chap. 263).

Oxygenation can also be improved by increasing mean airway pressure with "inverse ratio ventilation." In this technique, the inspiratory (*I*) time is lengthened so that it is longer than the expiratory (*E*) time (*I*:*E* > 1:1). With diminished time to exhale, dynamic hyperinflation leads to increased end-expiratory pressure, similar to ventilator-prescribed PEEP. This mode of ventilation has the advantage of improving oxygenation with lower peak pressures than conventional ventilation. Although inverse ratio ventilation can improve oxygenation and help reduce $F_{I_{O_2}}$ to ≤0.60 to avoid possible oxygen toxicity, no mortality benefit in ARDS has been demonstrated.

In several randomized trials, mechanical ventilation in the prone position improved arterial oxygenation, but its effect on survival and other important clinical outcomes remains uncertain. Moreover, unless the critical-care team is experienced in "proning," repositioning critically ill patients can be hazardous, leading to accidental endotracheal extubation, loss of central venous catheters, and orthopedic injury. Until validation of its efficacy, prone-position ventilation should be reserved for only the most critically ill ARDS patients.

FIGURE 262-4 A representative computed tomographic scan of the chest during the exudative phase of ARDS in which *dependent* alveolar edema and atelectasis predominate.

Other Strategies in Mechanical Ventilation Several additional mechanical ventilation strategies that utilize specialized equipment have been tested in ARDS patients, most with mixed or disappointing results in adults. These include high-frequency ventilation (HFV), i.e., ventilating at extremely high respiratory rates (5–20 cycles per second) and low tidal volumes (1–2 mL/kg). Also, lung-replacement therapy with extracorporeal membrane oxygenation (ECMO), which provides a clear survival benefit in neonatal respiratory distress syndrome, has yet to have proven survival benefit in adults with ARDS. Ongoing research on partial liquid ventilation (PLV) with perfluorocarbon, an inert, high-density liquid that easily solubilizes oxygen and carbon dioxide, has revealed promising preliminary data on pulmonary function in patients with ARDS, but also without survival benefit.

Data in support of the efficacy of "adjunctive" ventilator therapies (e.g., high PEEP, inverse ratio ventilation, prone positioning, HFV, ECMO, and PLV) remain incomplete, so these modalities are not routinely used.

FLUID MANAGEMENT (See also Chap. 261) Increased pulmonary vascular permeability leading to interstitial and alveolar edema rich in protein is a central feature of ARDS. In addition, impaired vascular integrity augments the normal increase in extravascular lung water that occurs with increasing left atrial pressure. Maintaining a normal or low left atrial filling pressure minimizes pulmonary edema and prevents further decrements in arterial oxygenation and lung compliance, improves pulmonary mechanics, shortens ICU stay and the duration of mechanical ventilation, and is associated with a lower mortality. Thus, aggressive attempts to reduce left atrial filling pressures with fluid restriction and diuretics should be an important aspect of ARDS management, limited only by hypotension and hypoperfusion of critical organs, such as the kidneys.

GLUCOCORTICOIDS Inflammatory mediators and leukocytes are abundant in the lungs of patients with ARDS. Many attempts have been made to treat both early and late ARDS with glucocorticoids to reduce this potentially deleterious pulmonary inflammation. Few studies have shown any benefit. Current evidence does *not* support the use of glucocorticoids in the care of ARDS patients. However, the ARDS Network is currently conducting a large-scale study of glucocorticoids in the late phase of ARDS.

OTHER THERAPIES Clinical trials of surfactant replacement therapy have proved disappointing. Similarly, although several randomized clinical trials of inhaled nitric oxide (NO) in ARDS have demonstrated improved oxygenation, no significant improvement in survival or decrements in time on mechanical ventilation has been observed. Therefore, the use of NO is *not* currently recommended in ARDS.

RECOMMENDATIONS Many clinical trials have been undertaken to improve the outcome of patients with ARDS; most have been unsuccessful in modifying the natural history. The large number and uncertain clinical efficacy of ARDS therapies can make it difficult for clinicians to select a rational treatment plan, and these patients' critical illness can tempt physicians to try unproven and potentially harmful therapies. While results of large clinical trials must be judiciously administered to *individual* patients, evidence-based recommendations are summarized in **Table 262-3**, and an algorithm for the initial therapeutic goals and limits in ARDS management is provided in **Fig. 262-5**.

TABLE 262-3 EVIDENCE-BASED RECOMMENDATIONS FOR ARDS THERAPIES

Treatment	Recommendation[a]
Mechanical ventilation:	
Low tidal volume	A
High-PEEP or "open-lung"	C
Prone position	C
Recruitment maneuvers	C
High-frequency ventilation and ECMO	D
Minimize left atrial filling pressures	B
Glucocorticoids	C
Surfactant replacement, inhaled nitric oxide, and other antiinflammatory therapy (e.g., ketoconazole, PGE_1, NSAIDs)	D

[a]**A**, recommended therapy based on strong clinical evidence from randomized clinical trials; **B**, recommended therapy based on supportive but limited clinical data; **C**, indeterminate evidence: recommended only as alternative therapy; **D**, not recommended based on clinical evidence against efficacy of therapy.

Note: PEEP, positive end-expiratory pressure; ECMO, extracorporeal membrane oxygenation; PGE_1, prostaglandin E_1; NSAIDs, nonsteroidal antiinflammatory drugs.

PROGNOSIS

Mortality Recent mortality estimates for ARDS range from 41 to 65%. There is substantial variability, but a trend toward improved ARDS outcomes appears evident. Of interest, mortality in ARDS is largely attributable to nonpulmonary causes, with sepsis and nonpulmonary organ failure accounting for >80% of deaths. Thus, improvement in survival is likely secondary to advances in the care of septic/infected patients and those with multiple organ failure (Chap. 261).

Several risk factors for mortality to help estimate prognosis have been identified. Similar to the risk factors for developing ARDS, the major risk factors for ARDS mortality are also nonpulmonary. Advanced age is an important risk factor. Patients >75 years have a substantially increased mortality (~60%) compared to those <45 (~20%). Also, patients >60 years with ARDS and sepsis have a threefold higher mortality compared to those <60. Preexisting organ dysfunction from chronic medical illness is an important additional risk factor for increased mortality. In particular, chronic liver disease, cirrhosis, chronic alcohol abuse, chronic immunosuppression, sepsis, chronic renal disease, any nonpulmonary organ failure, and increased APACHE II scores (Chap. 261) have also been linked to increased ARDS mortality. Several factors related to the presenting clinical disorders also increase risk for ARDS mortality. Patients with ARDS from direct lung injury (including pneumonia, pulmonary contusion, and aspiration; Table 262-1) have nearly twice the mortality of those with indirect causes of lung injury, while surgical and trauma patients with ARDS, especially those without direct lung injury, have a better survival rate than other ARDS patients.

Surprisingly, there is little value in predicting ARDS mortality from the extent of hypoxemia and any of the following measures of the severity of lung injury: the level of PEEP used in mechanical ventilation, the respiratory compliance, the extent of alveolar infiltrates on chest radiography, and the lung injury score (a composite of all these variables). However, recent data indicate that an early (within 24 h of presentation) elevation in dead space may predict increased mortality from ARDS.

Functional Recovery in ARDS Survivors While it is common for patients with ARDS to experience prolonged respiratory failure and re-

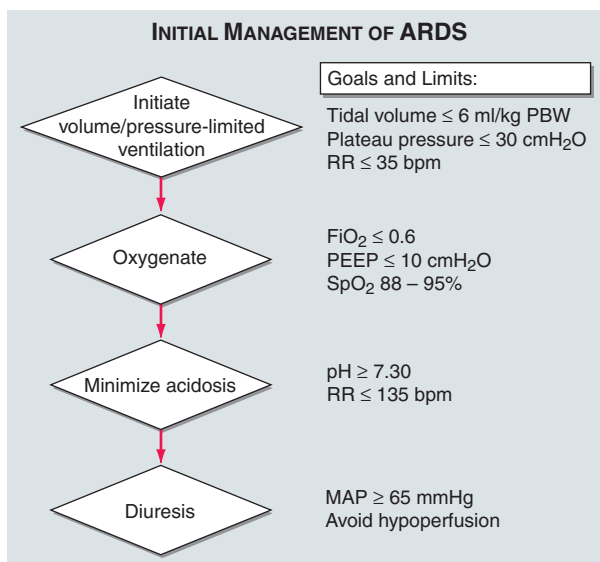

FIGURE 262-5 Algorithm for the initial management of ARDS. Clinical trials have provided evidence-based therapeutic goals for a step-wise approach to the early mechanical ventilation, oxygenation, correction of acidosis and diuresis of critically ill patients with ARDS.

main dependent on mechanical ventilation for survival, it is a testament to the resolving powers of the lung that the majority of patients recover nearly normal lung function. Patients usually recover their maximum lung function within 6 months. One year after endotracheal extubation, over a third of ARDS survivors have normal spirometry values and diffusion capacity. Most of the remaining patients have only mild abnormalities in their pulmonary function. Unlike the risk for mortality, recovery of lung function is strongly associated with the extent of lung injury in early ARDS. Low static respiratory compliance, high levels of required PEEP, longer durations of mechanical ventilation, and high lung injury scores are all associated with worse recovery of pulmonary function. When caring for ARDS survivors it is important to be aware of the potential for a substantial burden of emotional and respiratory symptoms. There are significant rates of depression and posttraumatic stress disorder in ARDS survivors.

263 Mechanical Ventilatory Support

Edward P. Ingenito

Ventilators are special pumps that can support the ventilatory function of the respiratory system and improve oxygenation through application of high oxygen content gas and positive pressure (Chap. 261).

INDICATIONS FOR MECHANICAL VENTILATION

The primary indication for initiation of mechanical ventilation is respiratory failure, of which there are two basic types.

1. *Hypoxemic respiratory failure* most commonly results from conditions such as pneumonia, pulmonary edema, pulmonary hemorrhage, and respiratory distress syndrome that cause ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch and shunt. Hypoxemic respiratory failure is present when arterial O_2 saturation (Sa_{O_2}) < 90% occurs despite an inspired O_2 fraction (FI_{O_2}) > 0.6. The goal of ventilator treatment in this setting is to provide adequate Sa_{O_2} through a combination of supplemental O_2 and specific patterns of ventilation that improve $\dot{V}/\dot{Q}$ matching and reduce intrapulmonary shunt.
2. *Hypercarbic respiratory failure* results from conditions that decrease minute ventilation or increase physiologic dead space such that alveolar ventilation is inadequate to meet metabolic demands. Clinical conditions associated with hypercarbic respiratory failure include neuromuscular diseases, such as myasthenia gravis, ascending polyradiculopathy, and myopathies, and diseases that cause respiratory muscle fatigue due to increased workload, such as asthma, chronic obstructive pulmonary disease, and restrictive lung disease. *Acute* hypercarbic respiratory failure is characterized by arterial P_{CO_2} values > 50 mmHg and an arterial pH < 7.30.

Mechanical ventilation generally should be instituted in acute hypercarbic respiratory failure. In contrast, initiation of ventilator support when components of both acute and chronic hypercarbic respiratory failure are present depends on blood gas parameters and clinical evaluation. If a patient is not in respiratory distress and is not mentally impaired by CO_2 accumulation, it is not mandatory to initiate mechanical ventilation while other forms of treatment are being administered. The goal of ventilator treatment in hypercarbic respiratory failure is to normalize arterial pH through changes in CO_2 tensions. In patients with severe obstructive or restrictive lung disease, potentially injurious elevation in airway pressures may limit tidal volumes such that normalization of pH is not possible, a situation known as *permissive hypercapnia*. This strategy generally requires sufficient sedation to prevent tachypnea and dyssynchrony between patient and ventilator.

Accepted therapeutic applications of mechanical ventilation include controlled hyperventilation to reduce cerebral blood flow in patients with increased intracranial pressure (ICP) or to improve pulmonary hemodynamics in patients with postoperative pulmonary hypertension. Mechanical ventilation has also been used to reduce the work of breathing and decrease cardiac preload and afterload in patients with congestive heart failure or myocardial ischemia. Ventilator support is also frequently used in conjunction with endotracheal intubation to prevent aspiration of gastric contents in otherwise unstable patients during gastric lavage for suspected drug overdose or during upper gastrointestinal endoscopy. In the critically ill patient, intubation and mechanical ventilation are indicated before essential diagnostic or therapeutic studies if it appears that respiratory failure may occur during these maneuvers.

PHYSIOLOGY OF MECHANICAL VENTILATION

Mechanical ventilators provide warmed and humidified gas to the airway in conformance with various specific volume, pressure, and time patterns. The ventilator serves as the energy source for inspiration, replacing the muscles of the diaphragm and chest wall. Expiration is passive, driven by the recoil of the lungs and chest wall; at the completion of inspiration, internal ventilator circuitry vents the airway to atmospheric pressure or a specified level of positive end-expiratory pressure (PEEP).

PEEP helps maintain patency of alveoli and small airways in the presence of destabilizing factors, improving matching of ventilation and perfusion by reversing atelectasis. PEEP levels between 0 and 10 cmH_2O are generally safe and effective; higher levels can be used with caution in the management of significant refractory hypoxemia unresponsive to increments in FI_{O_2} up to 0.6, but increase the risk of barotrauma and hypotension.

Positive-pressure ventilation affects the cardiovascular system through transmission of intrathoracic pressures to the heart and great vessels. Initiation of positive-pressure ventilation decreases both preload and afterload, while discontinuation increases both. The potential clinical impact of these effects should be considered when modifying ventilator support in hemodynamically tenuous patients.

ESTABLISHING AND MAINTAINING AN AIRWAY

A cuffed endotracheal tube is often inserted to allow positive-pressure ventilators to deliver conditioned gas, at pressures above atmospheric pressure, to the lungs. If neuromuscular paralysis is employed during intubation, the use of agents whose mechanism of action includes depolarization at the neuromuscular junction, such as succinylcholine chloride, should be avoided in patients with renal failure, tumor lysis syndrome, crush injuries, medical conditions associated with elevated serum potassium levels, and muscular dystrophy syndromes. Opiates and benzodiazepines can have a deleterious effect on hemodynamics in patients with depressed cardiac function or low systemic vascular resistance. Morphine can promote histamine release from tissue mast cells and may worsen bronchospasm in patients with asthma; fentanyl, sufentanil, and alfentanil are acceptable alternatives. Ketamine may increase systemic arterial pressure as well as ICP and has been associated with hallucinatory responses; it should be used with caution in patients with hypertensive crisis, increased ICP, or a history of psychiatric disorders. Newer agents such as etomidate and propofol have also been used for both induction and maintenance of anesthesia in ventilated patients. They are shorter acting, and etomidate has fewer adverse hemodynamic effects, but both agents are significantly more expensive than older agents.

Although definitive guidelines for performing a tracheostomy in the ventilated patient have not been established, in current clinical

TABLE 263-1 CLINICAL CHARACTERISTICS OF COMMONLY USED MODES OF MECHANICAL VENTILATION

Ventilator Mode	Independent Variables (Set by User)	Dependent Variables (Monitored by User)	Trigger/Cycle Limit	Advantages	Disadvantages	Initial Settings
ACMV[a]	FI_{O_2} Tidal volume Ventilator rate Level of PEEP Inspiratory flow pattern Peak inspiratory flow Pressure limit	Peak airway pressure, Pa_{O_2}, Pa_{CO_2} Mean airway pressure I/E ratio	Patient/timer Pressure limit	Timer backup Patient-vent synchrony Patient controls minute ventilation	Not useful for weaning Potential for dangerous respiratory alkalosis	$FI_{O_2} = 1.0$[b] V_t = 10–15 mL/kg[a] *f* = 12–15/min PEEP = 0–5 cmH_2O Inspiratory flow = 60 L/min
SIMV[a]	Same as for ACMV	Same as for ACMV	Same as for ACMV	Timer backup useful for weaning	Potential dyssynchrony	Same as for ACMV[a]
CPAP	FI_{O_2} Level of CPAP	Tidal volume Rate, flow pattern Airway pressure Pa_{O_2}, Pa_{CO_2}, I/E ratio	No trigger Pressure limit	Allows assessment of spontaneous function Helps prevent atelectasis	No backup	FI_{O_2} = 0.5–1.0[b] CPAP = 5–15 cmH_2O
PCV[a]	FI_{O_2} Inspiratory pressure level Ventilator rate Level of PEEP Pressure limit I/E ratio	Tidal volume Flow rate, pattern Minute ventilation Pa_{O_2}, Pa_{CO_2}	Timer/patient Timer/pressure limit	System pressures regulated Useful for barotrauma treatment Timer backup	Requires heavy sedation Not useful for weaning	$FI_{O_2} = 1.0$[b] PC = 20–40 cmH_2O[a] PEEP = 5–10 cmH_2O *f* = 12–15/min I/E = 0.7/1–4/1
PSV	FI_{O_2} Inspiratory pressure level PEEP Pressure limit	Same as for PCV + I/E ratio	Inspiratory flow Pressure limit	Assures synchrony Good for weaning	No timer backup	FI_{O_2} = 0.5–1.0[b] PS = 10–30 cmH_2O 5 cmH_2O usually the level used PEEP = 0–5 cmH_2O

[a]Open lung ventilation (OLV) involves the use of any of these specific modes with tidal volumes (or applied pressures) to achieve 5–6 mL/kg, and positive end-expiratory pressures achieve maximal alveolar recruitment.
[b]FI_{O_2} is usually set to 1.0 initially, unless there is a specific clinical indication to minimize FI_{O_2}, such as history of chemotherapy with bleomycin. Once adequate oxygenation is documented by blood gas analysis, FI_{O_2} should be decreased in decrements of 0.1–0.2 as tolerated, until the lowest FI_{O_2} required for an Sa_{O_2} > 90% is achieved.
Abbreviations: *f*, frequency; I/E, inspiration/expiration; FI_{O_2}, inspired O_2; PEEP, positive end-expiratory pressure; for ventilator modes, see text; V_t, tidal ventilation.

practice patients who are likely to require ventilator therapy for >3 weeks should be considered for this procedure. While it does not clearly reduce the incidence of laryngeal injury or tracheal stenosis, tracheostomy has been associated with improved patient comfort and enhanced ability to partake in rehabilitation-oriented activities.

VENTILATOR OPERATION

Terminology

Mode refers to the manner in which ventilator breaths are triggered, cycled, and limited; commonly used modes of mechanical ventilation are given in Table 263-1. The *trigger*, either an inspiratory effort or a time-based signal, defines what the ventilator senses to initiate an assisted breath. *Cycle* refers to the factors that determine the end of inspiration. For example, in volume-cycled ventilation, inspiration ends when a specific tidal volume is delivered. Other types of cycling include pressure cycling, time cycling, and flow cycling. *Limiting factors* are operator-specified values, such as airway pressure, that are monitored by transducers internal to the ventilator circuit throughout the respiratory cycle; if the specified values are exceeded, inspiratory flow is terminated, and the ventilator circuit is vented to atmospheric pressure or the specified PEEP.

ASSIST CONTROL MODE VENTILATION (ACMV) An inspiratory cycle is initiated either by the patient's inspiratory effort or, if none is detected within a specified time window, by a timer signal within the ventilator. Every breath delivered, whether patient or timer triggered, consists of the operator-specified tidal volume. Ventilatory rate is determined either by the patient or by the operator-specified backup rate, whichever is of higher frequency (Fig. 263-1*A*). ACMV is commonly used for initiation of mechanical ventilation because it ensures a backup minute ventilation in the absence of an intact respiratory drive and allows for synchronization of the ventilator cycle with the patient's inspiratory effort.

Problems can arise when ACMV is used in patients with tachypnea due to nonrespiratory or nonmetabolic factors such as anxiety, pain, or airway irritation. Respiratory alkalemia may develop and trigger myoclonus or seizures. Dynamic hyperinflation (so-called auto-PEEP) may occur if the patient's respiratory mechanics are such that inadequate time is available for complete exhalation between inspiratory cycles. Auto-PEEP can limit venous return, decrease cardiac output, and increase airway pressures, predisposing to barotrauma. ACMV is not effective for weaning patients from mechanical ventilation because it provides full ventilator assistance on each breath.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION (SIMV) The major difference between SIMV and ACMV is that in the former the patient is allowed to breathe spontaneously, i.e., without ventilator assist, between delivered ventilator breaths. However, mandatory breaths are delivered in synchrony with the patient's inspiratory efforts at a frequency determined by the operator. If the patient fails to initiate a breath, the ventilator delivers a fixed-tidal-volume breath and resets the internal timer for the next inspiratory cycle (Fig. 263-1*B*). SIMV differs from ACMV in that only the preset number of breaths is ventilator-assisted.

SIMV allows patients with an intact respiratory drive to exercise inspiratory muscles between assisted breaths, making it useful for both supporting and weaning intubated patients. SIMV may be difficult to use in patients with tachypnea because they may attempt to exhale during the ventilator-programmed inspiratory cycle. When this occurs, the airway pressure may exceed the inspiratory pressure limit, the ventilator-assisted breath will be aborted, and minute volume may drop below that programmed by the operator. In this setting, if the tachypnea is in response to respiratory or metabolic acidosis, a change to ACMV will increase minute ventilation and help normalize pH while the underlying process is further evaluated and treated.

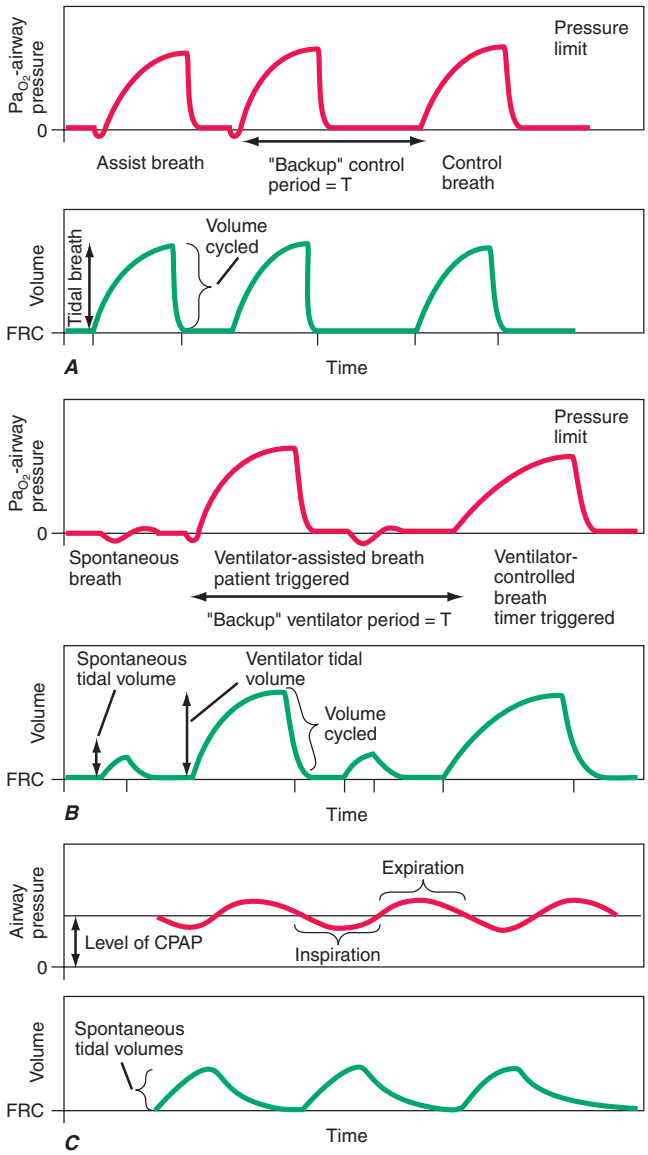

FIGURE 263-1 Airway pressure and lung volume versus time profiles. ***A.*** During assist control mode ventilation (ACMV). Assisted breaths are triggered by the patient's effort. Controlled breaths are triggered by the ventilator timer. Every breath, whether triggered by the patient or by the timer, is a complete volume-cycled breath, with airway pressure as a dependent variable. The pressure limit is set above the peak inspiratory pressure. ***B.*** During synchronized intermittent mandatory ventilation (SIMV). Spontaneous breaths occur between patient-triggered assisted breaths and timer-triggered breaths. The tidal volume of the spontaneous breaths is determined by the patient's effort and lung impedance. Assisted and controlled breaths are volume cycled. ***C.*** During continuous positive airway pressure (CPAP). Breathing is spontaneous, and no ventilator assist is provided. The spontaneous profile is superimposed on an elevated mean airway pressure that the user specifies. FRC, functional residual capacity.

CONTINUOUS POSITIVE AIRWAY PRESSURE (CPAP) This is not a true support-mode of ventilation, inasmuch as all ventilation occurs through the patient's spontaneous efforts. The ventilator provides fresh gas to the breathing circuit with each inspiration and charges the circuit to a constant, operator-specified pressure that can range from 0 to 20 cmH_2O (Fig. 263-1*C*). CPAP is used to assess extubation potential in patients who have been effectively weaned and are requiring little ventilator support and in patients with intact respiratory system function who require an endotracheal tube for airway protection.

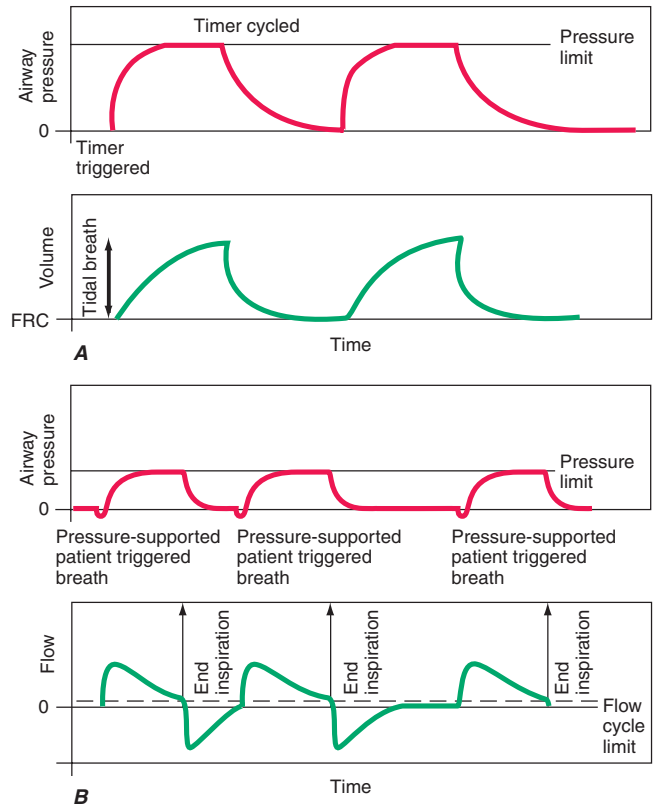

FIGURE 263-2 ***A.*** Airway pressure and lung volume versus time profiles during pressure-control ventilation (PCV). All breaths are timer triggered, timer cycled, and pressure limited. Peak airway pressure is set by the operator, and tidal volume is a dependent variable. The profiles shown here display the pressure limit as slightly higher than pressure-control level. This need not be the case, but it is appropriate to set the pressure limit only slightly above the pressure-control level when using this mode of ventilation for management of the patient with barotrauma. ***B.*** Airway pressure and airway flow versus time profiles during pressure-support ventilation (PSV). All breaths are patient triggered and flow cycled. Inspiration is cycled off when the inspiratory flow drops below a predetermined threshold internally set in the ventilator circuit. In the example shown, the pressure limit is slightly greater than the pressure-support level. Since each can be set independently, this need not be the case. FRC, functional residual capacity.

PRESSURE-CONTROL VENTILATION (PCV) This form of ventilation is time triggered, time cycled, and pressure limited. During the inspiratory phase, a specified pressure is imposed at the airway opening throughout inspiration (Fig. 263-2*A*). Since inspiratory airway pressure is specified by the operator, tidal volume and inspiratory flow rate are *dependent* rather than *independent* variables and are not user specified. PCV is the preferred mode of ventilation for patients in whom it is desirable to regulate peak airway pressures, such as those with preexisting barotrauma or postoperative thoracic surgical patients, in whom the shear forces across a fresh suture line should be limited. When PCV is used, minute ventilation and tidal volume must be monitored; minute ventilation is altered through changes in rate or in the pressure-control value, which changes tidal volume.

PCV with the use of a prolonged inspiratory time has been applied to patients with severe hypoxemic respiratory failure. This approach, called inverse inspiratory-to-expiratory ratio ventilation (IRV), increases mean distending pressures without increasing peak airway pressures. It is thought to work in conjunction with PEEP to open collapsed alveoli and improve oxygenation, although there are no conclusive data to show that IRV improves outcomes in clinical trials.

PRESSURE-SUPPORT VENTILATION (PSV) This form of ventilation is patient triggered, flow cycled, and pressure limited; it is specifically de-

signed for use in the weaning process. During PSV, the inspiration is terminated when inspiratory airflow falls below a certain level; in most ventilators this flow rate cannot be adjusted by the operator. When PSV is used, patients receive ventilator assist only when the ventilator detects an inspiratory effort (Fig. 263-2*B*). PSV can also be used in combination with SIMV to ensure volume-cycled backup for patients whose respiratory drive is depressed.

PSV is well tolerated by most patients who are being weaned; PSV parameters can be set to provide full or nearly full ventilatory support and can be withdrawn slowly over a period of days in a systematic fashion to gradually load the respiratory muscles.

NONINVASIVE VENTILATION (NIV) Noninvasive ventilator support through a tight-fitting face mask or nasal mask, traditionally used for treatment of sleep apnea, has recently been used as primary ventilator support in patients with impending respiratory failure. NIV is most frequently employed using PSV or bi-level positive airway pressure ventilation, inasmuch as both of these modes are well tolerated by the conscious patient and optimize patient-ventilator synchrony. NIV has met with varying degrees of success when applied to patients with acute or chronic respiratory failure. The major limitation to its widespread application has been patient intolerance, because the tight-fitting mask required for NIV can cause both physical and emotional discomfort.

NONCONVENTIONAL VENTILATION STRATEGIES Several nonconventional ventilator strategies have been evaluated for their ability to improve oxygenation and reduce mortality in advanced hypoxemic respiratory failure. These include high-frequency oscillatory ventilation (HFOV), extracorporeal membrane oxygenation (ECMO), and partial liquid ventilation using perfluorocarbons. Although case reports and small uncontrolled cohort studies have shown benefit, randomized controlled trials have failed to demonstrate consistent improvements in outcome with any of these strategies. Currently, these approaches should be considered as "salvage" techniques and considered for patients with hypoxemia refractory to conventional therapy.

Interventions Used with Ventilator Support • ***OPEN LUNG VENTILATION (OLV)*** OLV is not a distinct mode of ventilation, but rather a strategy for applying either volume-cycled or pressure-control ventilation to patients with severe hypoxemic respiratory failure. In OLV, the primary objectives of ventilator support are maintenance of adequate oxygenation and avoidance of cyclic opening and closing of alveolar units by selecting a tidal volume and level of PEEP that allows the majority of units to remain inflated during tidal ventilation. Achievement of eucapnia and normal blood pH are of lower priority, and permissive hypercapnia is accepted. Current data suggest that a small tidal volume (i.e., 6 mL/kg) provides adequate ventilatory support with a lower incidence of adverse effects than more conventional tidal volumes of 10 to 15 mL/kg. Hypercapnia and consequent respiratory acidosis tend to be well tolerated physiologically, except in patients with significant hemodynamic compromise, ventricular dysfunction, cardiac dysrhythmias, or increased ICP. OLV has been used most extensively in the management of patients with hypoxemic respiratory failure due to acute lung injury. Several randomized clinical trials of OLV have been performed and suggest that this strategy reduces mortality and improves gas exchange in patients with acute lung injury.

PRONE POSITIONING DURING MECHANICAL VENTILATION Patients with acute respiratory distress syndrome (ARDS) experience hypoxemia as a result of intrapulmonary shunting due to regional atelectasis (Chap. 262). Collapse occurs most extensively in dependent regions of the lung. Prone positioning increases transdiaphragmatic pressures in these regions by altering their position relative to the hydrostatic pressures generated by abdominal contents. Thus, prone positioning increases distending pressures in these areas without the need to apply additional airway pressures that can overdistend less damaged areas of lung and potentially cause additional lung damage. While conceptually appealing and simple to implement, a randomized trial in patients with acute lung injury failed to demonstrate a survival advantage with prone positioning despite demonstration of transient physiologic benefit.

NITRIC OXIDE ADMINISTRATION Nitric oxide (NO) gas has bronchodilator and pulmonary vasodilator effects when delivered through the airways and has been shown to improve arterial oxygenation in many patients with advanced hypoxemic respiratory failure. While physiologic benefits have been demonstrated in small cohort studies, randomized controlled trials have failed to confirm that therapeutic administration of NO reduces mortality in patients with advanced hypoxemic respiratory failure.

VENTILATOR MANAGEMENT PRINCIPLES

Most patients who are started on ventilator support receive ACMV or SIMV, because these modes ensure user-specified backup minute ventilation. Once the intubated patient has been stabilized with respect to oxygenation, definitive therapy for the underlying process responsible for respiratory failure is initiated. Subsequent modifications in ventilator therapy must be provided in parallel with changes in the patient's clinical status. As improvement in respiratory function is noted, the first priorities are to reduce PEEP and supplemental O_2. Once a patient can achieve adequate arterial saturation with an $FI_{O_2} \leq 0.5$ and 5 cmH_2O PEEP, attempts should be made to reduce the level of mechanical ventilatory support. Patients previously on full ventilator support should be switched to a mode that allows for weaning, such as SIMV, PSV, or SIMV combined with PSV. Ventilator therapy can then be gradually removed, as outlined in the section on weaning. Patients whose condition continues to deteriorate after ventilator support is initiated may require increased O_2, PEEP, and alternative modes of ventilation such as IRV or OLV.

GENERAL SUPPORT DURING VENTILATION

Patients started on mechanical ventilation usually require sedation and analgesia to maintain an acceptable level of comfort. Often, this consists of a combination of a benzodiazepine and opiate administered intravenously. Medications commonly used for this purpose include lorazepam, midazolam, diazepam, morphine, and fentanyl.

Immobilized patients in the intensive care unit on mechanical ventilator support are at increased risk for deep venous thrombosis and decubitus ulcers. To prevent venous thrombosis, prophylaxis in the form of subcutaneous heparin and/or pneumatic compression boots is frequently prescribed. Fractionated low-molecular-weight heparin appears to be equally effective for this purpose. To help prevent decubitus ulcers, frequent changes in body position, and use of soft mattress overlays and air mattresses are employed.

Prophylaxis against diffuse gastrointestinal mucosal injury is indicated for patients who have suffered a neurologic insult or those with severe respiratory failure in association with ARDS. Histamine receptor antagonists (H_2-receptor antagonists), antacids, and cytoprotective agents such as carafate have all been used for this purpose and appear to be effective. Recent data suggest that carafate use may be associated with a reduction in the incidence of nosocomial pneumonias, since it does not affect stomach pH and is less likely to permit colonization of the gastrointestinal tract by pathogenic organisms.

Nutrition support by enteral feeding through either a nasogastric or an orogastric tube should be maintained in all intubated patients whenever possible. In patients with a normal baseline nutritional state, support should be initiated within 7 days. In malnourished patients, nutrition support should be initiated within 72 h. Delayed gastric emptying is common in critically ill patients on sedative medications but often responds to promotility agents such as metoclopramide. Parenteral nutrition is an alternative to enteral nutrition in patients with severe gastrointestinal pathology.

COMPLICATIONS OF MECHANICAL VENTILATION

Endotracheal intubation and positive-pressure mechanical ventilation have direct and indirect effects on the lung and upper airways, the cardiovascular system, and the gastrointestinal system. Pulmonary complications include barotrauma, nosocomial pneumonia, oxygen toxicity, tracheal stenosis, and deconditioning of respiratory muscles. *Barotrauma*, which occurs when high pressures (i.e., >50 cmH_2O) overdistend and disrupt lung tissue, is clinically manifest by interstitial emphysema, pneumomediastinum, subcutaneous emphysema, or pneumothorax. Although the first three conditions may resolve spontaneously through the reduction of airway pressures, clinically significant pneumothorax requires tube thoracostomy.

Patients intubated for >72 h are at high risk for ventilator-associated pneumonia (VAP) as a result of aspiration from the upper airways through small leaks around the endotracheal tube cuff; the most common organisms responsible for this condition are *Pseudomonas aeruginosa*, enteric gram-negative rods, and *Staphylococcus aureus*. The diagnosis of VAP requires "protected brush" bronchoscopic sampling of airway secretions coupled with quantitative microbiologic techniques since this approach avoids sample contamination with bacteria that colonize the upper airways. Because this condition is associated with high mortality, early initiation of empirical antibiotics directed against likely pathogens is recommended.

Hypotension resulting from elevated intrathoracic pressures with decreased venous return is almost always responsive to intravascular volume repletion. In patients judged to have hypotension or respiratory failure on the basis of alveolar edema, hemodynamic monitoring with a pulmonary arterial catheter may be of value in optimizing O_2 delivery via manipulation of intravascular volume and FI_{O_2} and PEEP levels.

Gastrointestinal effects of positive-pressure ventilation include *stress ulceration* and *mild to moderate cholestasis*. It is common practice to provide prophylaxis with H_2-receptor antagonists or sucralfate for stress-related ulcers. Mild cholestasis [i.e., total bilirubin values ≤ 68 μmol/L (≤ 4.0 mg/dL)] attributable to the effects of increased intrathoracic pressures on portal vein pressures is common and generally self-limited. Cholestasis of a more severe degree should not be attributed to a positive-pressure ventilation response and is more likely due to a primary hepatic process.

WEANING FROM MECHANICAL VENTILATION

Removal of mechanical ventilator support requires that a number of criteria be met. Upper airway function must be intact for a patient to remain extubated but is difficult to assess in the intubated patient. Therefore, if a patient can breathe on his or her own through an endotracheal tube but develops stridor or recurrent aspiration once the tube is removed, upper airway dysfunction or an abnormal swallowing mechanism should be suspected and evaluated. Respiratory drive and chest wall function are assessed by observation of respiratory rate, tidal volume, inspiratory pressure, and vital capacity. The weaning index, defined as the ratio of breathing frequency to tidal volume (breaths per minute per liter), is both sensitive and specific for predicting the likelihood of successful extubation. When this ratio is <105 with the patient breathing without mechanical assistance through an endotracheal tube, successful extubation is likely. Alveolar ventilation is deemed adequate when elimination of CO_2 is sufficient to maintain arterial pH in the range of 7.35 to 7.40, and an Sa_{O_2} > 90% can be achieved with an FI_{O_2} < 0.5 and a PEEP ≤ 5 cmH_2O. Although many patients may not meet all criteria for weaning, the likelihood of successful extubation increases as more criteria are met.

Many approaches to weaning patients from ventilator support have been advocated. T-piece and CPAP weaning are best tolerated by patients who have undergone mechanical ventilation for brief periods and require little respiratory muscle reconditioning, whereas SIMV and PSV are best for patients intubated for extended periods likely to require gradual respiratory-muscle reconditioning.

T-piece and CPAP weaning involve brief spontaneous breathing trials with supplemental O_2. These trials are usually initiated for 5 min/h followed by a 1-h interval of rest. Trials are increased in 5- to 10-min/h increments until the patient can remain ventilator independent for periods of several hours. Extubation can then be attempted.

Weaning by means of SIMV involves gradually tapering the mandatory backup rate in increments of 2 to 4 breaths per minute while monitoring blood gas parameters and respiratory rates. Rates of >25 breaths per minute on withdrawal of mandatory ventilator breaths generally indicate respiratory muscle fatigue and the need to combine periods of exercise with rest. Exercise periods are gradually increased until a patient remains stable on SIMV at ≤ 4 breaths per minute. A CPAP or T-piece trial can then be attempted before extubation.

PSV, as described in detail above, is used primarily for weaning from mechanical ventilation. PSV is usually initiated at a level adequate for full ventilator support (PSV_{max}); i.e., PSV is set slightly below the peak inspiratory pressures required by the patient during volume-cycled ventilation. The level of pressure support is then gradually withdrawn in increments of 3–5 cmH_2O until a level is reached at which the respiratory rate increases to 25 breaths per minute. At this point, intermittent periods of higher-pressure support are alternated with periods of lower-pressure support to provide muscle reconditioning while avoiding diaphragmatic fatigue. Gradual withdrawal of PSV continues until the level of support is just adequate to overcome the resistance of the endotracheal tube (~5 to 10 cmH_2O). Support can be discontinued and the patient extubated.

264 Approach to the Patient with Shock

Ronald V. Maier

Shock is the clinical syndrome that results from inadequate tissue perfusion. Irrespective of cause, the hypoperfusion-induced imbalance between the delivery of and requirements for oxygen and substrate leads to cellular dysfunction. The cellular injury created by the inadequate delivery of oxygen and substrates also induces the production and release of inflammatory mediators that further compromise perfusion through functional and structural changes within the microvasculature. This leads to a vicious circle in which impaired perfusion is responsible for cellular injury, which causes maldistribution of blood flow, further compromising cellular perfusion; the latter causes multiple organ failure and, if the process is not interrupted, leads to death. The clinical manifestations of shock are the result, in part, of autonomic neuroendocrine responses to hypoperfusion as well as the breakdown in organ function induced by severe cellular dysfunction (Fig. 264-1).

When very severe and/or persistent, inadequate oxygen delivery leads to irreversible cell injury; thus, only rapid restoration of oxygen delivery can reverse the progression of the shock state. The fundamental approach to management, therefore, is to recognize overt and impending shock in a timely fashion and to intervene emergently to restore perfusion. This often requires the expansion or reexpansion of intravascular blood volume. Control of any inciting pathologic process, e.g., continued hemorrhage, impairment of cardiac function, or infection, must occur simultaneously.

Clinical shock is usually accompanied by hypotension, i.e., a mean arterial pressure <60 mmHg in previously normotensive persons. Multiple classification schemes have been developed in an attempt to synthesize the seemingly dissimilar processes leading to shock. Strict adherence to a classification scheme may be difficult from a clinical standpoint because of the frequent combination of two or more causes of shock in any individual patient, but the classification shown in Table 264-1 provides a useful reference point from which to discuss and further delineate the underlying processes.

TABLE 264-1 CLASSIFICATION OF SHOCK

PATHOGENESIS AND ORGAN RESPONSE

MICROCIRCULATION

Normally when cardiac output falls, systemic vascular resistance rises to maintain a level of systemic pressure that is adequate for perfusion of the heart and brain at the expense of other tissues such as muscle, skin, and especially the gastrointestinal tract. Systemic vascular resistance is determined primarily by the luminal diameter of arterioles. The metabolic rates of the heart and brain are high, and their stores of energy substrate are low. These organs are critically dependent on a continuous supply of oxygen and nutrients, and neither tolerates severe ischemia for more than brief periods. Autoregulation, i.e., the maintenance of blood flow over a wide range of perfusion pressures, is critical in sustaining cerebral and coronary perfusion despite significant hypotension. However, when mean arterial pressure drops to ≤60 mmHg, flow to these organs falls, and their function deteriorates.

Arteriolar vascular smooth muscle has both α- and β-adrenergic receptors. The α_1 receptors mediate vasoconstriction, while the β_2 receptors mediate vasodilation. Efferent sympathetic fibers release norepinephrine, which acts primarily on α_1 receptors in one of the most fundamental compensatory responses to reduced perfusion pressure. Other constrictor substances that are increased in most forms of shock include angiotensin II, vasopressin, endothelin 1, and thromboxane A_2. Both norepinephrine and epinephrine are released by the adrenal medulla, and the concentrations of these catecholamines in the bloodstream rise. Circulating vasodilators in shock include prostacyclin [prostaglandin (PG) I_2], nitric oxide (NO), and, importantly, products of local metabolism such as adenosine that match flow to the tissue's metabolic needs. The balance between these various vasoconstrictor and vasodilator influences acting upon the microcirculation determines local perfusion.

Transport to cells depends on microcirculatory flow; capillary permeability; the diffusion of oxygen, carbon dioxide, nutrients, and products of metabolism through the interstitium; and the exchange of these products across cell membranes. Impairment of the microcirculation, which is central to the pathophysiologic responses in the late stages of all forms of shock, results in the derangement of cellular metabolism, which is ultimately responsible for organ failure.

The endogenous response to mild or moderate hypovolemia is an attempt at restitution of intravascular volume through alterations in hydrostatic pressure and osmolarity. Constriction of arterioles leads to reductions in both the capillary hydrostatic pressure and the number of capillary beds perfused, thereby limiting the capillary surface area across which filtration occurs. When filtration is reduced while intravascular oncotic pressure remains constant or rises, there is net reabsorption of fluid into the vascular bed, in accord with Starling's law

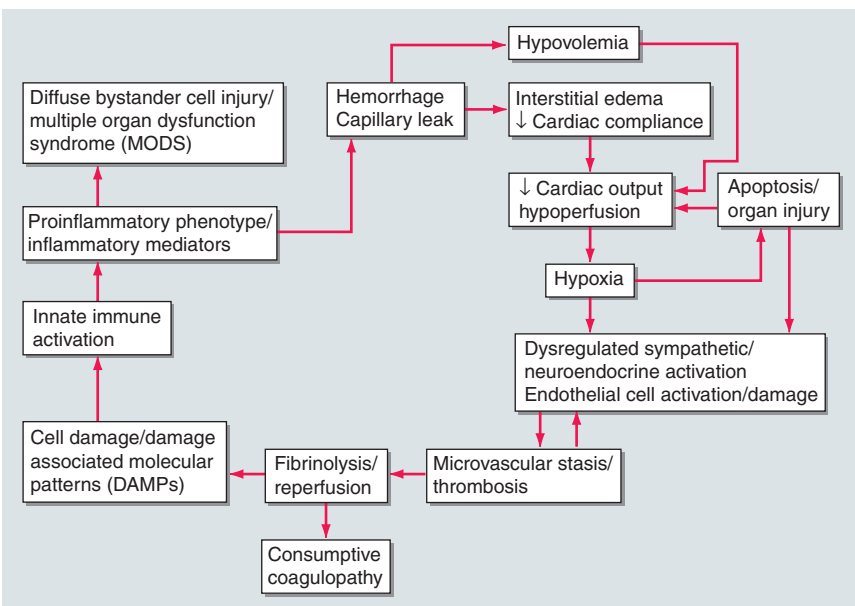

FIGURE 264-1 Shock-induced vicious circle.

of capillary-interstitial liquid exchange. Metabolic changes (including hyperglycemia and elevations in the products of glycolysis, lipolysis, and proteolysis) raise extracellular osmolarity, leading to an osmotic gradient between cells and interstitium that increases interstitial and intravascular volume at the expense of intracellular volume.

CELLULAR RESPONSES

Interstitial transport of nutrients is impaired in shock, leading to a decline of intracellular high-energy phosphate stores. Mitochondrial dysfunction and uncoupling of oxidative phosphorylation are the most likely causes for decreased amounts of ATP. As a consequence, there is an accumulation of hydrogen ions, lactate, and other products of anaerobic metabolism. As shock progresses, these vasodilator metabolites override vasomotor tone, causing further hypotension and hypoperfusion. Dysfunction of cell membranes is thought to represent a common end-stage pathophysiologic pathway in the various forms of shock. Normal cellular transmembrane potential falls, and there is an associated increase in intracellular sodium and water, leading to cell swelling, which interferes further with microvascular perfusion. In a preterminal event, homeostasis of calcium via membrane channels is lost with flooding of calcium intracellularly and a concomitant extracellular hypocalcemia. There is also increasing evidence for a widespread but selective apoptotic loss of cells, contributing to organ and immune failure.

NEUROENDOCRINE RESPONSE

Hypovolemia, hypotension, and hypoxia are sensed by baroreceptors and chemoreceptors, which contribute to an autonomic response that attempts to restore blood volume, maintain central perfusion, and mobilize metabolic substrates. Hypotension disinhibits the vasomotor center, resulting in increased adrenergic output and reduced vagal activity. Release of norepinephrine from adrenergic neurons induces peripheral and splanchnic vasoconstriction, a major contributor to the maintenance of central organ perfusion, while reduced vagal activity increases the heart rate and cardiac output. Vagal tone is also recognized to downregulate the innate immunity inflammatory response. The effects of circulating epinephrine released by the adrenal medulla in shock are largely metabolic, causing increased glycogenolysis and gluconeogenesis and reduced pancreatic insulin release. Epinephrine also inhibits production and release of inflammatory mediators through stimulation of β-adrenergic receptors on innate immune cells.

Severe pain and other severe stress cause the hypothalamic release of adrenocorticotropic hormone (ACTH). This stimulates cortisol secretion, which contributes to decreased peripheral uptake of glucose and amino acids, enhances lipolysis, and increases gluconeogenesis. Increased pancreatic secretion of glucagon during stress accelerates hepatic gluconeogenesis and further elevates blood glucose concentration. These hormonal actions act synergistically to increase blood glucose in the maintenance of blood volume. Many critically ill patients have recently been shown to exhibit low plasma cortisol levels and an impaired response to ACTH stimulation. Low levels of cortisol in response to stimulation are linked to a decrease in survival. The importance of the cortisol response to stress is illustrated by the profound circulatory collapse that occurs in patients with adrenal cortical insufficiency (Chap. 336).

Renin release is increased in response to adrenergic discharge and reduced perfusion of the juxtaglomerular apparatus in the kidney. Renin induces the formation of angiotensin I, which is then converted to angiotensin II, an extremely potent vasoconstrictor and stimulator of aldosterone release by the adrenal cortex and of vasopressin by the posterior pituitary. Aldosterone contributes to the maintenance of intravascular volume by enhancing renal tubular reabsorption of sodium, resulting in the excretion of a low-volume, concentrated, sodium-free urine. Vasopressin has a direct action on vascular smooth muscle, contributing to vasoconstriction, and acts on the distal renal tubules to enhance water reabsorption.

CARDIOVASCULAR RESPONSE

Three variables—ventricular filling (preload), the resistance to ventricular ejection (afterload), and myocardial contractility—are paramount in controlling stroke volume (Chap. 217). Cardiac output, the major determinant of tissue perfusion, is the product of stroke volume and heart rate. Hypovolemia leads to decreased ventricular preload, which in turn reduces the stroke volume. An increase in heart rate is a useful but limited compensatory mechanism to maintain cardiac output. A shock-induced reduction in myocardial compliance is frequent, reducing ventricular end-diastolic volume and hence stroke volume at any given ventricular filling pressure. Restoration of intravascular volume may return stroke volume to normal but only at elevated filling pressures. Increased filling pressures also stimulate release of brain natriuretic peptide (BNP) to secrete sodium and volume to relieve the pressure on the heart. Levels of BNP correlate with outcome following severe stress. In addition, sepsis, ischemia, myocardial infarction, severe tissue trauma, hypothermia, general anesthesia, prolonged hypotension, and acidemia may all impair myocardial contractility and also reduce the stroke volume at any given ventricular end-diastolic volume. The resistance to ventricular ejection is significantly influenced by the systemic vascular resistance, which is elevated in most forms of shock. However, resistance is depressed in the early hyperdynamic stage of septic shock (Chap. 265), thereby initially allowing the cardiac output to be maintained or elevated.

The venous system contains nearly two-thirds of the total circulating blood volume, most in the small veins, and serves as a dynamic reservoir for autoinfusion of blood. Active venoconstriction as a consequence of α-adrenergic activity is an important compensatory mechanism for the maintenance of venous return and therefore of ventricular filling during shock. On the other hand, venous dilatation, as occurs in neurogenic shock, reduces ventricular filling and hence stroke volume and cardiac output (see below).

PULMONARY RESPONSE

The response of the pulmonary vascular bed to shock parallels that of the systemic vascular bed, and the relative increase in pulmonary vascular resistance, particularly in septic shock, may exceed that of the systemic vascular resistance. Shock-induced tachypnea reduces tidal volume and increases both dead space and minute ventilation. Relative hypoxia and the subsequent tachypnea induce a respiratory alkalosis. Recumbency and involuntary restriction of ventilation secondary to pain reduce functional residual capacity and may lead to atelectasis. Shock is recognized as a major cause of acute lung injury and subsequent acute respiratory distress syndrome (ARDS; Chap. 262). These disorders are characterized by noncardiogenic pulmonary edema secondary to diffuse pulmonary capillary endothelial and alveolar epithelial injury, hypoxemia, and bilateral diffuse pulmonary infiltrates. Hypoxemia results from perfusion of underventilated and nonventilated alveoli. Loss of surfactant and lung volume in combination with increased interstitial and alveolar edema reduces lung compliance. The work of breathing and the oxygen requirements of respiratory muscles increase.

RENAL RESPONSE

Acute renal failure (Chap. 273), a serious complication of shock and hypoperfusion, occurs less frequently than heretofore because of early aggressive volume repletion. Acute tubular necrosis is now more frequently seen as a result of the interactions of shock, sepsis, the administration of nephrotoxic agents (such as aminoglycosides and angiographic contrast media), and rhabdomyolysis; the latter may be particularly severe in skeletal muscle trauma. The physiologic response of the kidney to hypoperfusion is to conserve salt and water. In addition to decreased renal blood flow, increased afferent arteriolar resistance accounts for diminished glomerular filtration rate, which together with increased aldosterone and vasopressin is responsible for reduced urine formation. Toxic injury causes necrosis of tubular epithelium and tubular obstruction by cellular debris with back-leak of filtrate. The depletion of renal ATP stores that occurs with prolonged renal hypoperfusion contributes to subsequent impairment of renal function.

METABOLIC DERANGEMENTS

During shock, there is disruption of the normal cycles of carbohydrate, lipid, and protein metabolism. Through the citric acid cycle, al-

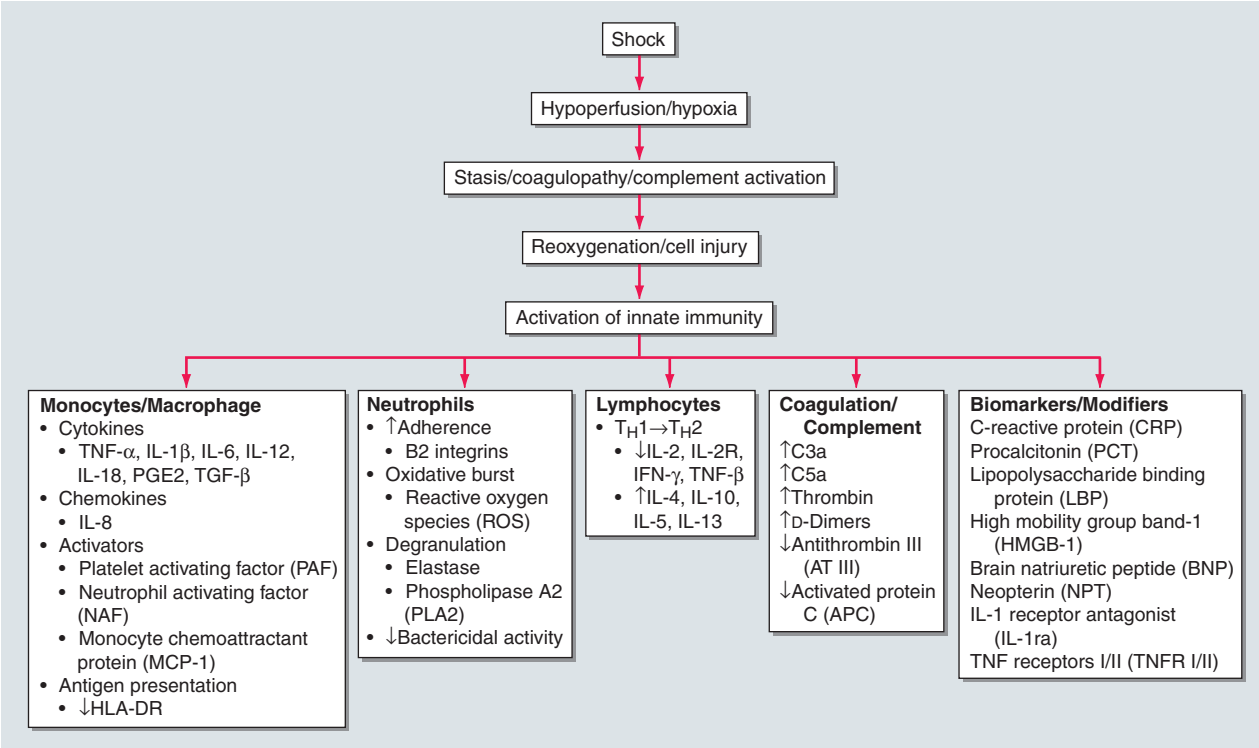

FIGURE 264-2 A schematic of the host immunoinflammatory response to shock.

anine in conjunction with lactate (which is converted from pyruvate in the periphery in the presence of oxygen deprivation) enhances the hepatic production of glucose. With reduced availability of oxygen, the breakdown of glucose to pyruvate and ultimately lactate represents an inefficient cycling of substrate with minimal net energy production. An elevated plasma lactate/pyruvate ratio is consistent with anaerobic metabolism and reflects inadequate tissue perfusion. Decreased clearance of exogenous triglycerides coupled with increased hepatic lipogenesis causes a significant rise in serum triglyceride concentrations. There is increased protein catabolism, a negative nitrogen balance, and, if the process is prolonged, severe muscle wasting.

INFLAMMATORY RESPONSES

Activation of an extensive network of proinflammatory mediator systems plays a significant role in the progression of shock and contributes importantly to the development of organ injury and failure (Fig. 264-2). In those surviving the acute insult, there is a delayed endogenous counterregulatory response to "turn off" the excessive proinflammatory response. If balance is restored, the patient does well. If the immunosuppressive response is excessive, the patient is highly susceptible to secondary nosocomial infections, which can then drive the inflammatory response and lead to delayed multiple organ failure.

Multiple humoral mediators are activated during shock and tissue injury. The complement cascade, activated through both the classic and alternate pathways, generates the anaphylatoxins C3a and C5a (Chap. 308). Direct complement fixation to injured tissues can progress to the C5-C9 attack complex, causing further cell damage. Activation of the coagulation cascade (Chap. 110) causes microvascular thrombosis, with subsequent fibrinolysis leading to repeated episodes of ischemia and reperfusion. Components of the coagulation system, such as thrombin, are potent proinflammatory mediators that cause expression of adhesion molecules on endothelial cells and activation of neutrophils, leading to microvascular injury. Coagulation also activates the kallikrein-kininogen cascade, contributing to hypotension.

Eicosanoids are vasoactive and immunomodulatory products of arachidonic acid metabolism that include cyclooxygenase-derived PGs and thromboxane A_2 as well as lipoxygenase-derived leukotrienes and lipoxins. Thromboxane A_2 is a potent vasoconstrictor that contributes to the pulmonary hypertension and acute tubular necrosis of shock. PGI_2 and PGE_2 are potent vasodilators that enhance capillary permeability and edema formation. The cysteinyl leukotrienes LTC_4 and LTD_4 are pivotal mediators of the vascular sequelae of anaphylaxis as well as of shock states resulting from sepsis or tissue injury. LTB_4 is a potent neutrophil chemoattractant and secretagogue that stimulates the formation of reactive oxygen species. Platelet-activating factor, an ether-linked, arachidonyl-containing phospholipid mediator, causes pulmonary vasoconstriction, bronchoconstriction, systemic vasodilation, increased capillary permeability, and the priming of macrophages and neutrophils to produce enhanced levels of inflammatory mediators.

Tumor necrosis factor α (TNF-α), produced by activated macrophages, reproduces many components of the shock state, including hypotension, lactic acidosis, and respiratory failure. Interleukin 1β (IL-1β), produced by tissue-fixed macrophages, is critical to the inflammatory response. Both are significantly elevated immediately following trauma and shock. IL-6, also produced predominantly by the macrophage, has a slightly delayed peak response but is the best predictor of prolonged recovery and development of multiple organ failure following shock. Chemokines such as IL-8 are potent neutrophil chemoattractants and activators that upregulate adhesion molecules on the neutrophil to enhance aggregation, adherence, and damage to the vascular endothelium. While the endothelium normally produces NO, the inflammatory response stimulates the inducible isoform of NO synthase (iNOS), which is overexpressed and produces toxic nitrosyl- and oxygen-derived free radicals that contribute to the hyperdynamic cardiovascular response in sepsis.

Multiple inflammatory cells, including neutrophils, macrophages, and platelets, are a major contributor to inflammation-induced injury. Margination of activated neutrophils in the microcirculation is a common pathologic finding in shock, causing secondary injury due to the release of toxic oxygen radicals, lipases, and proteases. Tissue-fixed macrophages produce virtually all major components of the inflammatory response and orchestrate the progression and duration of the inflammatory response. A major source of activation of the monocyte/macrophage is through the highly conserved membrane Toll-like receptors (TLRs), which recognize damage-associated molecular patterns (DAMPs) and pathogen-associated molecular patterns (PAMPs) released following tissue injury and by pathogenic microbial organisms, respectively. TLRs

TABLE 264-2 NORMAL HEMODYNAMIC PARAMETERS

Parameter	Calculation	Normal Values
Cardiac output (CO)	SV × HR	4–8 L/min
Cardiac index (CI)	CO/BSA	2.6–4.2 (L/min)/m^2
Stroke volume (SV)	CO/HR	50–100 mL/beat
Systemic vascular resistance (SVR)	[(MAP – RAP)/CO] × 80	700–1600 dynes · s/cm^5
Pulmonary vascular resistance (PVR)	[(PAP_m – PCWP)/CO] × 80	20–130 dynes · s/cm^5
Left ventricular stroke work (LVSW)	SV(MAP – PCWP) × 0.0136	60–80 g-m/beat
Right ventricular stroke work (RVSW)	SV(PAP_m – RAP)	10–15 g-m/beat

Note: HR, heart rate; BSA, body surface area; MAP, mean arterial pressure; RAP, right atrial pressure; PAP_m, pulmonary artery pressure—mean; PCWP, pulmonary capillary wedge pressure.

also appear important for the chronic inflammation seen in Crohn's disease, ulcerative colitis, and transplant rejection.

APPROACH TO THE PATIENT: Shock

MONITORING Patients in shock require care in an intensive care unit. Careful and continuous assessment of the physiologic status is necessary. Arterial pressure through an indwelling line, pulse, and respiratory rate should be monitored continuously; a Foley catheter should be inserted to follow urine flow; and mental status should be assessed frequently. Sedated patients should be allowed to awaken ("drug holiday") daily to assess their neurologic status and to shorten duration of ventilator support.

There is ongoing debate as to the indications for using the flow-directed pulmonary artery catheter (PAC, Swan-Ganz catheter). Most patients in the intensive care unit can be safely managed without the use of a PAC. However, in patients with significant ongoing blood loss, fluid shifts, and underlying cardiac dysfunction, a PAC may be useful. The PAC is placed percutaneously via the subclavian or jugular vein through the central venous circulation and right heart into the pulmonary artery. There are ports both proximal in the right atrium and distal in the pulmonary artery to provide access for infusions and for cardiac output measurements. Right atrial and pulmonary artery pressures are measured, and the pulmonary capillary wedge pressure (PCWP) serves as an approximation of the left atrial pressure. Normal hemodynamic parameters are shown in Table 223-1 and Table 264-2.

Cardiac output is determined by the thermodilution technique, and high-resolution thermistors can also be used to determine right ventricular end-diastolic volume to monitor further the response of the right heart to fluid resuscitation. A PAC with an oximeter port offers the additional advantage of on-line monitoring of the mixed venous oxygen saturation, an important index of tissue perfusion. Systemic and pulmonary vascular resistances are calculated as the ratio of the pressure drop across these vascular beds to the cardiac output (Chap. 223). Determinations of oxygen content in arterial and venous blood, together with cardiac output and hemoglobin concentration, allow calculation of oxygen delivery, oxygen consumption, and oxygen-extraction ratio (Table 264-3). The hemodynamic patterns associated with the various forms of shock are shown in Table 264-4.

In resuscitation from shock, it is critical to restore tissue perfusion and optimize oxygen delivery, hemodynamics, and cardiac function rapidly. A reasonable goal of therapy is to achieve normal mixed venous oxygen saturation and arteriovenous oxygen-extraction ratio. To enhance oxygen delivery, red cell mass, arterial oxygen saturation, and cardiac output may be augmented singly or simultaneously. An increase in oxygen delivery not accompanied by an increase in oxygen consumption implies that oxygen availability is adequate and that oxygen consumption is not flow-dependent. Conversely, an elevation of oxygen consumption with increased cardiac output implies that the oxygen supply was inadequate. A reduction in systemic vascular resistance accompanying an increase in cardiac output indicates that compensatory vasoconstriction is reversing due to improved tissue perfusion. The determination of stepwise expansion of blood volume on cardiac performance allows identification of the optimum preload (Starling's law). An algorithm for the resuscitation of the patient in shock is shown in Fig. 264-3.

SPECIFIC FORMS OF SHOCK

HYPOVOLEMIC SHOCK

This most common form of shock results either from the loss of red blood cell mass and plasma from hemorrhage or from the loss of plasma volume alone arising from extravascular fluid sequestration or gastrointestinal, urinary, and insensible losses. The signs and symptoms of nonhemorrhagic hypovolemic shock are the same as those of hemorrhagic shock, although they may have a more insidious onset. The normal physiologic response to hypovolemia is to maintain perfusion of the brain and heart while restoring an effective circulating blood volume. There is an increase in sympathetic activity, hyperventilation, collapse of venous capacitance vessels, release of stress hormones, and an attempt to limit the loss of intravascular volume through the recruitment of interstitial and intracellular fluid and reduction of urine output.

Mild hypovolemia (≤20% of the blood volume) generates mild tachycardia but relatively few external signs, especially in a supine resting young patient (Table 264-5). With moderate hypovolemia (~20–40% of the blood volume), the patient becomes increasingly anxious and tachycardic; although normal blood pressure may be maintained in the supine position, there may be significant postural hypotension and tachycardia. If hypovolemia is severe (≥40% of the blood volume), the classic signs of shock appear; the blood pressure declines and becomes unstable even in the supine position, and the patient develops marked tachycardia, oliguria, and agitation or confusion. Perfusion of the central nervous system is well maintained until shock becomes severe. Hence, mental obtundation is an ominous clinical sign. The transition from mild to severe hypovolemic shock can be insidious or extremely rapid. If severe shock is not reversed rapidly, especially in elderly patients and those with comorbid illnesses, death is imminent. A very narrow time frame separates the derangements found in severe shock that

TABLE 264-3 OXYGEN TRANSPORT CALCULATIONS

Parameter	Calculation	Normal Values
Oxygen-carrying capacity of hemoglobin		1.39 mL/g
Plasma O_2 concentration		P_{O_2} × 0.0031
Arterial O_2 concentration (Ca_{O_2})	1.39 Sa_{O_2} + 0.0031 Pa_{O_2}	20 vol%
Venous O_2 concentration (Cv_{O_2})	1.39 Sv_{O_2} + 0.0031 Pv_{O_2}	15.5 vol%
Arteriovenous O_2 difference (Ca_{O_2} – Cv_{O_2})	1.39 (Sa_{O_2} – Sv_{O_2}) + 0.0031 (Pa_{O_2} – Pv_{O_2})	3.5 vol%
Oxygen delivery (D_{O_2})	Ca_{O_2} × CO (L/min) × 10 (dL/L) 1.39 Sa_{O_2} × CO × 10	800–1600 mL/min
Oxygen uptake (V_{O_2})	(Ca_{O_2} – Cv_{O_2}) × CO × 10 1.39 (Sa_{O_2} – Sv_{O_2}) × CO × 10	150–400 mL/min
Oxygen delivery index (D_{O_2}I)	D_{O_2}/BSA	520–720 (mL/min)/m^2
Oxygen uptake index (V_{O_2}I)	V_{O_2}/BSA	115–165 (mL/min)/m^2
Oxygen extraction ratio (O_2ER)	[1 – (V_{O_2}/D_{O_2})] × 100	22–32%

Note: P_{O_2}, partial pressure of oxygen; Sa_{O_2}, saturation of hemoglobin with O_2 in arterial blood; Pa_{O_2}, partial pressure of O_2 in arterial blood; Sv_{O_2}, saturation of hemoglobin with O_2 in venous blood; Pv_{O_2}, partial pressure of O_2 in venous blood; CO, cardiac output; BSA, body surface area.

TABLE 264-4 PHYSIOLOGIC CHARACTERISTICS OF THE VARIOUS FORMS OF SHOCK

Type of Shock	CVP and PCWP	Cardiac Output	Systemic Vascular Resistance	Venous O_2 Saturation

TABLE 264-5 HYPOVOLEMIC SHOCK

Mild (<20% Blood Volume)	Moderate (20–40% Blood Volume)	Severe (>40% Blood Volume)
Cool extremities	Same, plus:	Same, plus:
Increased capillary refill time	Tachycardia	Hemodynamic instability
Diaphoresis	Tachypnea	Marked tachycardia
Collapsed veins	Oliguria	Hypotension
Anxiety	Postural changes	Mental status deterioration (coma)

can be reversed with aggressive resuscitation from those of progressive decompensation and irreversible cell injury.

Diagnosis Hypovolemic shock is readily diagnosed when there are signs of hemodynamic instability and the source of volume loss is obvious. The diagnosis is more difficult when the source of blood loss is occult, as into the gastrointestinal tract, or when plasma volume alone is depleted. After acute hemorrhage, hemoglobin and hematocrit values do not change until compensatory fluid shifts have occurred or exogenous fluid is administered. Thus, an initial normal hematocrit does not disprove the presence of significant blood loss. Plasma losses cause hemoconcentration, and free water loss leads to hypernatremia. These findings should suggest the presence of hypovolemia.

It is essential to distinguish between hypovolemic and cardiogenic shock (Chap. 266) because definitive therapy differs significantly. Both forms are associated with a reduced cardiac output and a compensatory sympathetic mediated response characterized by tachycardia and elevated systemic vascular resistance. However, the findings in cardiogenic shock of jugular venous distention, rales, and an S_3 gallop distinguish it from hypovolemic shock and signify that ongoing volume expansion is undesirable.

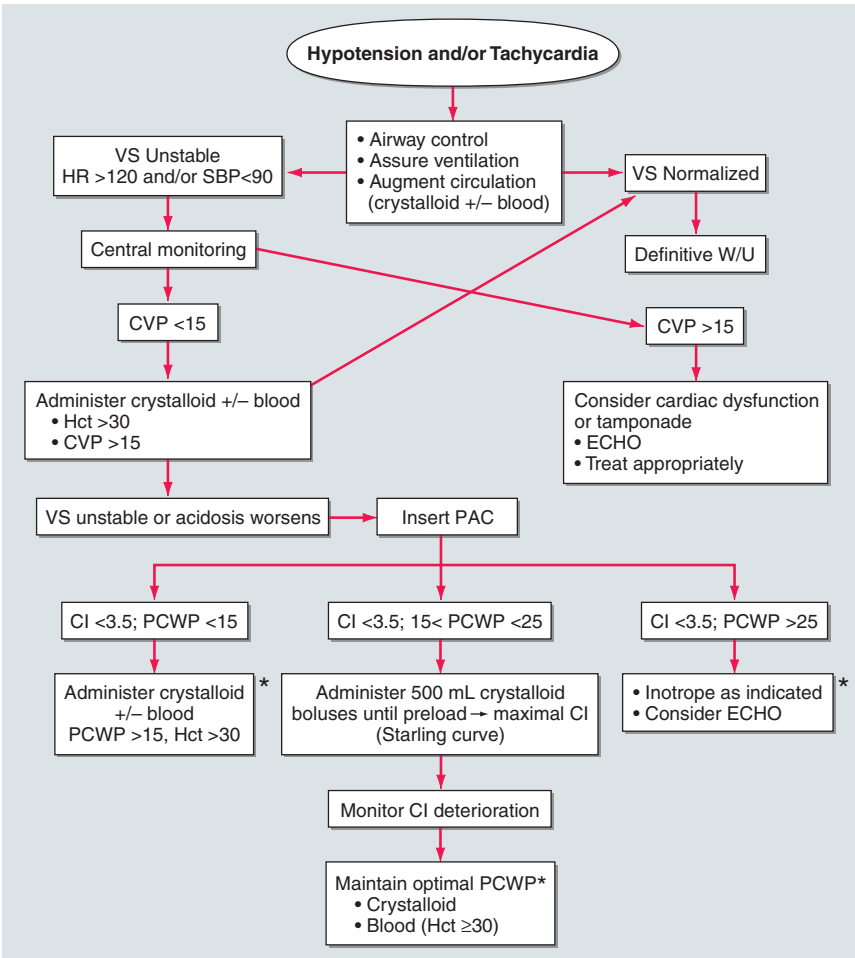

FIGURE 264-3 An algorithm for the resuscitation of the patient in shock. VS, vital signs; HR, heart rate; SBP, systolic blood pressure; W/U, work up; CVP, central venous pressure; Hct, hematocrit; ECHO, echocardiogram; PAC, pulmonary artery catheter; CI, cardiac index in (L/min) per m^2; PCWP, pulmonary capillary wedge pressure in mmHg. *Monitor SV_{O_2}, SVRI, and RVEDVI as additional markers of correction for perfusion and hypovolemia. Consider age-adjusted CI. SV_{O_2}, saturation of hemoglobin with O_2 in venous blood; SVRI, systemic vascular resistance index; RVEDVI, right-ventricular end-diastolic volume index.

℞ HYPOVOLEMIC SHOCK

Initial resuscitation requires rapid reexpansion of the circulating intravascular blood volume along with interventions to control ongoing losses. In accordance with Starling's law (Chap. 217), stroke volume and cardiac output rise with the increase in preload. After resuscitation, the compliance of the ventricles may remain reduced due to increased interstitial fluid in the myocardium. Therefore elevated filling pressures are required to maintain adequate ventricular performance.

Volume resuscitation is initiated with the rapid infusion of isotonic saline (although care must be taken to avoid hyperchloremic acidosis from loss of bicarbonate buffering capacity and replacement with excess chloride) or a balanced salt solution such as Ringer's lactate through large-bore intravenous lines. No distinct benefit from the use of colloid has been demonstrated, and in trauma patients it is associated with a higher mortality, particularly in patients with traumatic brain injury. The infusion of 2–3 L of salt solution over 20–30 min should restore normal hemodynamic parameters. Continued hemodynamic instability implies that shock has not been reversed and/or that there are significant ongoing blood or volume losses. Continuing blood loss, with hemoglobin concentrations declining to ≤100 g/L (10 g/dL), should initiate blood transfusion, preferably as fully cross-matched blood. In extreme emergencies, type-specific or O-negative packed red cells may be transfused. In the presence of severe and/or prolonged hypovolemia, inotropic support with dopamine, vasopressin, or dobutamine may be required to maintain adequate ventricular performance *after* blood volume has been restored. Infusion of norepinephrine to increase arterial pressure by raising peripheral resistance is inappropriate, other than as a temporizing measure in severe shock while blood volume is reexpanded. Once hemorrhage is controlled and the patient has stabilized, blood transfusions should not be continued unless the hemoglobin is <~7g/dL. Studies have demonstrated an increased survival in patients treated with this restrictive blood transfusion protocol.

Successful resuscitation also requires support of respiratory function. Supplemental oxygen should be provided, and endotracheal intubation may be necessary to maintain arterial oxygenation. Following resuscitation from isolated hemorrhagic shock, end-organ

damage is frequently less than following septic or traumatic shock. This may be due to the absence of the massive activation of inflammatory mediator response systems and the consequent nonspecific organ injury seen in the latter conditions.

TRAUMATIC SHOCK

Shock following trauma is, in large measure, due to hypovolemia. However, even when hemorrhage has been controlled, patients can continue to suffer loss of plasma volume into the interstitium of injured tissues. These fluid losses are compounded by injury-induced inflammatory responses, which contribute to the secondary microcirculatory injury. Recent evidence demonstrates release of mediators induced by DAMPs from injured tissue that are recognized by the highly conserved membrane receptors of the TLR family (see "Inflammatory Responses," above). These receptors on the cells of the innate immune system, particularly the circulating monocyte, tissue-fixed macrophage, and dendritic cell, are potent activators of an excessive proinflammatory phenotype in response to cellular injury. This causes secondary tissue injury and maldistribution of blood flow, intensifying tissue ischemia and leading to multiple organ system failure. In addition, direct trauma to the heart, chest, or head can also contribute to the shock. For example, pericardial tamponade or tension pneumothorax impairs ventricular filling, while myocardial contusion depresses myocardial contractility.

℞ TRAUMATIC SHOCK

Inability of the patient to maintain a systolic blood pressure ≥90 mmHg after trauma-induced hypovolemia is associated with a mortality rate of ~50%. To prevent decompensation of homeostatic mechanisms, therapy must be promptly administered.

The initial management of the seriously injured patient requires attention to the "ABCs" of resuscitation: assurance of an *airway* (A), adequate ventilation (*breathing*, B), and establishment of an adequate blood volume to support the *circulation* (C). Control of ongoing hemorrhage requires immediate attention. Early stabilization of fractures, debridement of devitalized or contaminated tissues, and evacuation of hematomata all reduce the subsequent inflammatory response to the initial insult and minimize subsequent diffuse organ injury. Supplementation of depleted endogenous antioxidants also reduces subsequent organ failure and mortality.

CARDIOGENIC SHOCK

See Chap. 266.

COMPRESSIVE CARDIOGENIC SHOCK

With compression, the heart and surrounding structures are less compliant, and thus normal filling pressures generate inadequate diastolic filling. Blood or fluid within the poorly distensible pericardial sac may cause tamponade (Chap. 232). Any cause of increased intrathoracic pressure, such as tension pneumothorax, herniation of abdominal viscera through a diaphragmatic hernia, or excessive positive pressure ventilation to support pulmonary function, can also cause compressive cardiogenic shock while simultaneously impeding venous return. Although initially responsive to increased filling pressures produced by volume expansion, as compression increases, cardiogenic shock recurs. The window of opportunity gained by volume loading may be very brief until irreversible shock recurs. Diagnosis and intervention must occur urgently.

The diagnosis of compressive cardiogenic shock is most frequently based on clinical findings, the chest radiograph, and an echocardiogram. The diagnosis of compressive cardiac shock may be more difficult to establish in the setting of trauma when hypovolemia and cardiac compression are present simultaneously. The classic findings of pericardial tamponade include the triad of hypotension, neck vein distention, and muffled heart sounds (Chap. 232). Pulsus paradoxus, i.e., an inspiratory reduction in systolic pressure >10 mmHg, may also be noted. The diagnosis is confirmed by echocardiography, and treatment consists of immediate pericardiocentesis. A tension pneumothorax produces ipsilateral decreased breath sounds, tracheal deviation away from the affected thorax, and jugular venous distention. Radiographic findings include increased intrathoracic volume, depression of the diaphragm of the affected hemithorax, and shifting of the mediastinum to the contralateral side. Chest decompression must be carried out immediately. Release of air and restoration of normal cardiovascular dynamics are both diagnostic and therapeutic.

SEPTIC SHOCK

See Chap. 265.

NEUROGENIC SHOCK

Interruption of sympathetic vasomotor input after a high cervical spinal cord injury, inadvertent cephalad migration of spinal anesthesia, or devastating head injury may result in neurogenic shock. In addition to arteriolar dilatation, venodilation causes pooling in the venous system, which decreases venous return and cardiac output. The extremities are often warm, in contrast to the usual vasoconstriction-induced coolness in hypovolemic or cardiogenic shock. Treatment involves a simultaneous approach to the relative hypovolemia and to the loss of vasomotor tone. Excessive volumes of fluid may be required to restore normal hemodynamics if given alone. Once hemorrhage has been ruled out, norepinephrine or a pure α-adrenergic agent (phenylephrine) may be necessary to augment vascular resistance and maintain an adequate mean arterial pressure.

HYPOADRENAL SHOCK

(See also Chap. 336) The normal host response to the stress of illness, operation, or trauma requires that the adrenal glands hypersecrete cortisol in excess of that normally required. Hypoadrenal shock occurs in settings in which unrecognized adrenal insufficiency complicates the host response to the stress induced by acute illness or major surgery. Adrenocortical insufficiency may occur as a consequence of the chronic administration of high doses of exogenous glucocorticoids. In addition, recent studies have shown that critical illness, including trauma and sepsis, may also induce a relative hypoadrenal state. Other, less common causes include adrenal insufficiency secondary to idiopathic atrophy, tuberculosis, metastatic disease, bilateral hemorrhage, and amyloidosis. The shock produced by adrenal insufficiency is characterized by loss of homeostasis with reductions in systemic vascular resistance, hypovolemia, and reduced cardiac output. The diagnosis of adrenal insufficiency may be established by means of an ACTH stimulation test.

℞ HYPOADRENAL SHOCK

In the persistently hemodynamically unstable patient, dexamethasone sodium phosphate, 4 mg, should be given intravenously. This agent is preferred if empiric therapy is required because, unlike hydrocortisone, it does not interfere with the ACTH stimulation test. If the diagnosis of absolute or relative adrenal insufficiency is established as shown by nonresponse to corticotropin stimulation (cortisol ≤9 μg/dL change poststimulation), the patient has a reduced risk of death if treated with hydrocortisone, 100 mg every 6–8 h, and tapered as the patient achieves hemodynamic stability. Simultaneous volume resuscitation and pressor support are required. The need for simultaneous mineralocoid is unclear.

ADJUNCTIVE THERAPIES

The sympathomimetic amines dobutamine, dopamine, and norepinephrine are widely used in the treatment of all forms of shock. Dobutamine is inotropic with simultaneous afterload reduction, thus minimizing cardiac-oxygen consumption increases as cardiac output increases. Dopamine is an inotropic and chronotropic agent that also supports vascular resistance in those whose blood pressure will not tolerate peripheral vascular dilation. Norepinephrine primarily supports blood pressure through vasoconstriction and increases myocar-

dial oxygen consumption while placing marginally perfused tissues, such as extremities and splanchnic organs, at risk for necrosis, but it is also inotropic without chronotropy. Arginine-vasopressin (antidiuretic hormone) is also being used increasingly and may better protect vital organ blood flow and prevent pathologic vasodilation.

POSITIONING

Positioning of the patient may be a valuable adjunct in the initial treatment of hypovolemic shock. Elevating the foot of the bed (i.e., placing it on "shock blocks") and assumption of the Trendelenburg position without flexion at the knees are effective but may increase work of breathing and risk for aspiration. Simply elevating both legs may be the optimal approach.

PNEUMATIC ANTISHOCK GARMENT (PASG)

The PASG and the military antishock trousers (MAST) are inflatable external compression devices that can be wrapped around the legs and abdomen and have been widely used in the prehospital setting as a means of providing temporary support of central hemodynamics in shock. However, they cause a significant increase in systemic vascular resistance and blood pressure by arterial compression, without causing a significant change in cardiac output or tissue perfusion. The most appropriate use appears to be as a means to tamponade and to prevent ongoing bleeding and augment hemostasis. Inflation of the suit provides splinting of fractures of the pelvis and lower extremities and helps to arrest hemorrhage.

REWARMING

Hypothermia is a potential adverse consequence of massive volume resuscitation. The infusion of large volumes of refrigerated blood products and room-temperature crystalloid solutions can rapidly drop core temperatures if fluid is not run through warming devices. Hypothermia may depress cardiac contractility and thereby further impair cardiac output and oxygen delivery. Hypothermia, particularly temperatures <35°C, directly impairs the coagulation pathway, sometimes causing a significant coagulopathy. Rapid rewarming to >35°C significantly decreases the requirement for blood products and produces an improvement in cardiac function. The most effective method for rewarming is endovascular countercurrent warmers through femoral vein cannulation. This process does not require a pump and can rewarm from 30° to 35°C in <30 min.

265 Severe Sepsis and Septic Shock

Robert S. Munford

DEFINITIONS

(See Table 265-1) Animals mount both local and systemic responses to microbes that traverse epithelial barriers and invade underlying tissues. Fever or hypothermia, leukocytosis or leukopenia, tachypnea, and tachycardia are the cardinal signs of the systemic response often called the *systemic inflammatory response syndrome* (SIRS). SIRS may have an infectious or a noninfectious etiology. If infection is suspected or proven, a patient with SIRS is said to have *sepsis*. When sepsis is associated with dysfunction of organs distant from the site of infection, the patient has *severe sepsis*. Severe sepsis may be accompanied by hypotension or evidence of hypoperfusion. When hypotension cannot be corrected by infusing fluids, the diagnosis is *septic shock*. These definitions were proposed by consensus conference committees in 1992 and 2001 and are now widely used; there is evidence that the different stages form a continuum. As sepsis progresses to septic shock, the risk of dying increases substantially. Sepsis is usually reversible, whereas patients with septic shock often succumb despite aggressive therapy.

ETIOLOGY

Severe sepsis can be a response to any class of microorganism. Microbial invasion of the bloodstream is not essential for the development of severe sepsis, since local inflammation can also elicit distant organ dysfunction and hypotension. In fact, blood cultures yield bacteria or fungi in only ~20–40% of cases of severe sepsis and 40–70% of cases of septic shock. Individual gram-negative or gram-positive bacteria account for ~70% of these isolates; the remainder are fungi or a mixture of microorganisms (Table 265-2). In patients whose blood cultures are negative, the etiologic agent is often established by culture or microscopic examination of infected material from a local site. In some case series, a majority of patients with a clinical picture of severe sepsis or septic shock have had negative microbiologic data.

EPIDEMIOLOGY

The septic response is a contributing factor in >200,000 deaths per year in the United States. The incidence of severe sepsis and septic shock has increased over the past 20 years, and the annual number of cases is now >700,000 (~3 per 1000 population). Approximately two-thirds of the cases occur in patients with significant underlying illness. Sepsis-related incidence and mortality rates increase with age and preexisting comorbidity. The rising incidence of severe sepsis in the United States is attributable to the aging of the population, the increasing longevity of patients with chronic diseases, and the relatively high frequency with which sepsis develops in patients with AIDS. The widespread use of antimicrobial agents, immunosuppressive drugs, indwelling catheters and mechanical devices, and mechanical ventilation also plays a role.

Invasive bacterial infections are prominent causes of death around the world, particularly among young children. In sub-Saharan Africa, for example, careful screening for positive blood cultures found that community-acquired bacteremia accounted for at least one-fourth of deaths of children >1 year of age. Nontyphoidal *Salmonella* species, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Escherichia coli* were the most commonly isolated bacteria. Bacteremic children often had HIV infection or were severely malnourished.

TABLE 265-1 DEFINITIONS USED TO DESCRIBE THE CONDITION OF SEPTIC PATIENTS

Bacteremia	Presence of bacteria in blood, as evidenced by positive blood cultures
Septicemia	Presence of microbes or their toxins in blood
Systemic inflammatory response syndrome (SIRS)	Two or more of the following conditions: (1) fever (oral temperature >38°C) or hypothermia (<36°C); (2) tachypnea (>24 breaths/min); (3) tachycardia (heart rate >90 beats/min); (4) leukocytosis (>12,000/μL), leukopenia (<4,000/μL), or >10% bands; may have a noninfectious etiology
Sepsis	SIRS that has a proven or suspected microbial etiology
Severe sepsis (similar to "sepsis syndrome")	Sepsis with one or more signs of organ dysfunction—for example: 1. *Cardiovascular:* Arterial systolic blood pressure ≤90 mmHg or mean arterial pressure ≤70 mmHg that responds to administration of intravenous fluid 2. *Renal:* Urine output <0.5 mL/kg per hour for 1 h despite adequate fluid resuscitation 3. *Respiratory:* Pa_{O_2}/FI_{O_2} ≤250 or, if the lung is the only dysfunctional organ, ≤200 4. *Hematologic:* Platelet count <80,000/μL or 50% decrease in platelet count from highest value recorded over previous 3 days 5. *Unexplained metabolic acidosis:* A pH ≤7.30 or a base deficit ≥5.0 mEq/L and a plasma lactate level >1.5 times upper limit of normal for reporting lab 6. *Adequate fluid resuscitation:* Pulmonary artery wedge pressure ≥12 mmHg or central venous pressure ≥8 mmHg
Septic shock	Sepsis with hypotension (arterial blood pressure <90 mmHg systolic, or 40 mmHg less than patient's normal blood pressure) for at least 1 h despite adequate fluid resuscitation; *or* Need for vasopressors to maintain systolic blood pressure ≥90 mmHg *or* mean arterial pressure ≥70 mmHg
Refractory septic shock	Septic shock that lasts for >1 h and does not respond to fluid or pressor administration
Multiple-organ dysfunction syndrome (MODS)	Dysfunction of more than one organ, requiring intervention to maintain homeostasis

PATHOPHYSIOLOGY

Most cases of severe sepsis are triggered by bacteria or fungi that do not ordinarily cause systemic disease in immunocompetent hosts (Table 265-2). These microbes probably exploit deficiencies in innate host defenses (e.g., phagocytes, complement, and natural antibodies) to survive within the body. Microbial pathogens, in contrast, are able to circumvent innate defenses by elaborating toxins or other virulence factors. In both cases, the body can fail to kill the invaders despite mounting a vigorous inflammatory reaction that can result in severe sepsis. The septic response may also be induced by microbial exotoxins that act as superantigens (e.g., toxic shock syndrome toxin 1; Chap. 129).

Host Mechanisms for Sensing Microbes Animals have exquisitely sensitive mechanisms for recognizing and responding to conserved microbial molecules. Recognition of the lipid A moiety of lipopolysaccharide (LPS, also called *endotoxin*; Chap. 114) is the best-studied example. A host protein (LPS-binding protein, or LBP) binds lipid A and transfers the LPS to CD14 on the surfaces of monocytes, macrophages, and neutrophils. LPS then is passed to MD-2, which interacts with Toll-like receptor (TLR) 4 to form a molecular complex that transduces the LPS recognition signal to the interior of the cell. This signal rapidly triggers the production and release of mediators, such as tumor necrosis factor (TNF; see below), that amplify the LPS signal and transmit it to other cells and tissues. Bacterial peptidoglycan and lipoteichoic acids elicit responses in animals that are generally similar to those induced by LPS; whereas these molecules also bind CD14, they interact with different TLRs. Having numerous TLR-based receptor complexes (10 different TLRs have been identified so far in humans) allows animals to recognize many conserved microbial molecules. The ability of some of the TLRs to serve as receptors for host ligands (e.g., hyaluronans, heparan sulfate, saturated fatty acids) raises the possibility that these molecules play a role in producing noninfectious sepsis-like states. Other host pattern-recognition proteins that are important for sensing microbial invasion and initiating host inflammation include the intracellular NOD1 and NOD2 proteins, which recognize discrete fragments of bacterial peptidoglycan; complement (principally the alternative pathway); mannose-binding lectin; and C-reactive protein.

The ability to recognize certain microbial molecules may influence both the potency of the host defense and the pathogenesis of severe sepsis. For example, MD-2–TLR4 best senses LPS that has a hexaacyl lipid A moiety (i.e., one with six fatty acyl chains). Most of the commensal aerobic and facultatively anaerobic gram-negative bacteria that trigger severe sepsis and shock (including *E. coli*, *Klebsiella*, and *Enterobacter*) make this lipid A structure. When they invade human hosts, often through breaks in an epithelial barrier, infection is typically localized to the subepithelial tissue. Bacteremia, if it occurs, is intermittent and low-grade, as these bacteria are efficiently cleared from the bloodstream by TLR4-expressing Kupffer cells and splenic macrophages. These mucosal commensals seem to induce severe sepsis most often by triggering severe local tissue inflammation rather than by circulating within the bloodstream. In contrast, gram-negative bacteria that do not make hexaacyl lipid A (*Yersinia pestis*, *Francisella tularensis*, *Vibrio vulnificus*, *Pseudomonas aeruginosa*, and *Burkholderia pseudomallei*, among others) are poorly recognized by MD-2–TLR4. These bacteria usually enter the body via nonmucosal routes—e.g., as a result of bites, cuts, or inhalation—and initially induce relatively little inflammation. When they do trigger severe sepsis, it is often in the setting of massive bacterial growth throughout the body. Engineering a virulent strain of *Y. pestis* to produce hexaacyl lipid A has rendered it avirulent in mice; this result attests to the importance of TLR4-based bacterial recognition in host defense. For most gram-negative bacteria, the pathogenesis of sepsis thus depends, at least in part, on whether the bacterium's LPS is sensed by the host receptor MD-2–TLR4.

Local and Systemic Host Responses to Invading Microbes Recognition of microbial molecules by tissue phagocytes triggers the production and/or release of numerous host molecules (cytokines, chemokines, prostanoids, leukotrienes, and others) that increase blood flow to the infected tissue, enhance the permeability of local blood vessels, recruit

neutrophils to the site of infection, and elicit pain. These phenomena are familiar elements of local inflammation, the body's frontline innate immune mechanism for eliminating microbial invaders. Systemic responses are activated by neural and/or humoral communication with the hypothalamus and brainstem; these responses enhance local defenses by increasing blood flow to the infected area, augmenting the number of circulating neutrophils, and elevating blood levels of numerous molecules (such as the microbial recognition proteins discussed above) that have anti-infective functions.

CYTOKINES AND OTHER MEDIATORS Cytokines can exert endocrine, paracrine, and autocrine effects (Chap. 308). TNF-α stimulates leukocytes and vascular endothelial cells to release other cytokines (as well as additional TNF-α), to express cell-surface molecules that enhance neutrophil-endothelial adhesion at sites of infection, and to increase prostaglandin and leukotriene production. Whereas blood levels of TNF-α are not elevated in individuals with localized infections, they increase in most patients with severe sepsis or septic shock. Moreover, IV infusion of TNF-α can elicit the characteristic abnormalities of SIRS. In animals, larger doses of TNF-α induce shock, disseminated intravascular coagulation (DIC), and death.

Although TNF-α is a central mediator, it is only one of many proinflammatory molecules that contribute to innate host defense. Chemokines, most prominently interleukin (IL) 8, attract circulating neutrophils to the infection site. IL-1β exhibits many of the same activities as TNF-α. TNF-α, IL-1β, interferon (IFN) γ, IL-12, and other cytokines probably interact synergistically with one another and with additional mediators. High-mobility group B-1, a transcription factor, can also be released from cells and interact with microbial products to induce host responses late in the course of the septic response.

COAGULATION FACTORS Intravascular thrombosis, a hallmark of the local inflammatory response, may help wall off invading microbes and prevent infection and inflammation from spreading to other tissues. Intravascular fibrin deposition, thrombosis, and DIC can also be important features of the systemic response. IL-6 and other mediators promote intravascular coagulation initially by inducing blood monocytes and vascular endothelial cells to express tissue factor (Chap. 59). When tissue factor is expressed on cell surfaces, it binds to factor VIIa to form an active complex that can convert factors X and IX to their enzymatically active forms. The result is activation of both extrinsic and intrinsic clotting pathways, culminating in the generation of fibrin. Clotting is also favored by impaired function of the protein C–protein S inhibitory pathway and depletion of antithrombin and protein C, while fibrinolysis is prevented by increased plasma levels of plasminogen activator inhibitor 1. Thus, there may be a striking propensity toward intravascular fibrin deposition, thrombosis, and bleeding; this propensity has been most apparent in patients with intravascular endothelial infections such as meningococcemia (Chap. 136). Contact-system activation occurs during sepsis but contributes more to the development of hypotension than to DIC.

CONTROL MECHANISMS Elaborate control mechanisms operate within both local sites of inflammation and the systemic circulation.

Local Control Mechanisms Host recognition of invading microbes within subepithelial tissues typically ignites immune responses that rapidly kill the invader and then subside to allow tissue recovery. The anti-inflammatory forces that put out the fire and clean up the battleground include molecules that neutralize or inactivate microbial signals. Among these molecules are LPS; intracellular factors (e.g., suppressor of cytokine signaling 3) that diminish the production of proinflammatory mediators by neutrophils and macrophages; anti-inflammatory cytokines (IL-10, IL-4); and molecules derived from essential polyunsaturated fatty acids (lipoxins, resolvins, and protectins) that promote tissue restoration.

Systemic Control Mechanisms The signaling apparatus that links microbial recognition to cellular responses in tissues is less active in the blood. For example, whereas LBP plays a role in recognizing the presence of LPS, in plasma it also prevents LPS signaling by transferring LPS molecules into plasma lipoprotein particles, which sequester the lipid A moiety so that it cannot interact with cells. At the high concentrations found in blood, LBP also inhibits monocyte responses to LPS, and the soluble (circulating) form of CD14 strips off LPS that has bound to monocyte surfaces.

Systemic responses to infection also diminish cellular responses to microbial molecules. Circulating levels of anti-inflammatory cytokines (e.g., IL-6 and IL-10) increase even in patients with mild infections. Glucocorticoids inhibit cytokine synthesis by monocytes in vitro; the increase in blood cortisol levels early in the systemic response presumably plays a similarly inhibitory role. Epinephrine inhibits the TNF-α response to endotoxin infusion in humans while augmenting and accelerating the release of IL-10; prostaglandin E_2 has a similar "reprogramming" effect on the responses of circulating monocytes to LPS and other bacterial agonists. Cortisol, epinephrine, IL-10, and C-reactive protein reduce the ability of neutrophils to attach to vascular endothelium, favoring their demargination and thus contributing to leukocytosis while preventing neutrophil-endothelial adhesion in uninflamed organs. The available evidence thus suggests that the body's systemic responses to injury and infection normally prevent inflammation within organs distant from a site of infection.

The acute-phase response increases the blood concentrations of numerous molecules that have anti-inflammatory actions. Blood levels of IL-1 receptor antagonist (IL-1Ra) often greatly exceed those of circulating IL-1β, for example, and this excess may result in inhibition of the binding of IL-1β to its receptors. High levels of soluble TNF receptors neutralize TNF-α that enters the circulation. Other acute-phase proteins are protease inhibitors; these may neutralize proteases released from neutrophils and other inflammatory cells.

Organ Dysfunction and Shock As the body's responses to infection intensify, the mixture of circulating cytokines and other molecules becomes very complex: elevated blood levels of more than 50 molecules have been found in patients with septic shock. Although high concentrations of both pro- and anti-inflammatory molecules are found, the net mediator balance in the plasma of these extremely sick patients may actually be anti-inflammatory. For example, blood leukocytes from patients with severe sepsis are often hyporesponsive to agonists such as LPS. In patients with severe sepsis, persistence of leukocyte hyporesponsiveness has been associated with an increased risk of dying. Apoptotic death of B cells, follicular dendritic cells, and CD4+ T lymphocytes also may contribute significantly to the immunosuppressive state.

ENDOTHELIAL INJURY Most investigators have favored widespread vascular endothelial injury as the major mechanism for multiorgan dysfunction. In keeping with this idea, one study found high numbers of vascular endothelial cells in the peripheral blood of septic patients. Leukocyte-derived mediators and platelet-leukocyte-fibrin thrombi may contribute to vascular injury, but the vascular endothelium also seems to play an active role. Stimuli such as TNF-α induce vascular endothelial cells to produce and release cytokines, procoagulant molecules, platelet-activating factor (PAF), nitric oxide, and other mediators. In addition, regulated cell-adhesion molecules promote the adherence of neutrophils to endothelial cells. While these responses can attract phagocytes to infected sites and activate their antimicrobial arsenals, endothelial cell activation can also promote increased vascular permeability, microvascular thrombosis, DIC, and hypotension.

Tissue oxygenation may decrease as the number of functional capillaries is reduced by luminal obstruction due to swollen endothelial cells, decreased deformability of circulating erythrocytes, leukocyte-platelet-fibrin thrombi, or compression by edema fluid. On the other hand, studies using orthogonal polarization spectral imaging of the microcirculation in the tongue found that sepsis-associated derangements in capillary flow could be reversed by applying acetylcholine to the surface of the tongue or giving nitroprusside intravenously; these observa-

tions suggest a neuroendocrine basis for the loss of capillary filling. Oxygen utilization by tissues may also be impaired by a state of "hibernation" in which ATP production is diminished as oxidative phosphorylation decreases because of mitochondrial dysfunction; nitric oxide or its metabolites may be responsible for inducing this response.

Remarkably, poorly functioning "septic" organs usually appear normal at autopsy. There is typically very little necrosis or thrombosis, and apoptosis is largely confined to lymphoid organs and the gastrointestinal tract. Moreover, organ function usually returns to normal if patients recover. These points suggest that organ dysfunction during severe sepsis has a basis that is principally biochemical, not anatomic.

SEPTIC SHOCK The hallmark of septic shock is a decrease in peripheral vascular resistance that occurs despite increased levels of vasopressor catecholamines. Before this vasodilatory phase, many patients experience a period during which oxygen delivery to tissues is compromised by myocardial depression, hypovolemia, and other factors. During this "hypodynamic" period, the blood lactate concentration is elevated, and central venous oxygen saturation is low. Fluid administration is usually followed by the hyperdynamic, vasodilatory phase during which cardiac output is normal (or even high) and oxygen consumption is independent of oxygen delivery. The blood lactate level may be normal or increased, and normalization of the central venous oxygen saturation (SvO_2) may reflect either improved oxygen delivery or left-to-right shunting.

Prominent hypotensive molecules include nitric oxide, β-endorphin, bradykinin, PAF, and prostacyclin. Agents that inhibit the synthesis or action of each of these mediators can prevent or reverse endotoxic shock in animals. However, in clinical trials, neither a PAF receptor antagonist nor a bradykinin antagonist improved survival rates among patients with septic shock, and a nitric oxide synthetase inhibitor, L-N^G-methylarginine HCl, actually increased the mortality rate.

Severe Sepsis: A Single Pathogenesis? In some cases, circulating bacteria and their products almost certainly elicit multiorgan dysfunction and hypotension by directly stimulating inflammatory responses within the vasculature. In patients with fulminant meningococcemia, for example, mortality rates have correlated well with blood endotoxin levels and with the occurrence of DIC (Chap. 136). In most patients with nosocomial infections, in contrast, circulating bacteria or bacterial molecules may reflect uncontrolled infection at a local tissue site and have little or no direct impact on distant organs; in these patients, inflammatory mediators or neural signals arising from the local site seem to be the key triggers for severe sepsis and septic shock. In a large series of patients with positive blood cultures, the risk of developing severe sepsis was strongly related to the site of primary infection: bacteremia arising from a pulmonary or abdominal source was eightfold more likely to be associated with severe sepsis than was bacteremic urinary tract infection, even after the investigators controlled for age, the kind of bacteria isolated from the blood, and other factors. A third pathogenesis may be represented by severe sepsis due to superantigen-producing *Staphylococcus aureus* or *Streptococcus pyogenes*, since the T cell activation induced by these toxins produces a cytokine profile that differs substantially from that elicited by gram-negative bacterial infection.

In summary, the pathogenesis of severe sepsis may differ according to the infecting microbe, the ability of the host's innate defense mechanisms to sense it, the site of the primary infection, the presence or absence of immune defects, and the prior physiologic status of the host. Genetic factors may also be important. For example, studies in different ethnic groups have identified associations between allelic polymorphisms in TLR4, caspase 12L, TNF-α, and IFN-γ genes and the risk of developing severe sepsis. Further studies in this area are needed.

CLINICAL MANIFESTATIONS

The manifestations of the septic response are usually superimposed on the symptoms and signs of the patient's underlying illness and primary infection. The rate at which signs and symptoms develop may differ from patient to patient, and there are striking individual variations in presentation. For example, some patients with sepsis are normo- or hypothermic; the absence of fever is most common in neonates, in elderly patients, and in persons with uremia or alcoholism.

Hyperventilation is often an early sign of the septic response. Disorientation, confusion, and other manifestations of encephalopathy may also develop early on, particularly in the elderly and in individuals with preexisting neurologic impairment. Focal neurologic signs are uncommon, although preexisting focal deficits may become more prominent.

Hypotension and DIC predispose to acrocyanosis and ischemic necrosis of peripheral tissues, most commonly the digits. Cellulitis, pustules, bullae, or hemorrhagic lesions may develop when hematogenous bacteria or fungi seed the skin or underlying soft tissue. Bacterial toxins may also be distributed hematogenously and elicit diffuse cutaneous reactions. On occasion, skin lesions may suggest specific pathogens. When sepsis is accompanied by cutaneous petechiae or purpura, infection with *Neisseria meningitidis* (or, less commonly, *H. influenzae*) should be suspected (Fig. 136-1); in a patient who has been bitten by a tick while in an endemic area, petechial lesions also suggest Rocky Mountain spotted fever (Fig. 167-1). A cutaneous lesion seen almost exclusively in neutropenic patients is ecthyma gangrenosum, usually caused by *P. aeruginosa*. It is a bullous lesion, surrounded by edema that undergoes central hemorrhage and necrosis (Fig. 145-1). Histopathologic examination shows bacteria in and around the wall of a small vessel, with little or no neutrophilic response. Hemorrhagic or bullous lesions in a septic patient who has recently eaten raw oysters suggest *V. vulnificus* bacteremia, while such lesions in a patient who has recently suffered a dog bite may indicate bloodstream infection due to *Capnocytophaga canimorsus* or *C. cynodegmi*. Generalized erythroderma in a septic patient suggests the toxic shock syndrome due to *S. aureus* or *S. pyogenes*.

Gastrointestinal manifestations such as nausea, vomiting, diarrhea, and ileus may suggest acute gastroenteritis. Stress ulceration can lead to upper gastrointestinal bleeding. Cholestatic jaundice, with elevated levels of serum bilirubin (mostly conjugated) and alkaline phosphatase, may precede other signs of sepsis. Hepatocellular or canalicular dysfunction appears to underlie most cases, and the results of hepatic function tests return to normal with resolution of the infection. Prolonged or severe hypotension may induce acute hepatic injury or ischemic bowel necrosis.

Many tissues may be unable to extract oxygen normally from the blood, so that anaerobic metabolism occurs despite near-normal mixed venous oxygen saturation. Blood lactate levels rise early because of increased glycolysis as well as impaired clearance of the resulting lactate and pyruvate by the liver and kidneys. The blood glucose concentration often increases, particularly in patients with diabetes, although impaired gluconeogenesis and excessive insulin release on occasion produce hypoglycemia. The cytokine-driven acute-phase response inhibits the synthesis of transthyretin while enhancing the production of C-reactive protein, fibrinogen, and complement components. Protein catabolism is often markedly accelerated. Serum albumin levels decline as a result of decreased hepatic synthesis and the movement of albumin into interstitial spaces, which is promoted by arterial vasodilation.

MAJOR COMPLICATIONS

Cardiopulmonary Complications Ventilation-perfusion mismatching produces a fall in arterial P_{O_2} early in the course. Increasing alveolar capillary permeability results in an increased pulmonary water content, which decreases pulmonary compliance and interferes with oxygen exchange. Progressive diffuse pulmonary infiltrates and arterial hypoxemia (Pa_{O_2}/FI_{O_2}, <200) indicate the development of the acute respiratory distress syndrome (ARDS). ARDS develops in ~50% of patients with severe sepsis or septic shock. Respiratory muscle fatigue can exacerbate hypoxemia and hypercapnia. An elevated pulmonary capillary wedge pressure (>18 mmHg) suggests fluid volume overload or cardiac failure rather than ARDS. Pneumonia caused by viruses or by *Pneumocystis* may be clinically indistinguishable from ARDS.

Sepsis-induced hypotension (see "Septic Shock," above) usually results initially from a generalized maldistribution of blood flow and

blood volume and from hypovolemia that is due, at least in part, to diffuse capillary leakage of intravascular fluid. Other factors that may decrease effective intravascular volume include dehydration from antecedent disease or insensible fluid losses, vomiting or diarrhea, and polyuria. During early septic shock, systemic vascular resistance is usually elevated and cardiac output may be low. After fluid repletion, in contrast, cardiac output typically increases and systemic vascular resistance falls. Indeed, normal or increased cardiac output and decreased systemic vascular resistance distinguish septic shock from cardiogenic, extracardiac obstructive, and hypovolemic shock; other processes that can produce this combination include anaphylaxis, beriberi, cirrhosis, and overdoses of nitroprusside or narcotics.

Depression of myocardial function, manifested as increased end-diastolic and systolic ventricular volumes with a decreased ejection fraction, develops within 24 h in most patients with severe sepsis. Cardiac output is maintained despite the low ejection fraction because ventricular dilatation permits a normal stroke volume. In survivors, myocardial function returns to normal over several days. Although myocardial dysfunction may contribute to hypotension, refractory hypotension is usually due to a low systemic vascular resistance, and death results from refractory shock or the failure of multiple organs rather than from cardiac dysfunction per se.

Renal Complications Oliguria, azotemia, proteinuria, and nonspecific urinary casts are frequently found. Many patients are inappropriately polyuric; hyperglycemia may exacerbate this tendency. Most renal failure is due to acute tubular necrosis induced by hypotension or capillary injury, although some patients also have glomerulonephritis, renal cortical necrosis, or interstitial nephritis. Drug-induced renal damage may complicate therapy, particularly when hypotensive patients are given aminoglycoside antibiotics.

Coagulopathy Although thrombocytopenia occurs in 10–30% of patients, the underlying mechanisms are not understood. Platelet counts are usually very low (<50,000/μL) in patients with DIC; these low counts may reflect diffuse endothelial injury or microvascular thrombosis.

Neurologic Complications When the septic illness lasts for weeks or months, "critical-illness" polyneuropathy may prevent weaning from ventilatory support and produce distal motor weakness. Electrophysiologic studies are diagnostic. Guillain-Barré syndrome, metabolic disturbances, and toxin activity must be ruled out.

LABORATORY FINDINGS

Abnormalities that occur early in the septic response may include leukocytosis with a left shift, thrombocytopenia, hyperbilirubinemia, and proteinuria. Leukopenia may develop. The neutrophils may contain toxic granulations, Döhle bodies, or cytoplasmic vacuoles. As the septic response becomes more severe, thrombocytopenia worsens (often with prolongation of the thrombin time, decreased fibrinogen, and the presence of D-dimers, suggesting DIC), azotemia and hyperbilirubinemia become more prominent, and levels of aminotransferases rise. Active hemolysis suggests clostridial bacteremia, malaria, a drug reaction, or DIC; in the case of DIC, microangiopathic changes may be seen on a blood smear.

During early sepsis, hyperventilation induces respiratory alkalosis. With respiratory muscle fatigue and the accumulation of lactate, metabolic acidosis (with increased anion gap) typically supervenes. Evaluation of arterial blood gases reveals hypoxemia, which is initially correctable with supplemental oxygen but whose later refractoriness to 100% oxygen inhalation indicates right-to-left shunting. The chest radiograph may be normal or may show evidence of underlying pneumonia, volume overload, or the diffuse infiltrates of ARDS. The electrocardiogram may show only sinus tachycardia or nonspecific ST–T-wave abnormalities.

Most diabetic patients with sepsis develop hyperglycemia. Severe infection may precipitate diabetic ketoacidosis, which may exacerbate hypotension (Chap. 338). Hypoglycemia occurs rarely. The serum albumin level, initially within the normal range, declines as sepsis continues. Hypocalcemia is rare.

DIAGNOSIS

There is no specific diagnostic test for the septic response. Diagnostically sensitive findings in a patient with suspected or proven infection include fever or hypothermia, tachypnea, tachycardia, and leukocytosis or leukopenia (Table 265-1); acutely altered mental status, thrombocytopenia, an elevated blood lactate level, or hypotension also should suggest the diagnosis. The septic response can be quite variable, however. In one study, 36% of patients with severe sepsis had a normal temperature, 40% had a normal respiratory rate, 10% had a normal pulse rate, and 33% had normal white blood cell counts. Moreover, the systemic responses of uninfected patients with other conditions may be similar to those characteristic of sepsis. Noninfectious etiologies of SIRS (Table 265-1) include pancreatitis, burns, trauma, adrenal insufficiency, pulmonary embolism, dissecting or ruptured aortic aneurysm, myocardial infarction, occult hemorrhage, cardiac tamponade, post–cardiopulmonary bypass syndrome, anaphylaxis, and drug overdose.

Definitive etiologic diagnosis requires isolation of the microorganism from blood or a local site of infection. At least two blood samples (10 mL each) should be obtained (from different venipuncture sites) for culture. Because gram-negative bacteremia is typically low-grade (<10 organisms/mL of blood), prolonged incubation of cultures may be necessary; *S. aureus* grows more readily and is detectable in blood cultures within 48 h in most instances. In many cases, blood cultures are negative; this result can reflect prior antibiotic administration, the presence of slow-growing or fastidious organisms, or the absence of microbial invasion of the bloodstream. In these cases, Gram's staining and culture of material from the primary site of infection or of infected cutaneous lesions may help establish the microbial etiology. The skin and mucosae should be examined carefully and repeatedly for lesions that might yield diagnostic information. With overwhelming bacteremia (e.g., pneumococcal sepsis in splenectomized individuals, fulminant meningococcemia, or infection with *V. vulnificus, B. pseudomallei*, or *Y. pestis*), microorganisms are sometimes visible on buffy coat smears of peripheral blood.

Rx SEVERE SEPSIS AND SEPTIC SHOCK

Patients in whom sepsis is suspected must be managed expeditiously. This task is best accomplished by personnel who are experienced in the care of the critically ill. Successful management requires urgent measures to treat the infection, to provide hemodynamic and respiratory support, and to eliminate the offending microorganism. Most emergency centers now aim to initiate these measures within 1 h of the patient's presentation with severe sepsis or shock. Rapid assessment and diagnosis are therefore essential.

ANTIMICROBIAL AGENTS Antimicrobial chemotherapy should be initiated as soon as samples of blood and other relevant sites have been cultured. A large retrospective review of patients who developed septic shock found that the interval between the onset of hypotension and the administration of appropriate antimicrobial chemotherapy was the major determinant of outcome; a delay of as little as 1 h was associated with lower survival rates.

It is important, pending culture results, to initiate empirical antimicrobial therapy that is effective against both gram-positive and gram-negative bacteria **(Table 265-3)**. Maximal recommended doses of antimicrobial drugs should be given intravenously, with adjustment for impaired renal function when necessary. Available information about patterns of antimicrobial susceptibility among bacterial isolates from the community, the hospital, and the patient should be taken into account. When culture results become available, the regimen can often be simplified, as a single antimicrobial agent is usually adequate for the treatment of a known pathogen. Meta-analyses have concluded that, with one exception, combination antimicrobial therapy is not superior to monotherapy for treating gram-negative bacteremia; the exception is that aminoglycoside monotherapy for *P. aeruginosa* bacteremia is less effective than the combination of an aminoglycoside with an antipseudomonal β-lactam agent. Most pa-

TABLE 265-3 INITIAL ANTIMICROBIAL THERAPY FOR SEVERE SEPSIS WITH NO OBVIOUS SOURCE IN ADULTS WITH NORMAL RENAL FUNCTION

Clinical Condition	Antimicrobial Regimens (Intravenous Therapy)
Immunocompetent adult	The many acceptable regimens include (1) ceftriaxone (2 g q24h) ***or*** ticarcillin-clavulanate (3.1 g q4–6h) ***or*** piperacillin-tazobactam (3.375 g q4–6h); (2) imipenem-cilastatin (0.5 g q6h) ***or*** meropenem (1 g q8h) ***or*** cefepime (2 g q12h). Gentamicin ***or*** tobramycin (5–7 mg/kg q24h) may be ***added*** to either regimen. If the patient is allergic to β-lactam agents, use ciprofloxacin (400 mg q12h) ***or*** levofloxacin (500–750 mg q12h) ***plus*** clindamycin (600 mg q8h). If the institution or the community has a high prevalence of MRSA isolates, add vancomycin (15 mg/kg q12h) to each of the above regimens.
Neutropenia[a] (<500 neutrophils/μL)	Regimens include (1) imipenem-cilastatin (0.5 g q6h) ***or*** meropenem (1 g q8h) ***or*** cefepime (2 g q8h); (2) ticarcillin-clavulanate (3.1 g q4h) ***or*** piperacillin-tazobactam (3.375 g q4h) ***plus*** tobramycin (5–7 mg/kg q24h). Vancomycin (15 mg/kg q12h) should be added if the patient has an infected vascular catheter, if staphylococci are suspected, if the patient has received quinolone prophylaxis, if the patient has received intensive chemotherapy that produces mucosal damage, if the institution has a high incidence of MRSA infections, or if there is a high prevalence of MRSA isolates in the community.
Splenectomy	Cefotaxime (2 g q6–8h) ***or*** ceftriaxone (2 g q12h) should be used. If the local prevalence of cephalosporin-resistant pneumococci is high, ***add*** vancomycin. If the patient is allergic to β-lactam drugs, vancomycin (15 mg/kg q12h) ***plus*** ciprofloxacin (400 mg q12h) ***or*** levofloxacin (750 mg q12h) ***or*** aztreonam (2 g q8h) should be used.
IV drug user	Nafcillin or oxacillin (2 g q8h) ***plus*** gentamicin (5–7 mg/kg q24h). If the local prevalence of MRSA is high or if the patient is allergic to β-lactam drugs, vancomycin (15 mg/kg q12h) with gentamicin should be used.
AIDS	Cefepime (2 g q8h), ticarcillin-clavulanate (3.1 g q4h), ***or*** piperacillin-tazobactam (3.375 g q4h) ***plus*** tobramycin (5–7 mg/kg q24h) should be used. If the patient is allergic to β-lactam drugs, ciprofloxacin (400 mg q12h) ***or*** levofloxacin (750 mg q12h) ***plus*** vancomycin (15 mg/kg q12h) ***plus*** tobramycin should be used.

Note: MRSA, methicillin-resistant *Staphylococcus aureus*.

tients require antimicrobial therapy for at least 1 week; the duration of treatment is typically influenced by factors such as the site of tissue infection, the adequacy of surgical drainage, the patient's underlying disease, and the antimicrobial susceptibility of the bacterial isolate(s).

REMOVAL OF THE SOURCE OF INFECTION Removal or drainage of a focal source of infection is essential. Sites of occult infection should be sought carefully. Indwelling IV catheters should be removed and the tip rolled over a blood agar plate for quantitative culture; after antibiotic therapy has been initiated, a new catheter should be inserted at a different site. Foley and drainage catheters should be replaced. The possibility of paranasal sinusitis (often caused by gram-negative bacteria) should be considered if the patient has undergone nasal intubation. In patients with abnormalities on chest radiographs, CT of the chest may identify unsuspected parenchymal, mediastinal, or pleural disease. In the neutropenic patient, cutaneous sites of tenderness and erythema, particularly in the perianal region, must be carefully sought. In patients with sacral or ischial decubitus ulcers, it is important to exclude pelvic or other soft tissue pus collections with CT or MRI. In patients with severe sepsis arising from the urinary tract, sonography or CT should be used to rule out ureteral obstruction, perinephric abscess, and renal abscess.

HEMODYNAMIC, RESPIRATORY, AND METABOLIC SUPPORT
The primary goals are to restore adequate oxygen and substrate delivery to the tissues as quickly as possible and to improve tissue oxygen utilization and cellular metabolism. Adequate organ perfusion is thus essential. Initial management of hypotension should include the administration of IV fluids, typically beginning with 1–2 L of normal saline over 1–2 h. To avoid pulmonary edema, the pulmonary capillary wedge pressure should be maintained at 12–16 mmHg or the central venous pressure at 8–12 cm H_2O. The urine output rate should be kept at >0.5 mL/kg per hour by continuing fluid administration; a diuretic such as furosemide may be used if needed. In about one-third of patients, hypotension and organ hypoperfusion respond to fluid resuscitation; a reasonable goal is to maintain a mean arterial blood pressure of >65 mmHg (systolic pressure, >90 mmHg) and a cardiac index of ≥4 L/min per m^2. If these guidelines cannot be met by volume infusion, vasopressor therapy is indicated. Circulatory adequacy is also assessed by clinical parameters (mentation, urine output, skin perfusion) and, when possible, by measurements of oxygen delivery and consumption.

A study of "early goal-directed therapy" (EGDT) found that prompt resuscitation based on maintenance of the SvO_2 at >70% was associated with significantly improved survival of patients who were admitted to an emergency department with severe sepsis. The treatment algorithm included rapid administration of fluids, antibiotics, and vasopressor support; erythrocyte transfusion (to maintain the hematocrit above 30%); and administration of dobutamine if fluids, erythrocytes, and pressors did not result in an SvO_2 of >70%. The extent to which the different components of the EGDT algorithm contribute to the overall effect has not been examined in controlled trials. In particular, neither the use of SvO_2 to manage therapy nor the need for continuous SvO_2 monitoring with a pulmonary artery catheter has been formally confirmed. A multicenter study (sponsored by the National Institutes of Health) of the efficacy of the EGDT approach is in progress.

In patients with septic shock, plasma vasopressin levels increase transiently but then decrease dramatically. Studies have found that vasopressin infusion can reverse septic shock in some patients, reducing or eliminating the need for catecholamine pressors. An adequately powered and randomized trial of vasopressin infusion has not been performed. Vasopressin is a potent vasoconstrictor that may be most useful in patients who have vasodilatory shock and relative resistance to other pressor hormones.

Adrenal insufficiency is very likely when the plasma cortisol level is <15 μg/dL in a patient with severe sepsis. Generally accepted criteria for *partial* adrenal insufficiency have not been devised; major problems have been the inability to raise cortisol levels in extremely stressed individuals above high baseline values in response to cosyntropin (α^{1-24}–ACTH) (Chap. 336) and the high frequency of hypoalbuminemia, which decreases total but not free (active) plasma cortisol levels. Adrenal insufficiency should be strongly considered in septic patients with refractory hypotension, fulminant meningococcal bacteremia, disseminated tuberculosis, AIDS, or prior use of glucocorticoids, megestrol, etomidate, or ketoconazole. Hydrocortisone (50 mg IV every 6 h) may be given as a trial therapeutic intervention. If clinical improvement occurs over 24–48 h, most experts would continue hydrocortisone therapy, tapering and discontinuing it after 5–7 days. Improved recommendations regarding hydrocortisone therapy may come from the European CORTICUS trial.

Ventilator therapy is indicated for progressive hypoxemia, hypercapnia, neurologic deterioration, or respiratory muscle failure. Sustained tachypnea (respiratory rate, >30 breaths/min) is frequently a harbinger of impending respiratory collapse; mechanical ventilation is often initiated to ensure adequate oxygenation, to divert blood from the muscles of respiration, to prevent aspiration of oropharyngeal contents, and to reduce the cardiac afterload. The results of recent studies favor the use of low tidal volumes (6 mL/kg of ideal body weight, or as low as 4 mL/kg if the plateau pressure exceeds 30 cmH_2O). Patients undergoing mechanical ventilation require careful sedation, with daily interruptions; elevation of the head of the bed helps to prevent nosocomial pneumonia. Stress-ulcer prophylaxis with a histamine H_2-receptor antagonist may decrease the risk of gastrointestinal hemorrhage in ventilated patients.

The use of erythrocyte transfusion continues to be debated. In the study of EGDT, packed erythrocytes were given to raise the hematocrit to 30% if the patient's SvO_2 was <70%. The extent to which this intervention contributed to the improvement reported in patients who received the EGDT regimen is uncertain.

Bicarbonate is sometimes administered for severe metabolic acidosis (arterial pH <7.2), but there is little evidence that it improves either hemo-

dynamics or the response to vasopressor hormones. DIC, if complicated by major bleeding, should be treated with transfusion of fresh-frozen plasma and platelets. Successful treatment of the underlying infection is essential to reverse both acidosis and DIC. Patients who are hypercatabolic and have acute renal failure may benefit greatly from hemodialysis or hemofiltration.

GENERAL SUPPORT In patients with prolonged severe sepsis (i.e., that lasting more than 2 or 3 days), nutritional supplementation may reduce the impact of protein hypercatabolism; the available evidence, which is not strong, favors the enteral delivery route. Prophylactic heparinization to prevent deep venous thrombosis is indicated for patients who do not have active bleeding or coagulopathy. Recovery is also assisted by preventing skin breakdown, nosocomial infections, and stress ulcers.

Investigators in Belgium reported in 2001 that maintaining blood glucose levels in the normal range (80–110 mg/dL) greatly improved survival rates among patients who had just undergone major surgery and had received IV glucose feeding for the previous 24 h. The same group then studied intensive glucose control in critically ill medical patients and found a survival benefit only for patients who remained in the intensive care unit for ≥3 days. Hypoglycemia was much more common in the intensive-insulin group. Until more experience with intensive glucose control is reported, it seems reasonable to maintain glucose levels of <150 mg/dL during the first 3 days of severe sepsis and then to target the normoglycemic range if the patient remains in the intensive care unit for a longer period. Frequent monitoring of blood glucose levels is indicated to avoid hypoglycemia during intensive insulin therapy.

OTHER MEASURES Despite aggressive management, many patients with severe sepsis or septic shock die. Numerous interventions have been tested for their ability to improve survival in patients with severe sepsis. The list includes endotoxin-neutralizing proteins, inhibitors of cyclooxygenase or nitric oxide synthase, anticoagulants, polyclonal immunoglobulins, glucocorticoids, and antagonists to TNF-α, IL-1, PAF, and bradykinin. Unfortunately, none of these agents has improved rates of survival among patients with severe sepsis/septic shock in more than one large, randomized, placebo-controlled clinical trial. This lack of reproducibility has had many contributing factors, including (1) heterogeneity in the patient populations studied and the inciting microbes and (2) the nature of the "standard" therapy also used. A dramatic example of this problem was seen in a trial of tissue factor pathway inhibitor **(Fig. 265-1)**. Whereas the drug appeared to improve survival rates after 722 patients had been studied (p = .006), it did not do so in the next 1032 patients, and the overall result was negative. This inconsistency, even within a carefully selected patient population, argues strongly that a sepsis intervention should show significant survival benefit in more than one placebo-controlled clinical trial before it is accepted as part of routine clinical practice.

Recombinant activated protein C (aPC) was the first drug to be approved by the U.S. Food and Drug Administration (FDA) for the treatment of patients with severe sepsis or septic shock. In a single randomized controlled trial in which drug or placebo was given within 24 h of the patient's first sepsis-related organ dysfunction, 28-day mortality was significantly lower among recipients of aPC than among patients who received placebo (24.7% vs. 30.8%; p <.005). In addition, aPC recipients were more likely than placebo recipients to have severe bleeding (3.5% vs. 2%). Survival improved only for patients who had an APACHE II score of ≥25 during the 24 h before initiation of aPC infusion. Midtrial changes in the protocol and drug were followed by improvement in the apparent efficacy of aPC. The FDA approved aPC for use in adults (>18 years of age) who meet the APACHE II criterion and have a low risk of hemorrhage-related side effects.

aPC is administered as a constant IV infusion of 24 μg/kg per hour for 96 h. Each patient's clotting parameters must be monitored carefully. aPC should not be given to patients who have platelet counts of <30,000/μL or to patients who have dysfunction of one organ system and have had surgery during the previous 30 days. Treatment with aPC should not be started >24 h after the onset of severe sepsis, nor should it be used in the patient subsets—e.g., patients with pancreatitis or AIDS—that were excluded from the clinical trial.

Although the theoretical rationale for treating septic patients with anticoagulants is strong and studies have found that aPC may have anti-inflammatory and anti-apoptotic properties in vitro, two additional randomized, placebo-controlled trials of aPC were stopped when interim analyses showed lack of efficacy. One trial was in children, and the other was in adults with APACHE II scores of ≤25. aPC has not been tested again in the patient population for which it was approved by the FDA: adults with high APACHE II scores.

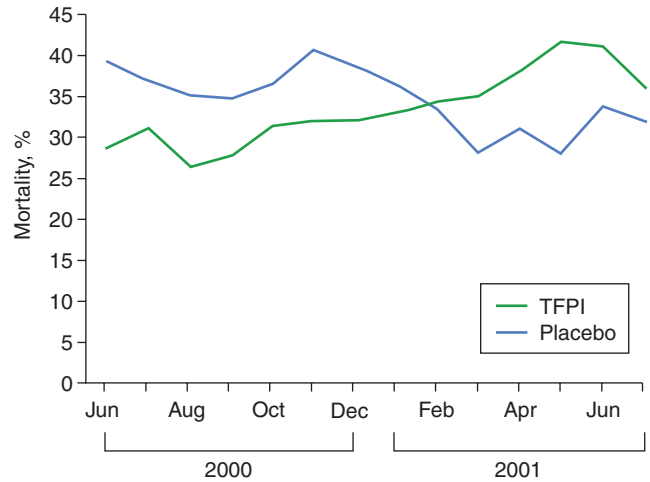

FIGURE 265-1 Mortality rates among patients who received tissue factor pathway inhibitor (TFPI) or placebo, shown as the running average over the course of the clinical trial. The drug seemed highly efficacious at the interim analysis in December 2000, but this trend reversed later in the trial. Demonstrating that therapeutic agents for sepsis have consistent, reproducible efficacy has been extremely difficult, even within well-defined patient populations. *(Reprinted with permission from Abraham et al.)*

Some experts have advocated "bundling" of multiple therapeutic maneuvers into a unified, algorithmic approach to management that would become the standard of care for severe sepsis. The proposed *resuscitation* (6-h) bundle incorporates most of the elements discussed above for acute (EGDT) resuscitation. The *management* (24-h) bundle includes three measures of uncertain or marginal benefit: tight control of blood glucose, administration of low-dose hydrocortisone, and treatment with aPC. Bundling of therapies obscures the efficacy and toxicity of the individual interventions and allows little room for individualizing therapy. The use of bundling in an industry-sponsored marketing program for aPC (the Surviving Sepsis Campaign) has also been criticized.

A careful retrospective analysis found that the apparent efficacy of all sepsis therapeutics studied to date has been greatest among the patients at greatest risk of dying before treatment; conversely, use of many of these drugs has been associated with increased mortality rates among patients who are less ill. The authors proposed that neutralizing one of many different mediators may help patients who are very sick, whereas disrupting the mediator balance may be harmful to those whose adaptive defense mechanisms are still working. This analysis suggests that if more aggressive early resuscitation improves survival rates among sicker patients, it should become more difficult to show additional benefit from other therapies; that is, if early resuscitation improves patients' status, moving them into a "less severe illness" category, the addition of another agent is less likely to be beneficial.

PROGNOSIS

Approximately 20–35% of patients with severe sepsis and 40–60% of patients with septic shock die within 30 days. Others die within the ensuing 6 months. Late deaths often result from poorly controlled infection, immunosuppression, complications of intensive care, failure of multiple organs, or the patient's underlying disease.

Prognostic stratification systems such as APACHE II indicate that factoring in the patient's age, underlying condition, and various physiologic variables can yield estimates of the risk of dying of severe sepsis. Of the individual covariates, the severity of underlying disease most strongly influences the risk of dying. Septic shock is also a strong predictor of short- and long-term mortality. Case-fatality rates are similar for culture-positive and culture-negative severe sepsis.

PREVENTION

Prevention offers the best opportunity to reduce morbidity and mortality. In developed countries, most episodes of severe sepsis and septic shock are complications of nosocomial infections. These cases might be prevented by reducing the number of invasive procedures undertaken, by limiting the use (and duration of use) of indwelling vascular and bladder catheters, by reducing the incidence and duration of profound neutropenia (<500 neutrophils/μL), and by more aggressively treating localized nosocomial infections. Indiscriminate use of antimicrobial agents and glucocorticoids should be avoided, and optimal infection-control measures (Chap. 125) should be used. Several studies point to associations between allelic polymorphisms in specific genes and risk of severe sepsis; if these associations prove to be broadly applicable, such polymorphisms can be used prospectively to identify high-risk patients and to target preventive and/or therapeutic measures to them. Studies indicate that 50–70% of patients who develop nosocomial severe sepsis or septic shock have experienced a less severe stage of the septic response (e.g., SIRS, sepsis) on at least one previous day in the hospital. Research is needed to develop adjunctive agents that can damp the septic response before organ dysfunction or hypotension occurs.

266 Cardiogenic Shock and Pulmonary Edema

Judith S. Hochman, David H. Ingbar

Cardiogenic shock and pulmonary edema are life-threatening conditions that should be treated as medical emergencies. The most common etiology for both is severe left ventricular (LV) dysfunction, leading to pulmonary congestion and/or systemic hypoperfusion (Fig. 266-1). **The pathophysiology of pulmonary edema and shock are discussed in Chaps. 33 and 264, respectively.**

CARDIOGENIC SHOCK

Cardiogenic shock (CS) is characterized by systemic hypoperfusion due to severe depression of the cardiac index [<2.2 (L/min)/m^2] and sustained systolic arterial hypotension (<90 mmHg), despite an elevated filling pressure [pulmonary capillary wedge pressure (PCWP) > 18 mmHg]. It is associated with in-hospital mortality rates >50%. The major causes of CS are listed in Table 266-1. Circulatory failure based on cardiac dysfunction may be caused by primary myocardial failure, most commonly secondary to acute myocardial infarction (MI) (Chap. 239), and less frequently by cardiomyopathy or myocarditis (Chap. 231) or cardiac tamponade (Chap. 232).

Incidence CS is the leading cause of death of patients hospitalized with MI. Early reperfusion therapy for acute MI decreases the incidence of CS. The rate of CS complicating acute MI fell from 20% in the 1960s but has plateaued at ~8% for >20 years. Shock is typically associated with ST elevation MI (STEMI) and is less common with non-ST elevation MI (Chap. 239).

LV failure accounts for ~80% of the cases of CS complicating acute MI. Acute severe mitral regurgitation (MR), ventricular septal rupture (VSR), predominant right ventricular (RV) failure, and free wall rupture or tamponade account for the remainder.

Pathophysiology CS is characterized by a vicious circle in which depression of myocardial contractility, usually due to ischemia, results in

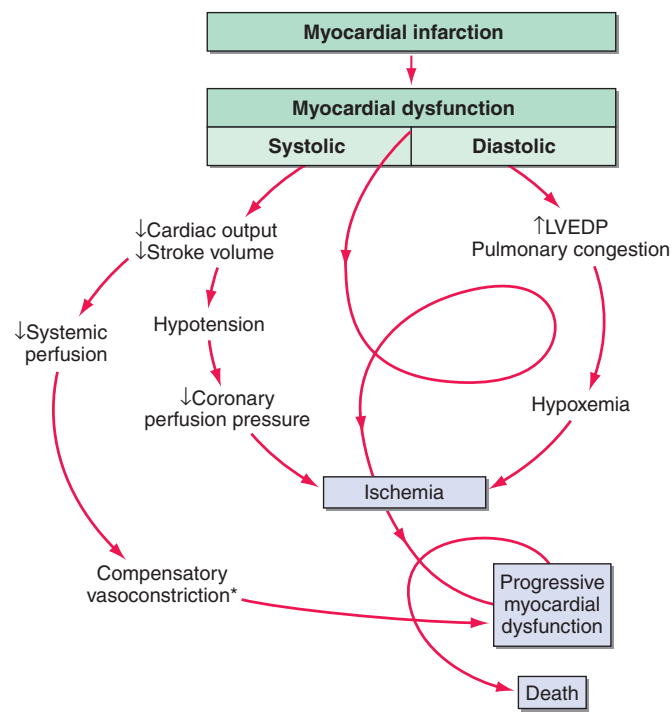

FIGURE 266-1 Pathophysiology of cardiogenic shock. Systolic and diastolic myocardial dysfunction result in a reduction in cardiac output and often pulmonary congestion. Systemic and coronary hypoperfusion occur, resulting in progressive ischemia. Although a number of compensatory mechanisms are activated in an attempt to support the circulation, these compensatory mechanisms may become maladaptive and produce a worsening of hemodynamics. *Release of inflammatory cytokines after myocardial infarction may lead to inducible nitrous oxide expression, excess NO, and inappropriate vasodilation. This causes further reduction in systemic and coronary perfusion. A vicious spiral of progressive myocardial dysfunction occurs that ultimately results in death if it is not interrupted. LVEDP, left ventricular end-diastolic pressure. (*From SM Hollenberg et al: Ann Intern Med 131:47, 1999.*)

TABLE 266-1 ETIOLOGIES OF CARDIOGENIC SHOCK (CS)[a] AND CARDIOGENIC PULMONARY EDEMA

Etiologies of Cardiogenic Shock or Pulmonary Edema
Acute myocardial infarction/ischemia
LV failure
VSR
Papillary muscle/chordal rupture—severe MR
Ventricular free wall rupture with subacute tamponade
Other conditions complicating large MIs
Hemorrhage
Infection
Excess negative inotropic or vasodilator medications
Prior valvular heart disease
Hyperglycemia/ketoacidosis
Post-cardiac arrest
Post-cardiotomy
Refractory sustained tachyarrhythmias
Acute fulminant myocarditis
End-stage cardiomyopathy
Left ventricular apical ballooning
Takotsubo cardiomyopathy
Hypertrophic cardiomyopathy with severe outflow obstruction
Aortic dissection with aortic insufficiency or tamponade
Pulmonary embolus
Severe valvular heart disease
Critical aortic or mitral stenosis
Acute severe aortic or MR
Toxic-metabolic
Beta-blocker or calcium channel antagonist overdose
Other Etiologies of Cardiogenic Shock[b]
RV failure due to:
Acute myocardial infarction
Acute coronary pulmonale
Refractory sustained bradyarrhythmias
Pericardial tamponade
Toxic/metabolic
Severe acidosis, severe hypoxemia

[a] The etiologies of CS are listed. Most of these can cause pulmonary edema instead of shock or pulmonary edema with CS.
[b] These cause CS but not pulmonary edema.
Note: LV, left ventricular; VSR, ventricular septal rupture; MR, mitral regurgitation; RV, right ventricular.

reduced cardiac output and arterial pressure (BP), which result in hypoperfusion of the myocardium and further ischemia and depression of the cardiac output (Fig. 266-1). Systolic myocardial dysfunction reduces stroke volume and, together with diastolic dysfunction, leads to elevated LV end-diastolic pressure and PCWP as well as to pulmonary congestion. Reduced coronary perfusion leads to worsening ischemia and progressive myocardial dysfunction and a rapid downward spiral, which, if uninterrupted, is often fatal. A systemic inflammatory response syndrome may accompany large infarctions and shock. Inflammatory cytokines, inducible nitric oxide synthase, and excess nitric oxide and peroxynitrite may contribute to the genesis of CS as they do to other forms of shock (Chap. 264). Lactic acidosis from poor tissue perfusion and hypoxemia from pulmonary edema may result from pump failure and then contribute to the vicious circle by worsening myocardial ischemia and hypotension. Severe acidosis (pH < 7.25) reduces the efficacy of endogenous and exogenously administered catecholamines. Refractory sustained ventricular or atrial tachyarrhythmias can cause or exacerbate CS.

Autopsy specimens often reflect the stuttering course and piecemeal necrosis of the LV, showing varying stages of infarction. Reinfarction is apparent as new areas of necrosis contiguous with or remote from a slightly older infarct. Infarctions that extend through the full myocardial thickness and result in rupture of the interventricular septum, papillary muscle, or ventricular free wall may result in shock (Chap. 239).

Patient Profile In patients with acute MI, older age, female sex, prior MI, diabetes, and anterior MI location are all associated with increased risk of CS. Shock associated with a first inferior MI should prompt a search for a mechanical cause. Reinfarction soon after MI increases the risk of CS. Two-thirds of patients with CS have flow-limiting stenoses in all three major coronary arteries, and 20% have left main coronary artery stenosis. CS may rarely occur in the absence of significant stenosis, as seen in LV apical ballooning/Takotsubo cardiomyopathy, often in response to sudden severe emotional stress.

Timing Shock is present on admission in only one-quarter of patients who develop CS complicating MI; one-quarter develop it rapidly thereafter, within 6 h of MI onset. Another quarter develop shock later on the first day. Subsequent onset of CS may be due to reinfarction, marked infarct expansion, or a mechanical complication.

Diagnosis Due to the unstable condition of these patients, supportive therapy must be initiated simultaneously with diagnostic evaluation (Fig. 266-2). A focused history and physical examination should be performed, blood specimens sent to the laboratory, and an electrocardiogram (ECG) and chest x-ray obtained.

Echocardiography is an invaluable diagnostic tool in patients suspected of CS.

CLINICAL FINDINGS Most patients have continuing chest pain and dyspnea and appear pale, apprehensive, and diaphoretic. Mentation may be altered, with somnolence, confusion, and agitation. The pulse is typically weak and rapid, often in the range of 90–110 beats/min, or severe bradycardia due to high-grade heart block may be present. Systolic blood pressure (BP) is reduced (<90 mmHg) with a narrow pulse pressure (<30 mmHg), but occasionally BP may be maintained by very high systemic vascular resistance. Tachypnea, Cheyne-Stokes respirations, and jugular venous distention may be present. The precordium is typically quiet, with a weak apical pulse. S1 is usually soft, and an S3 gallop may be audible. Acute, severe MR and VSR are usually associated with characteristic systolic murmurs (Chap. 239). Rales are audible in most patients with LV failure causing CS. Oliguria (urine output < 30 mL/h) is common.

LABORATORY FINDINGS The white blood cell count is typically elevated with a left shift. In the absence of prior renal insufficiency, renal function is initially normal, but blood urea nitrogen and creatinine rise progressively. Hepatic transaminases may be markedly elevated due to liver hypoperfusion. Poor tissue perfusion may result in an anion gap acidosis and elevation of lactic acid level. Prior to support with supplemental O_2, arterial blood gases usually demonstrate hypoxemia and metabolic acidosis, which may be compensated by respiratory alkalosis. Cardiac markers, creatine phosphokinase and its MB fraction, are markedly elevated, as are troponins I and T.

ELECTROCARDIOGRAM In CS due to acute MI with LV failure, Q waves and/or >2-mm ST elevation in multiple leads or left bundle branch block are usually present. More than one-half of all infarcts associated with shock are anterior. Global ischemia due to severe left main stenosis is usually accompanied by severe (e.g., >3 mm) ST depressions in multiple leads.

CHEST ROENTGENOGRAM The chest x-ray typically shows pulmonary vascular congestion and often pulmonary edema, but these findings may be absent in up to a third of patients. The heart size is usually normal when CS results from a first MI but is enlarged when it occurs in a patient with a previous MI.

ECHOCARDIOGRAM A two-dimensional echocardiogram with color flow Doppler (Chap. 222) should be obtained promptly in patients with suspected CS to help define its etiology. Doppler mapping demonstrates a left-to-right shunt in patients with VSR and the severity of MR when the latter is present. Proximal aortic dissection with aortic regurgitation or tamponade may be visualized or evidence for pulmonary embolism obtained (Chap. 256).

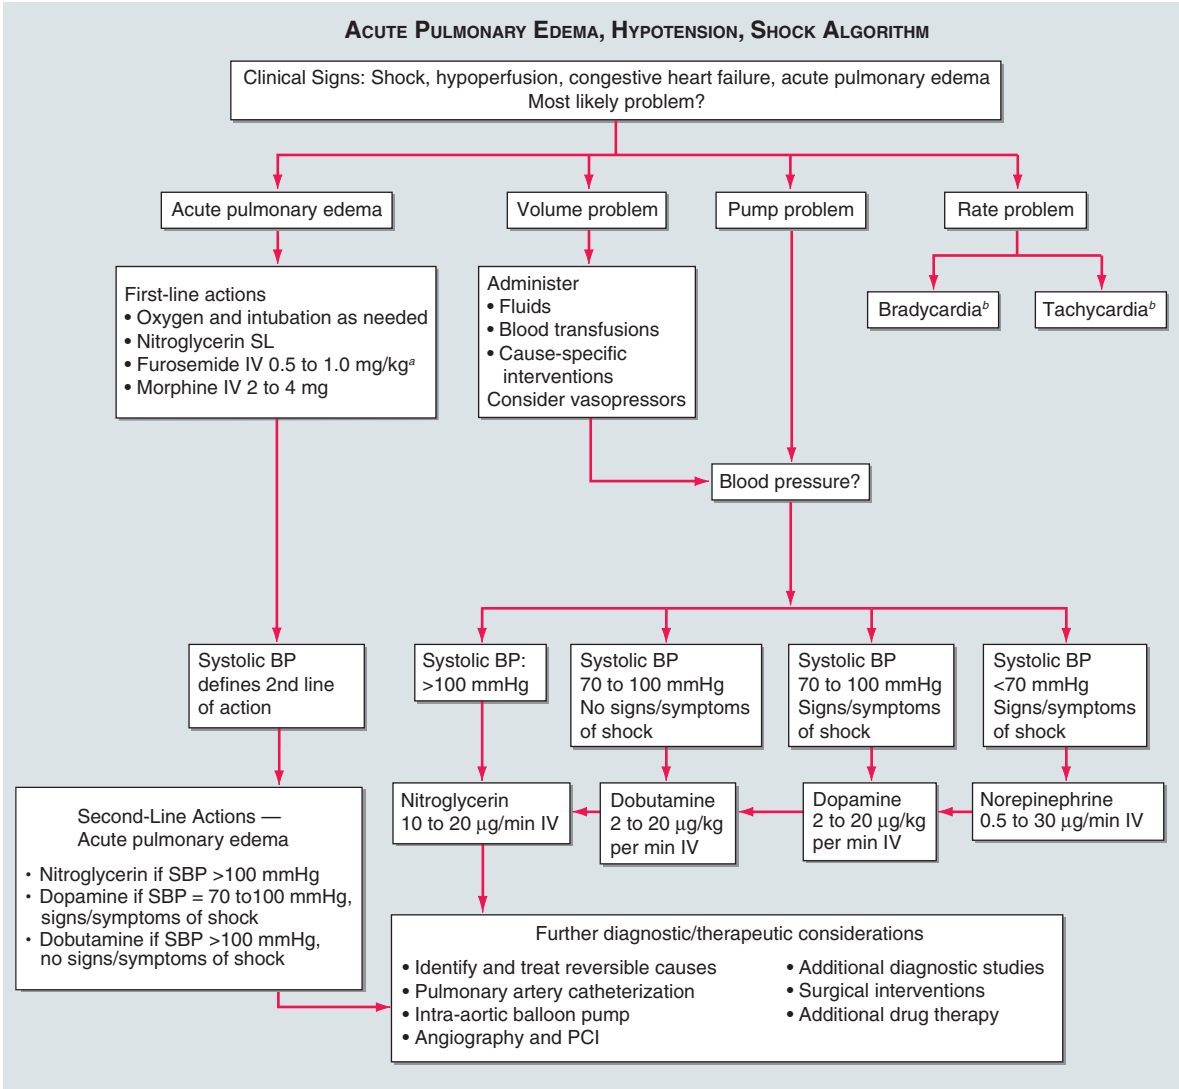

FIGURE 266-2 The emergency management of patients with cardiogenic shock, acute pulmonary edema, or both is outlined. [a]Furosemide: <0.5 mg/kg for new-onset acute pulmonary edema without hypervolemia; 1 mg/kg for acute on chronic volume overload, renal insufficiency. [b]For management of bradycardia and tachycardia, see Chaps. 225 and 226. ACE, angiotensin-converting enzyme; BP, blood pressure; MI, myocardial infarction. *[From J Fields et al (eds): Handbook of Emergency Cardiovascular Care for Healthcare Providers. Copyright 2006, American Heart Association, Inc. Reprinted with permission.]*

PULMONARY ARTERY CATHETERIZATION There is controversy regarding the use of pulmonary artery (Swan-Ganz) catheters in patients with established or suspected CS (Chaps. 223 and 261). However, their use is generally recommended for measurement of filling pressures and cardiac output to confirm the diagnosis and optimize use of IV fluids, inotropic agents, and vasopressors (Table 266-2). Blood samples for O_2 saturation measurement should be obtained from the right atrium, right ventricle, and pulmonary artery to rule out a left-to-right shunt. Mixed venous O_2 saturations are low and arterial-venous O_2 differences are elevated, reflecting low cardiac index and high fractional O_2 extraction. The PCWP is elevated. However, use of sympathomimetic amines may return these measurements and the systemic BP toward normal. Systemic vascular resistance may be low, normal, or elevated in CS. Equalization of right- and left-sided filling pressures (right atrial and PCWP) suggests cardiac tamponade as the cause of CS (Chap. 232).

LEFT HEART CATHETERIZATION AND CORONARY ANGIOGRAPHY Measurement of LV pressure, definition of the coronary anatomy, and left ventriculography provide useful information and are indicated in most patients with CS complicating MI. Because of the procedural risk in this critically ill population, cardiac catheterization should be performed when there is a plan and capability for immediate coronary intervention (see below) or when a definitive diagnosis has not been made by other tests.

℞ ACUTE MYOCARDIAL INFARCTION

GENERAL MEASURES (Fig. 266-2) In addition to the usual treatment of acute MI (Chap. 239), initial therapy is aimed at maintaining adequate systemic and coronary perfusion by raising systemic BP with vasopressors and adjusting volume status to a level that ensures optimum LV filling pressure. There is inter-patient variability, but the values that are generally associated with adequate perfusion are systolic BP of ~90 mmHg or mean BP > 60 mmHg and PCWP of ~20 mmHg. Hypoxemia and acidosis must be corrected; most patients require ventilatory support with either endotracheal intubation or bilevel positive airway pressure (Bi-PAP) to correct these abnormalities and reduce the work of breathing (see "Pulmonary Edema," below). Negative inotropic agents should be discontinued and the doses of renally cleared medications adjusted. Hyperglycemia should be corrected with continuous infusion of insulin. Bradyarrhythmias may require transvenous pacing. Recurrent ventricular tachycardia or rapid atrial fibrillation may require immediate treatment (Chap. 226).

TABLE 266-2 HEMODYNAMIC PATTERNS[a]

	RA, mmHg	RVS, mmHg	RVD, mmHg	PAS, mmHg	PAD, mmHg	PCW, mmHg	CI, (L/min)/m^2	SVR, (dyn · s)/cm^5

[a] There is significant patient-to-patient variation. Pressure may be normalized if cardiac output is low.

[b] Forrester et al classified non-reperfused MI patients into four hemodynamic subsets. (From Forrester JS et al: N Engl J Med 295:1356, 1976.) PCWP and CI in clinically stable subset 1 patients are shown. Values in parentheses represent range.

[c] "Isolated" or predominant RV failure.

[d] PCW and PA pressures may rise in RV failure after volume loading due to RV dilation, right-to-left shift of the interventricular septum, resulting in impaired LV filling. When biventricular failure is present, the patterns are similar to those shown for LV failure.

Note: RA, right atrium; RVS/D, right ventricular systolic/diastolic; PAS/D, pulmonary artery systolic/diastolic; PCW, pulmonary capillary wedge; CI, cardiac index; SVR, systemic vascular resistance; MI, myocardial infarction; P/SBF, pulmonary/systemic blood flow.

Source: Table prepared with the assistance of Krishnan Ramanathan, MD.

VASOPRESSORS Various IV drugs may be used to augment BP and cardiac output in patients with CS. All have important disadvantages, and none has been shown to change the outcome in patients with established shock. *Norepinephrine* is a potent vasoconstrictor and inotropic stimulant that increases myocardial O_2 consumption; it should be reserved for patients with CS and refractory hypotension, in particular those without elevated systemic vascular resistance. It should be started at a dosage of 2 to 4 μg/min and titrated upward as necessary. If systemic perfusion or systolic pressure cannot be maintained at >90 mmHg with a dosage of 15 μg/min, it is unlikely that a further increase will be beneficial.

Dopamine is useful in many patients; at low doses (≤ 2 μg/kg per min), it dilates the renal vascular bed; at moderate doses (2–10 μg/kg per min), it has positive chronotropic and inotropic effects as a consequence of β-adrenergic receptor stimulation. At higher doses, a vasoconstrictor effect results from α-receptor stimulation. It is started at an infusion rate of 2–5 μg/kg per min, and the dosage is increased every 2–5 min to a maximum of 20–50 μg/kg per min. *Dobutamine* is a synthetic sympathomimetic amine with positive inotropic action and minimal positive chronotropic activity at low doses (2.5 μg/kg per min), but moderate chronotropic activity at higher doses. Although the usual dosage is up to 10 μg/kg per min, its vasodilating activity precludes its use when a vasoconstrictor effect is required.

AORTIC COUNTERPULSATION In CS, mechanical assistance with an intraaortic balloon pumping (IABP) system capable of augmenting both arterial diastolic pressure and cardiac output is helpful in rapidly stabilizing patients. A sausage-shaped balloon is introduced percutaneously into the aorta via the femoral artery; the balloon is automatically inflated during early diastole, augmenting coronary blood flow. The balloon collapses in early systole, reducing the afterload against which the LV ejects. IABP improves hemodynamic status temporarily in most patients. In contrast to vasopressors and inotropic agents, myocardial O_2 consumption is reduced, ameliorating ischemia. IABP is useful as a stabilizing measure in patients with CS prior to and during cardiac catheterization and percutaneous coronary intervention (PCI) or prior to urgent surgery. IABP is contraindicated if aortic regurgitation is present or aortic dissection is suspected. Ventricular assist devices may be considered for eligible young patients with refractory shock as a bridge to cardiac transplantation (Chap. 228).

REPERFUSION-REVASCULARIZATION The rapid establishment of blood flow in the infarct-related artery is essential in the management of CS and forms the centerpiece of management. The randomized SHOCK Trial demonstrated 132 lives saved per 1000 patients treated with early revascularization with PCI or coronary artery bypass graft (CABG) compared to initial medical therapy including IABP with fibrinolytics followed by delayed revascularization **(Fig. 266-3)**. The benefit is seen across the risk strata and is sustained up to 11 years post MI. Early revascularization with PCI or CABG is a class I recommendation for patients age <75 years with ST elevation or left bundle branch block MI who develop CS within 36 h of MI and who can be revascularized within 18 h of development of CS. When mechanical revascularization is not possible, IABP and fibrinolytic therapy are recommended. Older patients who are suitable candidates for aggressive care should also be offered early revascularization.

Prognosis Within this high-risk condition, there is a wide range of expected death rates based on age, severity of hemodynamic abnormalities, severity of the clinical manifestations of hypoperfusion, and the performance of early revascularization. Independent risk factors are advanced age; depressed cardiac index, ejection fraction, and BP; more extensive coronary artery disease; and renal insufficiency.

SHOCK SECONDARY TO RIGHT VENTRICULAR INFARCTION

Although transient hypotension is common in patients with RV infarction and inferior MI (Chap. 239), persistent CS due to RV failure accounts for only 3% of CS complicating MI. The salient features of RV shock are absence of pulmonary congestion, high right atrial pressure (which may be seen only after volume loading), RV dilatation and dysfunction, only mildly or moderately depressed LV function, and predominance of single-vessel proximal right coronary artery occlusion. Management includes IV fluid administration to optimize right

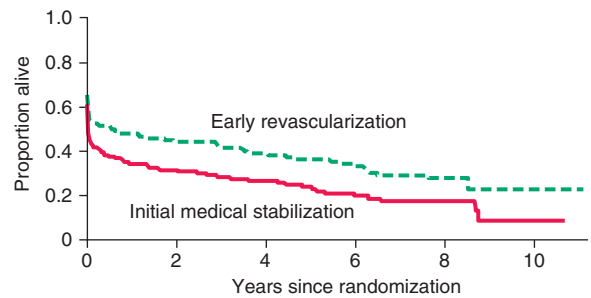

FIGURE 266-3 Early revascularization (ERV) (percutaneous coronary intervention or coronary artery bypass graft) for cardiogenic shock complicating acute myocardial infarction resulted in substantially improved 1-year and long-term survival compared to initial mechanical stabilization (IMS), including intraaortic balloon pumping and fibrinolytic agents, followed by selective delayed revascularization in the SHOCK Trial (SHould we emergently revascularize Occluded coronaries for Cardiogenic shocK?). *(From JS Hochman et al: JAMA 295:2511–2515, 2006; reprinted with permission from JAMA.)*

atrial pressure (10–15 mmHg); avoidance of excess fluids, which cause a shift of the interventricular septum into the LV; sympathomimetic amines; IABP; and the early reestablishment of infarct-artery flow.

MITRAL REGURGITATION

(See also Chap. 239) Acute severe MR due to papillary muscle dysfunction and/or rupture may complicate MI and result in CS and/or pulmonary edema. This complication most often occurs on the first day, with a second peak several days later. The diagnosis is confirmed by echo-Doppler. Rapid stabilization with IABP is recommended, with administration of dobutamine as needed to raise cardiac output. Reducing the load against which the LV pumps (afterload) reduces the volume of regurgitant flow of blood into the left atrium. Mitral valve surgery is the definitive therapy and should be performed early in the course in suitable candidates.

VENTRICULAR SEPTAL RUPTURE

(See also Chap. 239) Echo-Doppler demonstrates shunting of blood from the left to the right ventricle and may visualize the opening in the interventricular septum. Timing and management are similar to that for MR with IABP support and surgical correction for suitable candidates.

FREE WALL RUPTURE

Myocardial rupture is a dramatic complication of STEMI that is most likely to occur during the first week after the onset of symptoms; its frequency increases with the age of the patient. First infarction, a history of hypertension, no history of angina pectoris, and a relatively large Q-wave infarct are associated with a higher incidence of cardiac rupture. The clinical presentation typically is a sudden loss of pulse, blood pressure, and consciousness but sinus rhythm on ECG (pulseless electrical activity). The myocardium continues to contract, but forward flow is not maintained as blood escapes into the pericardium. Cardiac tamponade (Chap. 232) ensues, and closed-chest massage is ineffective. This condition is almost universally fatal, although dramatic cases of urgent pericardiotensis followed by successful surgical repair have been reported. Free wall rupture may also result in subacute tamponade when the pericardium temporarily seals the rupture sites. Definitive surgical repair is required.

ACUTE FULMINANT MYOCARDITIS

(See also Chap. 231) Myocarditis can mimic acute MI with ST deviation or bundle branch block on the ECG and marked elevation of cardiac markers. Acute myocarditis causes CS in ~15% of cases. These patients are typically younger than those with CS due to acute MI and often do not have typical ischemic chest pain. Echocardiography usually shows global LV dysfunction. Initial management is the same as for CS complicating acute MI (Fig. 266-2) but of course does not involve coronary revascularization.

PULMONARY EDEMA

The etiologies and pathophysiology of pulmonary edema are discussed in Chap. 33.

Diagnosis Acute pulmonary edema usually presents with the rapid onset of dyspnea at rest, tachypnea, tachycardia, and severe hypoxemia. Rales and wheezing due to airway compression from peribronchial cuffing may be audible. Hypertension is usually present due to release of endogenous catecholamines.

It is often difficult to distinguish cardiogenic and noncardiogenic causes of acute pulmonary edema. *Echocardiography* may identify systolic and diastolic ventricular dysfunction and valvular lesions. Pulmonary edema associated with electrocardiographic ST elevation and evolving Q waves is usually diagnostic of acute MI and should prompt immediate institution of MI protocols and coronary artery reperfusion therapy (Chap. 239). Brain natriuretic peptide levels, when substantially elevated, support heart failure as the etiology of acute dyspnea with pulmonary edema (Chap. 227).

The use of a *Swan-Ganz catheter* permits measurement of PCWP and helps differentiate high pressure (cardiogenic) and normal pressure (noncardiogenic) causes of pulmonary edema. Pulmonary artery catheterization is indicated when the etiology of the pulmonary edema is uncertain, when it is refractory to therapy, or when it is accompanied by hypotension. Data derived from use of a catheter often alters the treatment plan, but impact on mortality has not been demonstrated.

Rx PULMONARY EDEMA

The treatment of pulmonary edema depends upon the specific etiology. Given the acute, life-threatening nature of the condition, a number of measures must be applied immediately to support the circulation, gas exchange, and lung mechanics. In addition, conditions that frequently complicate pulmonary edema, such as infection, acidemia, anemia, and renal failure, must be corrected.

SUPPORT OF OXYGENATION AND VENTILATION Patients with acute cardiogenic pulmonary edema generally have an identifiable cause of acute LV failure such as arrhythmia, ischemia/infarction, or myocardial decompensation (Chap. 227) that can be rapidly treated, with improvement in gas exchange. In contrast, noncardiogenic edema usually resolves much less quickly, and most patients require mechanical ventilation.

Oxygen Therapy Support of oxygenation is essential to ensure adequate O_2 delivery to peripheral tissues, including the heart.

Positive-Pressure Ventilation Pulmonary edema increases the work of breathing and the O_2 requirements of this work and may pose a significant physiologic stress on the heart. For patients with inadequate oxygenation or ventilation in spite of supplemental O_2, assisted ventilation by face or nasal mask or by endotracheal intubation should be initiated. Continuous or bilevel positive airway pressure (Chap. 263) can rest the respiratory muscles, improve oxygenation and cardiac function, and reduce the need for intubation. In refractory cases, mechanical ventilation can relieve the work of breathing more completely than noninvasive ventilation. Mechanical ventilation with positive end-expiratory pressure can have multiple beneficial effects on pulmonary edema: (1) it can decrease both preload and afterload, thereby improving cardiac function; (2) it can redistribute lung water from the intraalveolar to the extraalveolar space where the fluid does not interfere as much with gas exchange; and (3) it can increase lung volume to avoid atelectasis.

REDUCTION OF PRELOAD In most forms of pulmonary edema, the quantity of extravascular lung water is related to both the PCWP and the intravascular volume status.

Diuretics The "loop diuretics" furosemide, bumetanide, and torsemide are effective in most forms of pulmonary edema, even in the presence of hypoalbuminemia, hyponatremia, or hypochloremia. Furosemide is also a venodilator that can reduce preload rapidly, prior to any diuresis, and is the diuretic of choice. The initial dose of furosemide should be ≤ 0.5 mg/kg, but a higher dose (1 mg/kg) is required in patients with renal insufficiency, chronic diuretic use, or hypervolemia or after failure of a lower dose.

Nitrates Nitroglycerin and isosorbide dinitrate act predominantly as venodilators, with coronary vasodilating properties as well. They are rapid in onset and effective when administered by a variety of routes. Sublingual nitroglycerin (0.4 mg × 3 every 5 min) is first-line therapy for acute cardiogenic pulmonary edema. If pulmonary edema persists in the absence of hypotension, sublingual may be followed by IV nitroglycerin, commencing at 5–10 μg/min. IV nitroprusside (0.1–5 μg/kg per min) is a potent venous and arterial vasodilator. It is useful for patients with pulmonary edema and hypertension, but is not recommended in states of reduced coronary artery perfusion. It requires close monitoring and titration, including the use of an arterial catheter for continuous BP measurement in the intensive care unit.

Morphine Given in 2- to 4-mg IV boluses, morphine is a transient venodilator that reduces preload while relieving dyspnea and anxiety. These effects can diminish stress, catecholamine levels, tachycardia, and ventricular afterload in patients with pulmonary edema and systemic hypertension.

Angiotensin-Converting Enzyme (ACE) Inhibitors ACE inhibitors reduce both afterload and preload and are recommended in hypertensive

patients. A low dose of a short-acting agent may be initiated and followed by increasing oral doses. In acute MI with heart failure, ACE inhibitors reduce short- and long-term mortality.

Other Preload-Reducing Agents IV recombinant brain natriuretic peptide (nesiritide) is a potent vasodilator with diuretic properties and is effective in the treatment of cardiogenic pulmonary edema. It should be reserved for refractory patients and is not recommended in the setting of ischemia or MI.

Physical Methods Reduction of venous return reduces preload. Patients without hypotension should be maintained in the sitting position with the legs dangling along the side of the bed.

Inotropic and Inodilator Drugs The sympathomimetic amines dopamine and dobutamine (see above) are potent inotropic agents. The bipyridine phosphodiesterase-3 inhibitors (inodilators), such as milrinone (50 μg/kg followed by 0.25–0.75 μg/kg per min), stimulate myocardial contractility while promoting peripheral and pulmonary vasodilation. Such agents are indicated in patients with cardiogenic pulmonary edema and severe LV dysfunction.

Digitalis Glycosides Once a mainstay of treatment because of their positive inotropic action (Chap. 227), digitalis glycosides are rarely used at present. However, they may be useful for control of ventricular rate in patients with rapid atrial fibrillation or flutter and LV dysfunction, since they do not have the negative inotropic effects of other drugs that inhibit atrioventricular nodal conduction.

Intraaortic Counterpulsation IABP may help to relieve cardiogenic pulmonary edema. It is indicated as a stabilizing measure when acute severe mitral regurgitation or ventricular septal rupture causes refractory pulmonary edema, especially in preparation for surgical repair. IABP or LV-assist devices (Chap. 228) are useful as bridging therapy to cardiac transplantation in patients with refractory pulmonary edema secondary to myocarditis or cardiomyopathy.

Treatment of Tachyarrhythmias and Atrial-Ventricular Resynchronization (See also Chap. 226) Sinus tachycardia or atrial fibrillation can result from elevated left atrial pressure and sympathetic stimulation. Tachycardia itself can also limit LV filling time and raise left atrial pressure further. While relief of pulmonary congestion will slow the sinus rate or ventricular response in atrial fibrillation, a primary tachyarrhythmia may require cardioversion. In patients with reduced LV function and without atrial contraction or with lack of synchronized atrioventricular contraction, placement of an atrioventricular sequential pacemaker should be considered (Chap. 225).

Stimulation of Alveolar Fluid Clearance Recent mechanistic studies on alveolar epithelial ion transport have defined a variety of ways to upregulate the clearance of solute and water from the alveolar space. In patients with acute lung injury (noncardiogenic pulmonary edema) IV β-adrenergic agonist treatment decreases extravascular lung water.

SPECIAL CONSIDERATIONS The Risk of Iatrogenic Cardiogenic Shock In the treatment of pulmonary edema vasodilators lower BP, and, particularly when used in combination, their use may lead to hypotension, coronary artery hypoperfusion, and shock (Fig. 266-1). In general, patients with a *hypertensive* response to pulmonary edema tolerate and are benefited by these medications. In normotensive patients, low doses of single agents should be instituted sequentially, as needed.

Acute Coronary Syndromes (See also Chap. 239) Acute STEMI complicated by pulmonary edema is associated with in-hospital mortality rates of 20–40%. After immediate stabilization, coronary artery blood flow must be reestablished rapidly. When available, primary PCI is preferable; alternatively, a fibrinolytic agent should be administered. Early coronary angiography and revascularization by PCI or CABG are also indicated for patients with non-ST elevation acute coronary syndrome. IABP use may be required to stabilize patients for coronary angiography if hypotension develops or for refractory pulmonary edema in patients with LV failure who are candidates for revascularization.

Unusual Types of Edema Specific etiologies of pulmonary edema may require particular therapy. Reexpansion pulmonary edema can develop after removal of air or fluid that has been in the pleural space for some time. These patients may develop hypotension or oliguria resulting from rapid fluid shifts into the lung. In contrast to cardiogenic edema, diuretics and preload reduction are contraindicated, and intravascular volume repletion is often needed while supporting oxygenation and gas exchange.

High-altitude pulmonary edema can often be prevented by use of dexamethasone, calcium channel-blocking drugs, or long-acting inhaled β_2-adrenergic agonists. Treatment includes descent from altitude, bed rest, oxygen, and, if feasible, inhaled nitric oxide; nifedipine may also be effective.

For pulmonary edema resulting from upper airway obstruction, recognition of the obstructing cause is key, since treatment then is to relieve or bypass the obstruction.

267 Cardiovascular Collapse, Cardiac Arrest, and Sudden Cardiac Death

Robert J. Myerburg, Agustin Castellanos

OVERVIEW AND DEFINITIONS

The vast majority of naturally occurring sudden deaths are caused by cardiac disorders. The magnitude of sudden *cardiac* death (SCD) as a public health problem is highlighted by the estimate that ~50% of all cardiac deaths are sudden and unexpected, at least two-thirds of which are first cardiac events or occur among population subsets with previously known heart disease considered to be relatively low risk. The total SCD burden is estimated to range from <200,000 to >450,000 deaths each year in the United States. SCD is a direct consequence of cardiac arrest, which may be reversible if responded to promptly. Since resuscitation techniques and emergency rescue systems are available to respond to victims of out-of-hospital cardiac arrest, which was uniformly fatal in the past, understanding the SCD problem has practical importance.

SCD must be defined carefully. In the context of time, "sudden" is defined, for most clinical and epidemiologic purposes, as 1 h or less

TABLE 267-1 DISTINCTION BETWEEN CARDIOVASCULAR COLLAPSE, CARDIAC ARREST, AND DEATH

Term	Definition	Qualifiers or Exceptions
Cardiovascular collapse	A sudden loss of effective blood flow due to cardiac and/or peripheral vascular factors which may reverse spontaneously (e.g., neurocardiogenic syncope; vasovagal syncope) or only with interventions (e.g., cardiac arrest)	Nonspecific term that includes cardiac arrest and its consequences and also events that characteristically revert spontaneously
Cardiac arrest	Abrupt cessation of cardiac pump function which may be reversible by a prompt intervention but will lead to death in its absence	Rare spontaneous reversions; likelihood of successful interventions relates to mechanism of arrest, clinical setting, and prompt return of circulation
Death	Irreversible cessation of all biologic functions	None

between a change in clinical status heralding the onset of the terminal clinical event and the cardiac arrest itself. An exception is unwitnessed deaths in which pathologists may expand the definition of time to 24 h after the victim was last seen to be alive and stable.

Because of community-based interventions, victims may remain biologically alive for days or even weeks after a cardiac arrest that has resulted in irreversible central nervous system damage. Confusion in terms can be avoided by adhering strictly to definitions of cardiovascular collapse, cardiac arrest, and death (Table 267-1). Death is biologically, legally, and literally an absolute and irreversible event. Death may be delayed in a survivor of cardiac arrest, but "survival after sudden death" is an irrational term. A generally accepted definition of SCD is *natural death due to cardiac causes*, heralded by abrupt loss of consciousness within *1 h* of the onset of acute symptoms, in an individual who may have known *preexisting* heart disease but in whom the *time* and *mode* of death are *unexpected*. When biologic death of the cardiac arrest victim is delayed because of interventions, the relevant pathophysiologic event remains the sudden and unexpected cardiac arrest that leads ultimately to death, even though delayed by artificial methods. The language used should reflect the fact that the index event was a cardiac arrest and that death was due to its delayed consequences. Accordingly, for statistical purposes, deaths that occur during hospitalization or within 30 days after resuscitated cardiac arrest are counted as sudden deaths.

CLINICAL DEFINITION OF FORMS OF CARDIOVASCULAR COLLAPSE

Cardiovascular collapse is a general term connoting loss of effective blood flow due to acute dysfunction of the heart and/or peripheral vasculature. Cardiovascular collapse may be caused by vasodepressor syncope (vasovagal syncope, postural hypotension with syncope, neurocardiogenic syncope; Chap. 21), a transient severe bradycardia, or cardiac arrest. The latter is distinguished from the transient forms of cardiovascular collapse in that it usually requires an intervention to achieve resuscitation. In contrast, vasodepressor syncope and other primary bradyarrhythmic syncopal events are transient and non-life-threatening, with spontaneous return of consciousness.

The most common electrical mechanism for cardiac arrest is ventricular fibrillation (VF), which is responsible for 50–80% of cardiac arrests. Severe persistent bradyarrhythmias, asystole, and pulseless electrical activity (PEA; an organized electrical activity without mechanical response, formerly called electromechanical dissociation) cause another 20–30%. Pulseless sustained ventricular tachycardia (VT) is a less-common mechanism. Acute low cardiac output states, having precipitous onset, may also present clinically as a cardiac arrest. These hemodynamic causes include massive acute pulmonary emboli, internal blood loss from ruptured aortic aneurysm, intense anaphylaxis, and cardiac rupture with tamponade after myocardial infarction (MI).

ETIOLOGY, INITIATING EVENTS, AND CLINICAL EPIDEMIOLOGY

Clinical and epidemiologic studies have identified population subgroups at high risk for SCD. In addition, a large body of pathologic data provides information on the underlying *structural abnormalities* in victims of SCD, and studies of clinical physiology have begun to identify a group of *transient functional factors* that may convert a long-standing underlying structural abnormality from a stable to an unstable state (Table 267-2).

Cardiac disorders constitute the most common causes of sudden *natural* death. After an initial peak incidence of sudden death between birth and 6 months of age (the sudden infant death syndrome), the incidence of sudden death declines sharply and remains low through childhood and adolescence. Among adolescents and young adults, the incidence of SCD is approximately 1 per 100,000 population per year. The incidence begins to increase in adults over the age of 30 years, reaching a second peak in the age range of 45–75 years, when the incidence approximates 1–2 per 1000 per year among the unselected adult population. Increasing age within this range is associated with increasing risk for sudden *cardiac* death (Fig. 267-1*A*). From 1 to 13 years of age, only one of five sudden *natural* deaths is due to cardiac causes. Between 14 and 21 years of age, the proportion increases to 30%, and then to 88% in the middle aged and elderly.

TABLE 267-2 CARDIAC ARREST AND SUDDEN CARDIAC DEATH

Structural Causes

- I. Coronary heart disease
  - A. Coronary artery abnormalities
    - 1. Chronic atherosclerotic lesions
    - 2. Acute (active) lesions (plaque fissuring, platelet aggregation, acute thrombosis)
    - 3. Anomalous coronary artery anatomy
  - B. Myocardial infarction
    - 1. Healed
    - 2. Acute
- II. Myocardial hypertrophy
  - A. Secondary
  - B. Hypertrophic cardiomyopathy
    - 1. Obstructive
    - 2. Nonobstructive
- III. Dilated cardiomyopathy—primary muscle disease
- IV. Inflammatory and infiltrative disorders
  - A. Myocarditis
  - B. Noninfectious inflammatory diseases
  - C. Infiltrative diseases
  - D. Right ventricular dysplasia
- V. Valvular heart disease
- VI. Electrophysiologic abnormalities, structural
  - A. Anomalous pathways in Wolff-Parkinson-White syndrome
  - B. Conducting system disease
- VII. Inherited disorders of molecular structure associated with electrophysiologic abnormalities (e.g., congenital long QT syndromes, Brugada syndrome)

Functional Contributing Factors

- I. Alterations of coronary blood flow
  - A. Transient ischemia
  - B. Reperfusion after ischemia
- II. Low cardiac output states
  - A. Heart failure
    - 1. Chronic
    - 2. Acute decompensation
  - B. Shock
- III. Systemic metabolic abnormalities
  - A. Electrolyte imbalance (e.g., hypokalemia)
  - B. Hypoxemia, acidosis
- IV. Neurophysiologic disturbances
  - A. Autonomic fluctuations: central, neural, humoral
  - B. Receptor function
- V. Toxic responses
  - A. Proarrhythmic drug effects
  - B. Cardiac toxins (e.g., cocaine, digitalis intoxication)
  - C. Drug interactions

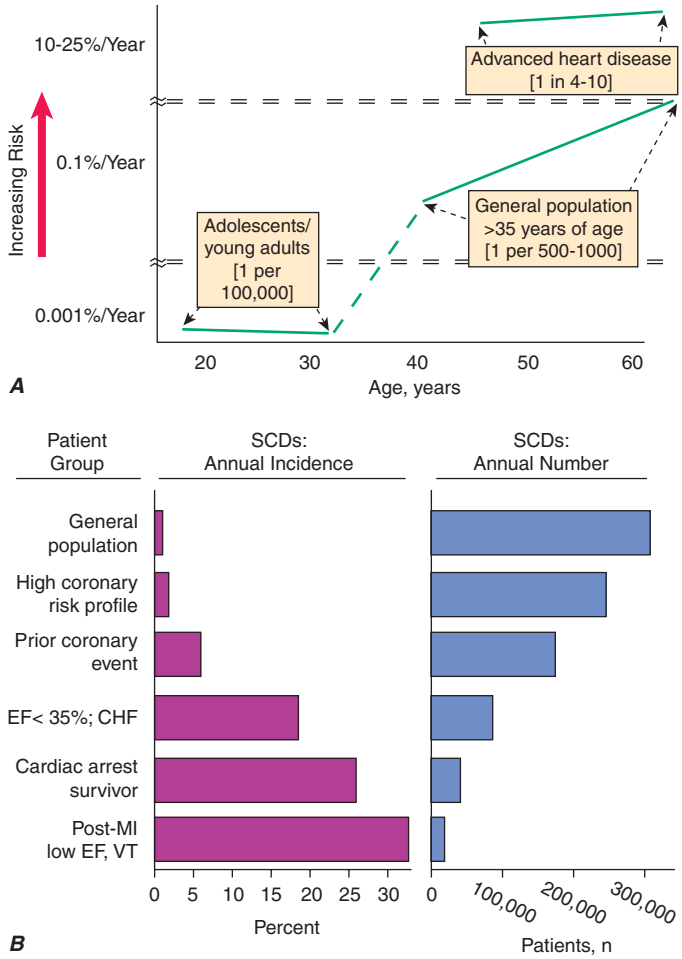

FIGURE 267-1 ***Panel A*** **demonstrates age-related risk for SCD.** For the general population age 35 years and older, SCD risk is 0.1–0.2 percent per year (1 per 500–1,000 population). Among the general population of adolescents and adults younger than the age of 30 years, the overall risk of SCD is 1 per 100,000 population, or 0.001 percent per year. The risk of SCD increases dramatically beyond the age of 35 years. The greatest rate of increase is between 40 and 65 years (vertical axis is discontinuous). Among patients older than 30 years of age, with advanced structural heart disease and markers of high risk for cardiac arrest, the event rate may exceed 25% per year, and age-related risk attenuates. ***Panel B*** **demonstrates the incidence of SCD in population subgroups** and the relation of total number of events per year to incidence figures. Approximations of subgroup incidence figures and the related population pool from which they are derived are presented. Approximately 50% of all cardiac deaths are sudden and unexpected. The incidence triangle on the left ("Percent/Year") indicates the approximate percentage of sudden and nonsudden deaths in each of the population subgroups indicated, ranging from the lowest percentage in unselected adult populations (0.1–2% per year) to the highest percentage in patients with VT or VF during convalescence after an MI (approximately 50% per year). The triangle on the right indicates the total number of events per year in each of these groups, to reflect incidence in context with the size of the population subgroups. The highest risk categories identify the smallest number of total annual events, and the lowest incidence category accounts for the largest number of events per year. EF, ejection fraction; VT, ventricular tachycardia; VF, ventricular fibrillation; MI, myocardial infarction. *[After RJ Myerburg et al, Circulation 85(Suppl 1):2, 1992. Reproduced with permission of the American Heart Association.]*

Young and middle aged men and women have different susceptibilities to SCD, but the gender differences decrease with advancing age. The difference in risk for SCD parallels the differences in age-related risks for other manifestations of coronary heart disease (CHD) between men and women. As the gender gap for manifestations of CHD closes in the sixth to eighth decades of life, the excess risk of SCD in males progressively narrows. Despite the lower incidence among younger women, coronary risk factors such as cigarette smoking, diabetes, hyperlipidemia, and hypertension are highly influential, and SCD remains an important clinical and epidemiologic problem. The incidence of SCD among the African-American population appears to be higher than among the white population; the reasons remain uncertain.

Genetic factors contribute to the risk of SCD. In one sense, they contribute to familial predisposition to CHD and its expression as acute coronary syndromes. In addition, however, there are data suggesting a familial predisposition to SCD as a specific form of expression of CHD. A strong parental history of SCD as an initial coronary event increases the probability of a similar expression in the offspring. In a few syndromes, such as hypertrophic cardiomyopathy, congenital long QT interval syndromes, right ventricular dysplasia, and the syndrome of right bundle branch block and nonischemic ST-segment elevations (Brugada syndrome), there is a specific inherited risk of SCD (Chap. 226).

The structural causes of and functional factors contributing to the SCD syndrome are listed in Table 267-2. Worldwide, and especially in western cultures, coronary atherosclerotic heart disease is the most common structural abnormality associated with SCD in middle-aged and older adults. Up to 80% of all SCDs in the United States are due to the consequences of coronary atherosclerosis. The cardiomyopathies (dilated and hypertrophic, collectively; Chap. 231) account for another 10–15% of SCDs, and all the remaining diverse etiologies cause only 5–10% of all SCDs. The inherited arrhythmia syndromes (see above and Table 267-2) are more common causes in adolescents and young adults. For some of these syndromes, such as hypertrophic cardiomyopathy (Chap. 231), risk of SCD begins to increase after puberty.

Transient ischemia in the previously scarred or hypertrophied heart, hemodynamic and fluid and electrolyte disturbances, fluctuations in autonomic nervous system activity, and transient electrophysiologic changes caused by drugs or other chemicals (e.g., proarrhythmia) have all been implicated as mechanisms responsible for the transition from electrophysiologic stability to instability. In addition, reperfusion of ischemic myocardium may cause transient electrophysiologic instability and arrhythmias.

PATHOLOGY

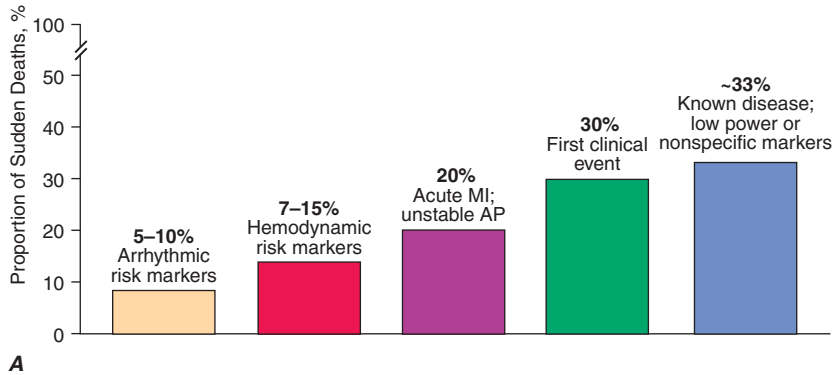
Data from postmortem examinations of SCD victims parallel the clinical observations on the prevalence of CHD as the major structural etiologic factor. More than 80% of SCD victims have pathologic findings of CHD. The pathologic description often includes a combination of long-standing, extensive atherosclerosis of the epicardial coronary arteries and unstable coronary artery lesions, which include various permutations of fissured or ruptured plaques, platelet aggregates, hemorrhage, and/or thrombosis. As many as 70–75% of males who die suddenly have preexisting healed MIs, while only 20–30% have recent acute MIs, despite the prevalence of unstable plaques and thrombi. The latter suggests transient ischemia as the mechanism of onset. Regional or global left ventricular (LV) hypertrophy often coexists with prior MIs.

PREDICTION AND PREVENTION OF CARDIAC ARREST AND SUDDEN CARDIAC DEATH

SCD accounts for approximately one-half the total cardiovascular mortality rate. As shown in Fig. 267-1*B*, the very-high-risk subgroups provide more focused populations ("percent per year") for predicting cardiac arrest or SCD; but the impact of such subgroups on the overall problem of SCD, indicated by the absolute number of events ("events per year"), is relatively small. The requirements for achieving a major population impact are effective prevention of underlying diseases and/or new epidemiologic probes that will allow better resolution of subgroups at specific risk within the large general populations.

Strategies for predicting and preventing SCD are categorized as primary and secondary, in addition to responses intended to abort cardiac arrests. *Primary prevention*, as defined in various implantable defibrillator trials, refers to the attempt to identify individual patients

at specific risk for SCD and institute preventive strategies. *Secondary prevention* refers to measures taken to prevent recurrent cardiac arrest or death in individuals who have survived a previous cardiac arrest. The primary prevention strategies currently used depend upon magnitude of risk among the various population subgroups. Because the annual incidence of SCD among the unselected adult population is limited to 1–2 per 1000 population per year (Fig. 267-1), and more than 30% of all SCDs due to coronary artery disease occur as the first clinical manifestation of the disease (Fig. 267-2*A*), the only practical strategies are profiling for risk of developing CHD and risk factor control (Fig. 267-2*B*). The most powerful long-term risk factors include age, cigarette smoking, elevated serum cholesterol, diabetes mellitus, elevated blood pressure, LV hypertrophy, and nonspecific electrocardiographic abnormalities. Markers of inflammation (e.g., C-reactive protein levels) that may predict plaque destabilization, have been added to risk classifications. The presence of multiple risk factors progressively increases incidence, but not sufficiently or specifically enough to warrant therapies targeted to potentially fatal arrhythmias (Fig. 267-1*A*). However, recent studies offer the hope that genetic markers for specific risk may become available. These studies suggest that a family history of SCD associated with acute coronary syndromes predicts a higher likelihood of cardiac arrest as the initial manifestation of coronary artery disease in first-degree family members.



A

Target	*Examples*	*Goal*	*Sensitivity*
• ASHD risk factors	• Framingham risk index	• Predict evolution of disease	• Very low
• Anatomic screening	• Electron beam tomography	• Identify CAD	• Very low
• Clinical markers	• EF; angiography	• Define extent of disease	• Variable; extent of disease; low specificity
	• EPS	• Identify arrhythmia markers	• Low-to-intermediate for screening
	• EPS combined with EF	• Define high risk groups	• High for specific groups
• Transient risk predictors	• T-wave alternans; QT dispersions	• EKG markers of risk	• Primary predictive value unknown
	• Pathophysiologic controls (e.g., HRV)	• Quantify autonomic regulation	• Uncertain; some measures useful(?)
	• Inflammatory markers	• Predict unstable plaques	• Unknown; potentially high
• Individual risk predictors	• Familial/genetic profiles	• Predict specific SCD risk before disease expression	• High potential for future profiling

B

FIGURE 267-2 Population subsets, risk predictors, and distribution of sudden cardiac deaths (SCDs) according to clinical circumstances. *A.* The population subset with high-risk arrhythmia markers in conjunction with low ejection fraction is a group at high risk of SCD but accounts for <10% of the total SCD burden attributable to coronary artery disease. In contrast, nearly two-thirds of all SCD victims present with SCD as the first and only manifestation of underlying disease or have known disease but are considered relatively low-risk because of the absence of high-risk markers. ***B.*** Risk profile for prediction and prevention of SCD is difficult. The highest absolute numbers of events occur among the general population who may have risk factors for coronary heart disease or expressions of disease that do not predict high risk. This results in a low sensitivity for predicting and preventing SCD. New approaches that include epidemiologic modeling of transient risk factors and methods of predicting individual patient risk offer hope for greater sensitivity in the future. AP, angina pectoris; ASHD, arteriosclerotic heart disease; CAD, coronary artery disease; EPS, electrophysiologic study; HRV, heart rate variability. *(From Myerburg, reproduced with permission of the publisher.)*

After coronary artery disease has been identified in a patient, additional strategies for risk profiling become available (Fig. 267-2*B*), but the majority of SCDs occur among the large unselected groups rather than in the specific high-risk subgroups that become evident among populations with established disease (compare events per year with percent per year in Fig. 267-1*B*). Under most conditions of higher level of risk, particularly those indexed to a major recent cardiovascular event (e.g., MI, recent onset of heart failure, survival after out-of-hospital cardiac arrest), the highest risk of death occurs during the initial 6–18 months and then plateaus toward the baseline risk of the underlying disease. However, many of the early deaths are nonsudden, diluting the potential benefit of strategies targeted specifically to SCD. Thus, even though post-myocardial infarction beta-blocker therapy has an identifiable benefit for both early SCD and nonsudden mortality risk, a total mortality benefit for ICD therapy early after MI has not been observed.

Among patients in the acute, convalescent, and chronic phases of myocardial infarction (Chap. 239), subgroups at high absolute risk of SCD can be identified. During the acute phase, the potential risk of cardiac arrest from onset through the first 48 hours may be as high as 15%, emphasizing the importance for patients to respond promptly to the onset of symptoms. Those who survive acute-phase VF, however, are not at continuing risk for recurrent cardiac arrest indexed to that event. During the convalescent phase after MI (3 days to ~6 weeks), an episode of sustained VT or VF, associated with a large infarct, predicts a natural history mortality risk of up to 50% at 12 months. At least 50% of the deaths are sudden. Aggressive intervention techniques may reduce this incidence.

After passage into the chronic phase of MI, the longer-term risk for total and SCD mortality is predicted by a number of factors (Fig. 267-2*B*). The most important for both SCD and nonsudden death is the extent of myocardial damage sustained as a result of the acute MI. This is measured by the magnitude of reduction of the ejection fraction (EF), functional capacity, and/or the occurrence of heart failure. Various studies have demonstrated that ventricular arrhythmias identified by ambulatory monitoring contribute significantly to this risk, especially in patients with an EF <40%. In addition, inducibility of VT or VF during electrophysiologic testing of patients who have ambient ventricular arrhythmias [premature ventricular contractions (PVCs) and nonsustained VT] and an EF < 35 or 40% is a strong predictor of SCD risk. Patients in this subgroup are now considered candidates for implantable cardioverter defibrillators (ICDs) (see below). Risk falls off sharply with EFs >40% after MI and the absence of ambient arrhythmias, and conversely is high with EFs <30% even without the ambient arrhythmia markers.

The cardiomyopathies (dilated and hypertrophic, Chap. 231) are the second most common category of diseases associated with risk of SCD,

following CHD (Table 267-2). Some risk factors have been identified, largely related to extent of disease, documented ventricular arrhythmias, and symptoms of arrhythmias (e.g., unexplained syncope). The less common causes of SCD include valvular heart disease (primarily aortic), and inflammatory and infiltrative disorders of the myocardium. The latter include viral myocarditis, sarcoidosis, and amyloidosis.

Among adolescents and young adults, rare inherited disorders, such as hypertrophic cardiomyopathy, the long QT interval syndromes, right ventricular dysplasia, and the Brugada syndrome, have received attention as important causes of SCD because of advances in genetics and the ability to identify some of those at risk before a fatal event. The subgroup of young competitive athletes has received special attention. The incidence of SCD among athletes appears to be higher than the general adolescent and young adult population, perhaps up to 1 in 75,000. Hypertrophic cardiomyopathy (Chap. 231) is the most common cause in the United States, compared to Italy, where more comprehensive screening programs remove potential victims from the population of athletes.

Secondary prevention strategies should be applied to surviving victims of a cardiac arrest that was not associated with an acute MI or a transient risk of SCD (e.g., drug exposures, correctable electrolyte imbalances). Multivessel coronary artery disease or dilated cardiomyopathy with left ventricular EF <40% or the presences of life-threatening arrhythmias with long QT syndromes or right ventricular dysplasia predict a 1–2-year risk of recurrence of a SCD or cardiac arrest of up to 30% in the absence of specific interventions (see below).

CLINICAL CHARACTERISTICS OF CARDIAC ARREST

PRODROME, ONSET, ARREST, DEATH

SCD may be presaged by days, weeks, or months of increasing angina, dyspnea, palpitations, easy fatigability, and other nonspecific complaints. However, these *prodromal complaints* are generally predictive of any major cardiac event; they are not specific for predicting SCD.

The *onset of the clinical transition*, leading to cardiac arrest, is defined as an acute change in cardiovascular status preceding cardiac arrest by up to 1 h. When the onset is instantaneous or abrupt, the probability that the arrest is cardiac in origin is >95%. Continuous ECG recordings, fortuitously obtained at the onset of a cardiac arrest, commonly demonstrate changes in cardiac electrical activity during the minutes or hours before the event. There is a tendency for the heart rate to increase and for advanced grades of PVCs to evolve. Most cardiac arrests that are caused by VF begin with a run of sustained or nonsustained VT, which then degenerates into VF.

The probability of achieving successful resuscitation from cardiac arrest is related to the interval from onset to institution of resuscitative efforts, the setting in which the event occurs, the mechanism (VF, VT, pulseless electrical activity, asystole), and the clinical status of the patient prior to the cardiac arrest. Return of circulation and survival rates as a result of defibrillation decrease linearly from the first minute to 10 min. By 5 min, survival rates are no better than 25–30% in out-of-hospital settings. Those settings in which it is possible to institute prompt cardiopulmonary resuscitation (CPR) with rapid defibrillation of VF provide a better chance of a successful outcome. However, the outcome in intensive care units and other in-hospital environments is heavily influenced by the patient's preceding clinical status. The immediate outcome is good for cardiac arrest occurring in the intensive care unit in the presence of an acute cardiac event or transient metabolic disturbance, but survival among patients with far-advanced chronic cardiac disease or advanced noncardiac diseases (e.g., renal failure, pneumonia, sepsis, diabetes, cancer) is low, and not much more successful in the in-hospital than in the out-of-hospital setting.

The success rate for initial resuscitation and survival to hospital discharge after an out-of-hospital cardiac arrest depends heavily on the mechanism of the event. When the mechanism is VT, the outcome is best; VF is the next most successful; and asystole and pulseless electrical activity (PEA) generate dismal outcome statistics. Advanced age also adversely influences the chances of successful resuscitation.

Progression to biologic death is a function of the mechanism of cardiac arrest and the length of the delay before interventions. VF or asystole without CPR within the first 4–6 min has a poor outcome even if defibrillation is successful, because of superimposed brain damage; there are few survivors among patients who had no life support activities for the first 8 min after onset. Outcome statistics are improved by lay bystander intervention (basic life support—see below) prior to definitive interventions (advanced life support), and even more by early defibrillation. In regard to the latter, evaluations of deployment of automatic external defibrillators (AEDs) in communities (e.g., police vehicles, large buildings, airports, and stadiums) are beginning to generate encouraging data. Increased deployment is to be encouraged.

Death during the hospitalization after a successfully resuscitated cardiac arrest relates closely to the severity of central nervous system injury. Anoxic encephalopathy and infections subsequent to prolonged respirator dependence account for 60% of the deaths. Another 30% occur as a consequence of low cardiac output states that fail to respond to interventions. Recurrent arrhythmias are the least common cause of death, accounting for only 10% of in-hospital deaths.

In the setting of acute MI (Chap. 239), it is important to distinguish between primary and secondary cardiac arrests. *Primary cardiac arrests* refer to those that occur in the absence of hemodynamic instability, and *secondary cardiac arrests* are those that occur in patients in whom abnormal hemodynamics dominate the clinical picture before cardiac arrest. The success rate for immediate resuscitation in primary cardiac arrest during acute MI in a monitored setting should approach 100%. In contrast, as many as 70% of patients with secondary cardiac arrest succumb immediately or during the same hospitalization.

Rx CARDIAC ARREST

The individual who collapses suddenly is managed in five stages: (1) the initial response and basic life support, (2) public access defibrillation (if available), (3) advanced life support, (4) postresuscitation care, and (5) long-term management. The initial response, including basic life support and public access defibrillation, can be carried out by physicians, nurses, paramedical personnel, and trained lay persons. There is a requirement for increasingly specialized skills as the patient moves through the stages of advanced life support, postresuscitation care, and long-term management.

INITIAL RESPONSE AND BASIC LIFE SUPPORT The initial evaluation will confirm whether a sudden collapse is indeed due to a cardiac arrest. Observations of the state of consciousness, respiratory movements, skin color, and the presence or absence of pulses in the carotid or femoral arteries can promptly determine whether a life-threatening cardiac arrest has occurred. For lay responders, the pulse check is no longer recommended. As soon as a cardiac arrest is suspected, confirmed, or even considered to be impending, calling an emergency rescue system (e.g., 911) is the immediate priority. With the development of AEDs that are easily used by nonconventional emergency responders, an additional layer for response has evolved (see below).

Agonal respiratory movements may persist for a short time after the onset of cardiac arrest, but it is important to observe for severe stridor with a persistent pulse as a clue to aspiration of a foreign body or food. If this is suspected, a Heimlich maneuver (see below) may dislodge the obstructing body. A precordial blow, or "thump," delivered firmly by the clenched fist to the junction of the middle and lower third of the sternum may occasionally revert VT or VF, but there is concern about converting VT to VF. Therefore, it is recommended to use precordial thumps as an advanced life support technique when monitoring and defibrillation are available. This conservative application of the technique remains controversial.

The third action during the initial response is to clear the airway. The head is tilted back and chin lifted so that the oropharynx can be explored to clear the airway. Dentures or foreign bodies are removed, and the Heimlich maneuver is performed if there is reason to suspect that a foreign body is lodged in the oropharynx. If respiratory arrest precipitating cardiac arrest is suspected, a second precordial thump is delivered after the airway is cleared.

Basic life support, more popularly known as CPR, is intended to maintain organ perfusion until definitive interventions can be instituted. The elements of CPR are the maintenance of ventilation of the lungs and

compression of the chest. Mouth-to-mouth respiration may be used if no specific rescue equipment is immediately available (e.g., plastic oropharyngeal airways, esophageal obturators, masked Ambu bag). Conventional ventilation techniques during single-responder CPR require the lungs to be inflated twice in succession every 30 chest compressions.

Chest compression is based on the assumption that cardiac compression allows the heart to maintain a pump function by sequential filling and emptying of its chambers, with competent valves maintaining forward direction of flow. The palm of one hand is placed over the lower sternum, with the heel of the other resting on the dorsum of the lower hand. The sternum is depressed, with the arms remaining straight, at a rate of approximately 100 per minute. Sufficient force is applied to depress the sternum 4–5 cm, and relaxation is abrupt.

AUTOMATED EXTERNAL DEFIBRILLATION (AED) AEDs that are easily used by nonconventional responders, such as nonparamedic firemen, police, ambulance drivers, trained security guards, and minimally trained or untrained lay persons, have been developed. This advance has inserted another level of response into the cardiac arrest paradigm. A number of studies have demonstrated that AED use by nonconventional and lay responders in strategic response systems can improve cardiac arrest survival rates. This strategy is based on shortening the time to first defibrillation attempt while awaiting arrival of advanced life support.

ADVANCED LIFE SUPPORT This is intended to achieve adequate ventilation, control cardiac arrhythmias, stabilize blood pressure and cardiac output, and restore organ perfusion. The activities carried out to achieve these goals include (1) defibrillation/cardioversion and/or pacing, (2) intubation with an endotracheal tube, and (3) insertion of an intravenous line. The speed with which defibrillation/cardioversion is carried out is an important element for successful resuscitation, both for restoration of spontaneous circulation and protection of the central nervous system. Immediate defibrillation should precede intubation and insertion of an intravenous line; CPR should be carried out while the defibrillator is being charged. As soon as a diagnosis of VF or VT is established, a shock of at least 300 J should be delivered. Additional shocks, up to a maximum of 360 J, are tried if the initial shock does not successfully abolish VT or VF, but it is now recommended that 60–90 s of CPR be carried out before repeated shocks, if the first shock fails to restore an organized rhythm, or before the first shock if 5 min has elapsed between the onset of cardiac arrest and ability to deliver a shock. Epinephrine, 1 mg intravenously, is given after failed defibrillation, and attempts to defibrillate are repeated. The dose of epinephrine may be repeated after intervals of 3–5 min **(Fig. 267-3*A*)**. Vasopressin (a single 40 Unit dose given IV) has been suggested as an alternative to epinephrine.

If the patient is less than fully conscious upon reversion, or if two or three attempts fail, prompt intubation, ventilation, and arterial blood gas analysis should be carried out. Ventilation with O_2 (room air if O_2 is not immediately available) may promptly reverse hypoxemia and acidosis. The patient who is persistently acidotic after successful defibrillation and intubation should be given 1 meq/kg $NaHCO_3$ initially and an additional 50% of the dose repeated every 10–15 min. However, it should not be used routinely.

After initial unsuccessful defibrillation attempts, or with persistent/recurrent electrical instability, antiarrhythmic therapy should be instituted. Intravenous amiodarone has emerged as the initial treatment of choice (150 mg over 10 min, followed by 1 mg/min for up to 6 h and 0.5 mg/min thereafter) (Fig. 267-3*A*). For cardiac arrest due to VF in the early phase of an acute coronary syndrome, a bolus of 1 mg/kg of lidocaine may be given intravenously as an alternative, and the dose may be repeated in 2 min. It also may be tried in those patients in whom amiodarone is unsuccessful. Intravenous procainamide (loading infusion of 100 mg/5 min to a total dose of 500–800 mg, followed by continuous infusion at 2–5 mg/min) is now rarely used in this setting but may be tried for persisting, hemodynamically stable arrhythmias. Intravenous calcium gluconate is no longer considered safe or necessary for routine administration. It is used only in patients in whom acute hyperkalemia is known to be the triggering event for resistant VF, in the presence of known hypocalcemia, or in patients who have received toxic doses of calcium channel antagonists.

Cardiac arrest secondary to bradyarrhythmias or asystole is managed differently (Fig. 267-3*B*). The patient is promptly intubated, CPR is continued, and an attempt is made to control hypoxemia and acidosis. Epinephrine and/or atropine are given intravenously or by an intracardiac route.

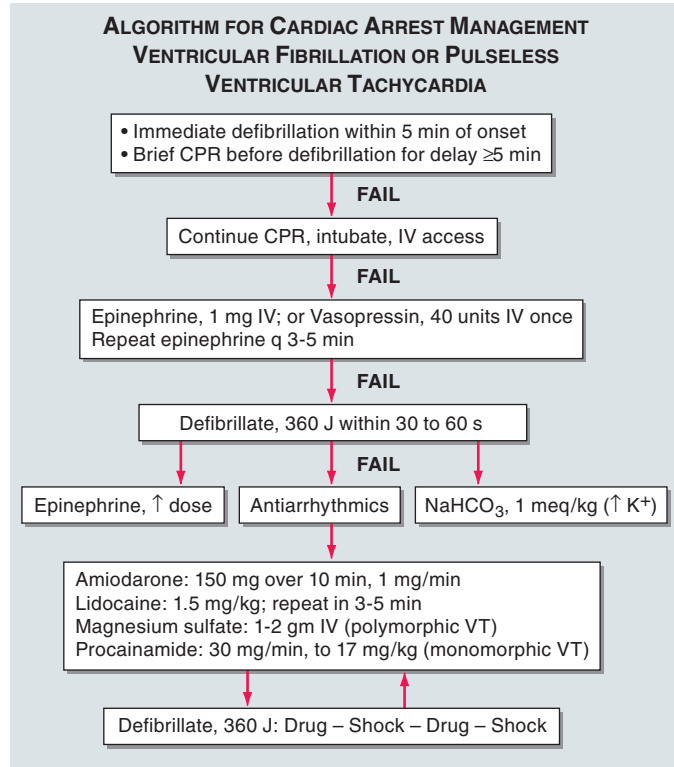


FIGURE 267-3 ***A.*** **The algorithm of ventricular fibrillation** or pulseless ventricular tachycardia begins with defibrillation attempts. If that fails, it is followed by epinephrine and then antiarrhythmic drugs. See text for details. ***B.*** **The algorithms for bradyarrhythmia/asystole** (left) or pulseless electrical activity (right) is dominated first by continued life support and a search for reversible causes. Subsequent therapy is nonspecific and accompanied by a low success rate. See text for details. CPR, cardiopulmonary resuscitation; MI, myocardial infarction.

External pacing devices are now available to attempt to establish a regular rhythm, but the prognosis is generally very poor in this form of cardiac arrest, even with successful electrical pacing. PEA is treated similarly to bradyarrhythmias, but its outcome is also dismal. The one exception is bradyarrhythmic/asystolic cardiac arrest secondary to airway obstruction.

This form of cardiac arrest may respond promptly to removal of foreign bodies by the Heimlich maneuver or, in hospitalized patients, by intubation and suctioning of obstructing secretions in the airway.

POSTRESUSCITATION CARE This phase of management is determined by the clinical setting of the cardiac arrest. Primary VF in acute MI (Chap. 239) is generally very responsive to life-support techniques and easily controlled after the initial event. In the in-hospital setting, respirator support is usually not necessary or is needed for only a short time, and hemodynamics stabilize promptly after defibrillation or cardioversion. In secondary VF in acute MI (those events in which hemodynamic abnormalities predispose to the potentially fatal arrhythmia), resuscitative efforts are less often successful; and in those patients who are successfully resuscitated, the recurrence rate is high. The clinical picture and outcome are dominated by hemodynamic instability and the ability to control hemodynamic dysfunction. Bradyarrhythmias, asystole, and PEA are commonly secondary events in hemodynamically unstable patients. The in-hospital phase of care of the out-of-hospital cardiac arrest survivor is dictated by specific clinical circumstances. The most difficult is the presence of anoxic encephalopathy, which is a strong predictor of in-hospital death. A recent addition to the management of this condition is induced hypothermia to reduce metabolic demands and cerebral edema.

The outcome after in-hospital cardiac arrest associated with noncardiac diseases is poor, and in the few successfully resuscitated patients, the postresuscitation course is dominated by the nature of the underlying disease. Patients with end-stage cancer, renal failure, acute central nervous system disease, and uncontrolled infections, as a group, have a survival rate of <10% after in-hospital cardiac arrest. Some major exceptions are patients with transient airway obstruction, electrolyte disturbances, proarrhythmic effects of drugs, and severe metabolic abnormalities, most of whom may have an excellent chance of survival if they can be resuscitated promptly and maintained while the transient abnormalities are being corrected.

LONG-TERM MANAGEMENT AFTER SURVIVAL OF OUT-OF-HOSPITAL CARDIAC ARREST Patients who survive cardiac arrest without irreversible damage to the central nervous system, and who achieve hemodynamic stability, should have extensive diagnostic testing and appropriate therapeutic interventions for their long-term management. This aggressive approach is driven by the fact that survival after out-of-hospital cardiac arrest was followed by a 25–30% mortality rate during the first 2 years after the event, and there are data suggesting that significant reductions in risk can be achieved by implantation of an internal cardiac defibrillator (ICD).

Among patients in whom an acute transmural MI is identified as the specific mechanism triggering an out-of-hospital cardiac arrest, the management is dictated in part by the transient nature of life-threatening arrhythmia risk in the acute phase of MI, and in part by the extent of permanent myocardial damage that results. Several clinical trials have now documented an improved survival among cardiac arrest survivors who have EFs <40% and receive ICDs.

For patients with cardiac arrest thought to be due to a transient ischemic mechanism, particularly with higher EFs, anti-ischemic therapy by pharmacologic or interventional methods is generally accepted as appropriate management. However, despite the absence of supportive clinical trial evidence, some adopt a more aggressive attitude about the use of ICDs in this group of cardiac arrest survivors as well, given the unpredictability of recurrent ischemia.

The principles guiding therapy for patients with coronary artery disease who survive a cardiac arrest generally apply to the other cardiac disorders as well, with the exception that there is less focus on the extent of disease in certain disorders. Generally, cardiac arrest survivors from other categories of disease, such as the hypertrophic or dilated cardiomyopathies and various rare inherited disorders (e.g., RV dysplasia, long QT syndrome, Brugada syndrome, arrhythmic VF) are all considered ICD candidates.

PREVENTION OF SCD IN HIGH-RISK INDIVIDUALS WITHOUT PRIOR CARDIAC ARREST

Post-MI patients have been the subject of clinical trials for ICD benefit. It is now established that for post-MI patients with EFs <40%, ambient ventricular arrhythmias, and inducible ventricular tachyarrhythmias in the electrophysiology laboratory, ICDs provide a significant reduction in relative risk of SCD and total mortality. Total mortality benefits in the range of a 20–30% reduction over 2–3 years have been observed, and ICD has emerged as preferred therapy for such patients. One study suggests that when the EF <30%, electrophysiologic testing is not necessary to identify ICD benefit, and another demonstrates benefit for patients with Functional Class 2 or 3 heart failure and ejection fractions ≤35%, regardless of etiology (ischemic or nonischemic) or ambient or induced arrhythmias (see Chaps. 226 and 227).

Decision-making for primary prevention in disorders other than coronary artery disease and dilated cardiomyopathy is generally driven by observational data and judgment based on clinical observations. Controlled clinical trials providing evidence-based indicators for ICDs are lacking for these smaller population subgroups. In general, for the rare disorders listed above, indicators of arrhythmic risk such as syncope, documented ventricular tachyarrhythmias, aborted cardiac arrest or perhaps a family history of premature SCD, and a number of other clinical or ECG markers, may be used as indicators for ICDs.

268 Coma

Allan H. Ropper

Coma is among the most common and striking problems in general medicine. It accounts for a substantial portion of admissions to emergency wards and occurs on all hospital services. Because coma demands immediate attention, the physician must employ an organized approach.

There is a continuum of states of reduced alertness, the severest form being *coma*, a deep sleeplike state from which the patient cannot be aroused. *Stupor* refers to a higher degree of arousability in which the patient can be awakened only by vigorous stimuli, accompanied by motor behavior that leads to avoidance of uncomfortable or aggravating stimuli. *Drowsiness*, which is familiar to all persons, simulates light sleep and is characterized by easy arousal and the persistence of alertness for brief periods. Drowsiness and stupor are usually attended by some degree of confusion (Chap. 26). A narrative description of the level of arousal and of the type of responses evoked by various stimuli, precisely as observed at the bedside, is preferable to ambiguous terms such as lethargy, semicoma, or obtundation.

Several other neurologic conditions render patients apparently unresponsive and thereby simulate coma, and certain subsyndromes of coma must be considered separately because of their special significance. Among the latter, the *vegetative state* signifies an awake but nonresponsive state. These patients have emerged from coma after a period of days or weeks to a state in which the eyelids are open, giving the appearance of wakefulness. Yawning, coughing, swallowing, as well as limb and head movements persist, but there are few, if any, meaningful responses to the external and internal environment—in essence, an "awake coma." Respiratory and autonomic functions are retained. The term "vegetative" is unfortunate as it is subject to misinterpretation by laypersons. The possibility of incorrectly attributing meaningful behavior to these patients has created inordinate problems. There are always accompanying signs that indicate extensive damage in both cerebral hemispheres, e.g., decerebrate or decorticate limb posturing and absent responses to visual stimuli (see below). In the closely related but less severe *minimally conscious state* the patient may make intermittent rudimentary vocal or motor responses. Cardiac arrest with cerebral hypoperfusion and head injuries are the most common causes of the vegetative and minimally conscious states (Chaps. 267 and 269). The prognosis for regaining mental faculties once the vegetative state has supervened for several months is very poor, and after a year, almost nil, hence the term *persistent vegetative state*. Most reports of dramatic recovery, when investigated carefully, are found to yield to the usual rules for prognosis, but there have been rare instances in which recovery has occurred to a demented condition and, in rare childhood cases, to an even better state.

Quite apart from the above conditions, certain syndromes that affect alertness are prone to be misinterpreted as stupor or coma. *Akinetic mutism* refers to a partially or fully awake state in which the patient is able to form impressions and think but remains virtually immobile and mute. The condition results from damage in the regions of the medial thalamic nuclei or the frontal lobes (particularly lesions situated deeply or on the orbitofrontal surfaces), or from hydrocephalus. The term *abulia* is in essence a milder form of akinetic mutism, used to describe mental and physical slowness and diminished ability to initiate activity. It is also generally the result of damage to the frontal lobe network (Chap. 27). *Catatonia* is a curious hypomobile and mute syndrome that arises as part of a major psychosis, usually schizophrenia or major depression. Catatonic patients make few voluntary or responsive movements, although they blink, swallow, and may not appear distressed. There are nonetheless signs that the patient is responsive, although it may take some ingenuity on the part of the examiner to demonstrate them. For example, eyelid elevation is actively resisted, blinking occurs in response to a visual threat, and the eyes move concomitantly with head rotation, all of which are inconsistent with the presence of a brain lesion. It is characteristic but not invariable in catatonia for the limbs to retain the postures in which they have been placed by the examiner ("waxy flexibility," or catalepsy). Upon recovery, such patients have some memory of events that occurred during their catatonic stupor. The appearance is superficially similar to akinetic mutism, but clinical evidence of cerebral damage such as Babinski signs and hypertonicity of the limbs is lacking. The singular problem of brain death is discussed below.

The *locked-in state* describes yet another type of pseudocoma in which an awake patient has no means of producing speech or volitional movement, but retains voluntary vertical eye movements and lid elevation, thus allowing the patient to signal with a clear mind. The pupils are normally reactive. Such individuals have written entire treatises using Morse code. The usual cause is an infarction or hemorrhage of the ventral pons, which transects all descending corticospinal and corticobulbar pathways. A similar awake but de-efferented state occurs as a result of total paralysis of the musculature in severe cases of Guillain-Barré syndrome (Chap. 380), critical illness neuropathy (Chap. 269), and pharmacologic neuromuscular blockade.

THE ANATOMY AND PHYSIOLOGY OF COMA

Almost all instances of diminished alertness can be traced to widespread abnormalities of the cerebral hemispheres or to reduced activity of a special thalamocortical alerting system termed the *reticular activating system*. The proper functioning of this system, its ascending projections to the cortex, and the cortex itself are required to maintain alertness and coherence of thought. It follows that the principal causes of coma are (1) lesions that damage the RAS or its projections; (2) destruction of large portions of both cerebral hemispheres; and (3) suppression of reticulocerebral function by drugs, toxins, or metabolic derangements such as hypoglycemia, anoxia, uremia, and hepatic failure.

The proximity of the RAS to structures that control pupillary function and eye movements permits clinical localization of the cause of coma in many cases. Pupillary enlargement with loss of light reaction and loss of vertical and adduction movements of the eyes suggests that the likely location of the lesion is in the upper brainstem. Conversely, preservation of pupillary reactivity and eye movements absolves the upper brainstem and indicates that widespread structural lesions or metabolic suppression of the cerebral hemispheres is responsible.

Coma Due to Cerebral Mass Lesions and Herniations The cranial cavity is separated into compartments by infoldings of the dura. The two cerebral hemispheres are separated by the falx, and the anterior and posterior fossae by the tentorium. Herniation refers to displacement of brain tissue into a compartment that it normally does not occupy. Many of the signs associated with coma, and indeed coma itself, can be attributed to these tissue shifts, and certain clinical configurations are characteristic of specific herniations (Fig. 268-1). They are in essence "false localizing" signs since they derive from compression of brain structures at a distance from the mass.

The most common herniations are from the supratentorial to the infratentorial compartments through the tentorial opening, hence *transtentorial*. *Uncal transtentorial herniation* refers to impaction of the anterior medial temporal gyrus (the uncus) into the tentorial opening just anterior to and adjacent to the midbrain (Fig. 268-1, A). The displaced brain tissue compresses the third nerve as it traverses the subarachnoid space, and results in enlargement of the ipsilateral pupil

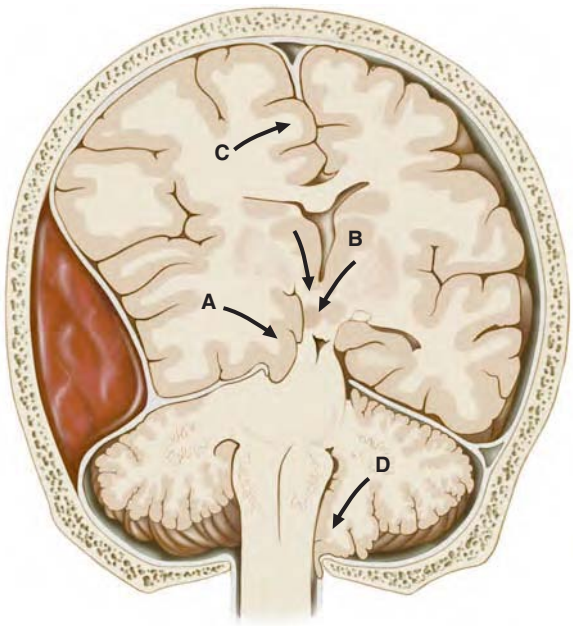

FIGURE 268-1 Types of cerebral herniation. (A) uncal; (B) central; (C) transfalcial; (D) foraminal.

(putatively because the fibers subserving parasympathetic pupillary function are located peripherally in the nerve). The coma that follows is due to compression of the midbrain against the opposite tentorial edge by the displaced parahippocampal gyrus (Fig. 268-2). In some cases, the lateral displacement of the midbrain causes compression of the opposite cerebral peduncle, producing a Babinski sign and hemiparesis contralateral to the original hemiparesis (the Kernohan-Woltman sign). In addition to compressing the upper brainstem, tissue shifts, including herniations, may compress major blood vessels, particularly the anterior and posterior cerebral arteries as they pass over the tentorial reflections, thus producing brain infarctions. The distortions may also entrap portions of the ventricular system, resulting in regional hydrocephalus.

Central transtentorial herniation denotes a symmetric downward movement of the thalamic medial structures through the tentorial opening with compression of the upper midbrain (Fig. 268-1, B). Miotic pupils and drowsiness are the heralding signs. Both temporal and central herniations have classically been considered to cause a progressive compression of the brainstem from above in an orderly manner: first the midbrain, then the pons, and finally the medulla. The result is a sequence of neurologic signs that corresponds to each affected level. Other forms of herniation are *transfalcial herniation* (displacement of the cingulate gyrus under the falx and across the midline, Fig. 268-1, C), and *foraminal herniation* (downward forcing of the cerebellar tonsils into the foramen magnum, Fig. 268-1, D), which causes compression of the medulla and respiratory arrest.

A direct relationship between the various configurations of transtentorial herniations and coma is not always found. Drowsiness and stupor typically occur with moderate horizontal shifts at the level of the diencephalon (thalami) well before transtentorial or other herniations are evident. Lateral shift may be quantified on axial images of CT and MRI scans (Fig. 268-2). In cases of *acutely appearing masses*, horizontal displacement of the pineal calcification of 3–5 mm is generally associated with drowsiness, 6–8 mm with stupor, and >9 mm with coma. Intrusion of the medial temporal lobe into the tentorial opening may be apparent on MRI and CT scans by an obliteration of the cisterns that surround the upper brainstem.

Coma Due to Metabolic Disorders Many systemic metabolic abnormalities cause coma by interrupting the delivery of energy substrates (hypoxia, ischemia, hypoglycemia) or by altering neuronal excitability (drug and alcohol intoxication, anesthesia, and epilepsy). The same metabolic abnormalities that produce coma may in milder form induce widespread cortical dysfunction and an acute confusional state. Thus, in metabolic encephalopathies, clouded consciousness and coma are in a continuum.

Cerebral neurons are fully dependent on cerebral blood flow (CBF) and the related delivery of oxygen and glucose. CBF is ~75 mL per 100g/min in gray matter and 30 mL per 100 g/min in white matter (mean = 55 mL per 100 g/min); oxygen consumption is 3.5 mL per 100 g/min, and glucose utilization is 5 mg per 100 g/min. Brain stores of glucose provide energy for ~2 min after blood flow is interrupted, and oxygen stores last 8–10 s after the cessation of blood flow. Simultaneous hypoxia and ischemia exhaust glucose more rapidly. The electroencephalogram (EEG) rhythm in these circumstances becomes diffusely slowed, typical of metabolic encephalopathies, and as conditions of substrate delivery worsen, eventually all recordable brain electrical activity ceases. In almost all instances of metabolic encephalopathy, the global metabolic activity of the brain is reduced in proportion to the degree of diminished consciousness.

Conditions such as hypoglycemia, hyponatremia, hyperosmolarity, hypercapnia, hypercalcemia, and hepatic and renal failure are associated with a variety of alterations in neurons and astrocytes. Unlike hypoxia-ischemia, which causes neuronal destruction, metabolic disorders generally cause only minor neuropathologic changes. The reversible effects of these conditions on the brain are not understood but may result from impaired energy supplies, changes in ion fluxes across neuronal membranes, and neurotransmitter abnormalities. For example, the high brain ammonia concentration of hepatic coma interferes with cerebral energy metabolism and with the Na^+, K^+-ATPase pump, increases the number and size of astrocytes, alters nerve cell function, and causes increased concentrations of potentially toxic products of ammonia metabolism; it may also result in abnormalities of neurotransmitters, including putative "false" neurotransmitters that are active at receptor sites. Apart from hyperammonemia, which of these mechanisms is of critical importance is not clear. The mechanism of the encephalopathy of renal failure is also not known. Unlike ammonia, urea itself does not produce central nervous system (CNS) toxicity. A multifactorial causation has been proposed, including increased permeability of the blood-brain barrier to toxic substances such as organic acids and an increase in brain calcium or cerebrospinal fluid (CSF) phosphate content.

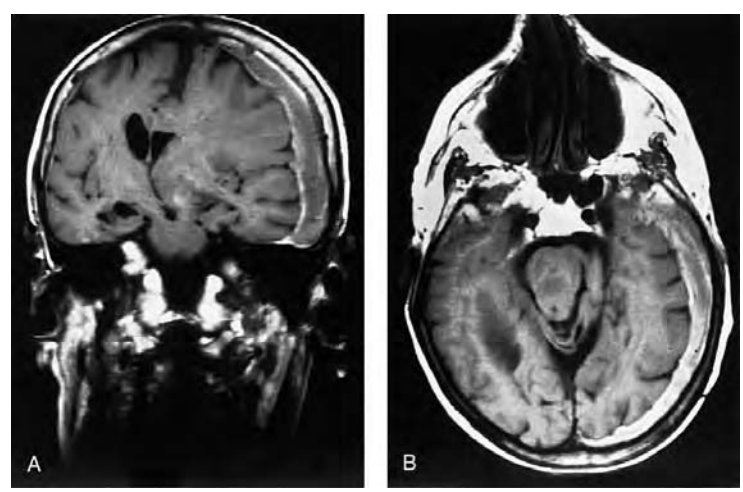

FIGURE 268-2 Coronal (*A*) and axial (*B*) magnetic resonance images from a stuporous patient with a left third nerve palsy as a result of a large left-sided subdural hematoma (seen as a gray-white rim). The upper midbrain and lower thalamic regions are compressed and displaced horizontally away from the mass, and there is transtentorial herniation of the medial temporal lobe structures, including the uncus anteriorly. The lateral ventricle opposite to the hematoma has become enlarged as a result of compression of the third ventricle.

Coma and seizures are a common accompaniment of any large shifts in sodium and water balance in the brain. These changes in osmolarity arise from systemic medical disorders including diabetic ketoacidosis, the nonketotic hyperosmolar state, and hyponatremia from any cause (e.g., water intoxication, excessive secretion of antidiuretic hormone or atrial natriuretic peptides). Sodium levels <125 mmol/L induce confusion, and <115 mmol/L are associated with coma and convulsions. In hyperosmolar coma the serum osmolarity is generally >350 mosmol/L. Hypercapnia depresses the level of consciousness in proportion to the rise in CO_2 tension in the blood. *In all of these metabolic encephalopathies, the degree of neurologic change depends to a large extent on the rapidity with which the serum changes occur*. The pathophysiology of other metabolic encephalopathies such as hypercalcemia, hypothyroidism, vitamin B_{12} deficiency, and hypothermia are incompletely understood but must also reflect derangements of CNS biochemistry and membrane function.

Epileptic Coma Continuous, generalized electrical discharges of the cortex (*seizures*) are associated with coma even in the absence of epileptic motor activity (*convulsions*). The self-limited coma that follows seizures, termed the *postictal state*, may be due to exhaustion of energy reserves or effects of locally toxic molecules that are the byproduct of seizures. The postictal state produces a pattern of continuous, generalized slowing of the background EEG activity similar to that of other metabolic encephalopathies.

Toxic Drug–Induced Coma This common class of encephalopathy is in large measure reversible and leaves no residual damage providing hypoxia does not supervene. Many drugs and toxins are capable of depressing nervous system function. Some produce coma by affecting both the brainstem nuclei, including the RAS, and the cerebral cortex. The combination of cortical and brainstem signs, which occurs in certain drug overdoses, may lead to an incorrect diagnosis of structural brainstem disease. Overdose of medications that have atropinic actions produces physical signs such as dilated pupils, tachycardia, and dry skin.

Coma Due to Widespread Damage to the Cerebral Hemispheres This special category, comprising a number of unrelated disorders, results from widespread structural cerebral damage, thereby simulating a metabolic disorder of the cortex. The effect of prolonged hypoxia-ischemia is perhaps the best known and one in which it is not possible to distinguish the acute effects of hypoperfusion of the brain from the further effects of generalized neuronal damage. Similar bihemispheral damage is produced by disorders that occlude small blood vessels throughout the brain; examples include cerebral malaria, thrombotic thrombocytopenic purpura, and hyperviscosity. The presence of seizures and the bihemispheral damage are sometimes an indication of this class of disorder.

APPROACH TO THE PATIENT: Coma

Acute respiratory and cardiovascular problems should be attended to prior to neurologic assessment. In most instances, a complete medical evaluation, except for vital signs, funduscopy, and examination for nuchal rigidity, may be deferred until the neurologic evaluation has established the severity and nature of coma. The approach to the patient with cranial trauma is discussed in Chap. 373.

HISTORY In many cases, the cause of coma is immediately evident (e.g., trauma, cardiac arrest, or known drug ingestion). In the remainder, certain points are especially useful: (1) the circumstances and rapidity with which neurologic symptoms developed; (2) the antecedent symptoms (confusion, weakness, headache, fever, seizures, dizziness, double vision, or vomiting); (3) the use of medications, illicit drugs, or alcohol; and (4) chronic liver, kidney, lung, heart, or other medical disease. Direct interrogation of family and observers on the scene, in person or by telephone, is an important part of the initial evaluation. Ambulance technicians often provide the most useful information.

GENERAL PHYSICAL EXAMINATION The temperature, pulse, respiratory rate and pattern, and blood pressure should be measured quickly. Fever suggests a systemic infection, bacterial meningitis, or encephalitis; only rarely is it attributable to a brain lesion that has disturbed hypothalamic temperature-regulating centers ("*central fever*"). A slight elevation in temperature may follow vigorous convulsions. High body temperature, 42–44°C, associated with dry skin should arouse the suspicion of heat stroke or anticholinergic drug intoxication. Hypothermia is observed with alcoholic, barbiturate, sedative, or phenothiazine intoxication; hypoglycemia; peripheral circulatory failure; or hypothyroidism. Hypothermia itself causes coma only when the temperature is <31°C. Tachypnea may indicate systemic acidosis or pneumonia. Aberrant respiratory patterns that reflect brainstem disorders are discussed below. Marked hypertension either indicates hypertensive encephalopathy or is the result of a rapid rise in intracranial pressure (ICP; the Cushing response) most often after cerebral hemorrhage or head injury. Hypotension is characteristic of coma from alcohol or barbiturate intoxication, internal hemorrhage, myocardial infarction, sepsis, profound hypothyroidism, or Addisonian crisis.

The funduscopic examination can detect subarachnoid hemorrhage (subhyaloid hemorrhages), hypertensive encephalopathy (exudates, hemorrhages, vessel-crossing changes, papilledema), and increased ICP (papilledema). Cutaneous petechiae suggest thrombotic thrombocytopenic purpura, meningococcemia, or a bleeding diathesis from which an intracerebral hemorrhage has arisen.

NEUROLOGIC EXAMINATION First, the patient should be observed without intervention by the examiner. Tossing about in the bed, reaching up toward the face, crossing legs, yawning, swallowing, coughing, or moaning denote a state close to normal awakeness. Lack of restless movements on one side or an outturned leg suggests a hemiplegia. Intermittent twitching movements of a foot, finger, or facial muscle may be the only sign of seizures. Multifocal myoclonus almost always indicates a metabolic disorder, particularly uremia, anoxia, or drug intoxication (lithium and haloperidol are particularly likely to cause this sign), or the rare conditions of a prion disease (Chap. 378) or "Hashimoto encephalopathy." In a drowsy and confused patient bilateral *asterixis* is a certain sign of metabolic encephalopathy or drug intoxication.

The terms *decorticate rigidity* and *decerebrate rigidity*, or "posturing," describe stereotyped arm and leg movements occurring spontaneously or elicited by sensory stimulation. Flexion of the elbows and wrists and supination of the arm (decortication) suggests bilateral damage rostral to the midbrain, whereas extension of the elbows and wrists with pronation (decerebration) indicates damage to motor tracts in the midbrain or caudal diencephalon. The less frequent combination of arm extension with leg flexion or flaccid legs is associated with lesions in the pons. These concepts have been adapted from animal work and cannot be applied with the same precision to coma in humans. In fact, acute and widespread disorders of any type, regardless of location, frequently cause limb extension, and almost all such extensor posturing becomes predominantly flexor as time passes. Posturing may also be unilateral and may coexist with purposeful limb movements, usually reflecting incomplete damage to the motor system.

LEVEL OF AROUSAL A sequence of increasingly intense stimuli is used to determine the threshold for arousal and the optimal motor response of each side of the body. The results of testing may vary from minute to minute and serial examinations are most useful. Tickling the nostrils with a cotton wisp is a moderate stimulus to arousal—all but deeply stuporous and comatose patients will move the head away and rouse to some degree. Using the hand to remove the offending stimulus represents an even greater degree of responsiveness. Stereotyped posturing in response to noxious stimuli indicates severe dysfunction of the corticospinal system. Abduction-avoidance movement of a limb is usually purposeful and denotes an intact

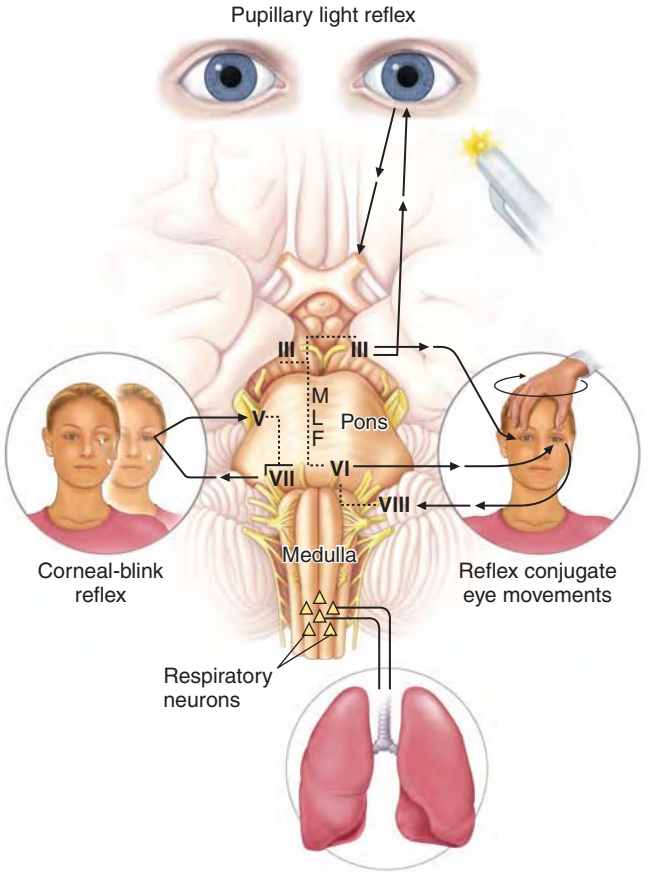

FIGURE 268-3 Examination of brainstem reflexes in coma. Midbrain and third nerve function are tested by pupillary reaction to light, pontine function by spontaneous and reflex eye movements and corneal responses, and medullary function by respiratory and pharyngeal responses. Reflex conjugate, horizontal eye movements are dependent on the medial longitudinal fasciculus (MLF) interconnecting the sixth and contralateral third nerve nuclei. Head rotation (oculocephalic reflex) or caloric stimulation of the labyrinths (oculovestibular reflex) elicits contraversive eye movements (for details see text).

corticospinal system. Pressure on the knuckles or bony prominences and pinprick stimulation are humane forms of noxious stimuli; pinching the skin causes unsightly ecchymoses and is generally not necessary but may be useful in eliciting abduction withdrawal movements of the limbs.

BRAINSTEM REFLEXES Assessment of brainstem function is essential to localization of the lesion in coma (Fig. 268-3). The brainstem reflexes that are conveniently examined are pupillary responses to light, spontaneous and elicited eye movements, corneal responses, and the respiratory pattern. As a rule, when these brainstem activities are preserved, particularly the pupil reactions and eye movements, coma must be ascribed to bilateral hemispheral disease. The converse, however, is not always true, as a mass in the hemispheres may be the underlying cause of coma but nonetheless produce brainstem signs by inducing transtentorial herniation.

Pupillary Signs Pupillary reactions are examined with a bright, diffuse light (not an ophthalmoscope); if the response is absent, this should be confirmed by observation through a magnifying lens. Normally reactive and round pupils of midsize (2.5–5 mm) essentially exclude midbrain damage, either primary or secondary to compression. Reaction to light is often difficult to appreciate in pupils < 2 mm in diameter, and bright room lighting mutes pupillary reactivity. One unreactive and enlarged pupil (>6 mm) or one that is poorly reactive signifies compression of the third nerve from the effects of a mass above. Enlargement of the pupil contralateral to a mass may occur first but is infrequent. An oval and slightly eccentric pupil is a transitional sign that accompanies early midbrain–third nerve compression. The most extreme pupillary sign, bilaterally dilated and unreactive pupils, indicates severe midbrain damage, usually from compression by a supratentorial mass. Ingestion of drugs with anticholinergic activity, the use of mydriatic eye drops, and direct ocular trauma are among the causes of misleading pupillary enlargement.

Unilateral miosis in coma has been attributed to dysfunction of sympathetic efferents originating in the posterior hypothalamus and descending in the tegmentum of the brainstem to the cervical cord. It is an occasional finding with a large cerebral hemorrhage that affects the thalamus. Reactive and bilaterally small (1–2.5 mm) but not pinpoint pupils are seen in metabolic encephalopathies or in deep bilateral hemispheral lesions such as hydrocephalus or thalamic hemorrhage. Very small but reactive pupils (<1 mm) characterize narcotic or barbiturate overdoses but also occur with extensive pontine hemorrhage. The response to naloxone and the presence of reflex eye movements (see below) distinguish these.

Ocular Movements The eyes are first observed by elevating the lids and noting the resting position and spontaneous movements of the globes. Lid tone, tested by lifting the eyelids and noting their resistance to opening and the speed of closure, is reduced progressively as coma deepens. Horizontal divergence of the eyes at rest is normal in drowsiness. As coma deepens, the ocular axes may become parallel again.

Spontaneous eye movements in coma often take the form of conjugate horizontal roving. This finding alone exonerates the midbrain and pons and has the same significance as normal reflex eye movements (see below). Conjugate horizontal ocular deviation to one side indicates damage to the pons on the opposite side or alternatively, to the frontal lobe on the same side. This phenomenon is summarized by the following maxim: *The eyes look toward a hemispheral lesion and away from a brainstem lesion.* Seizures also drive the eyes to one side. On rare occasions, the eyes may turn paradoxically away from the side of a deep hemispheral lesion ("wrong-way eyes"). The eyes turn down and inward as a result of thalamic and upper midbrain lesions, typically with thalamic hemorrhage. "Ocular bobbing" describes brisk downward and slow upward movements of the eyes associated with loss of horizontal eye movements and is diagnostic of bilateral pontine damage, usually from thrombosis of the basilar artery. "Ocular dipping" is a slower, arrhythmic downward movement followed by a faster upward movement in patients with normal reflex horizontal gaze; it indicates diffuse cortical anoxic damage. Many other complex eye movements are known but do not have the same clinical importance as those mentioned earlier.

The oculocephalic reflexes depend on the integrity of the ocular motor nuclei and their interconnecting tracts that extend from the midbrain to the pons and medulla. These reflexes are elicited by moving the head from side to side or vertically and observing evoked eye movements in the direction opposite to the head movement (Fig. 268-3). The movements, called somewhat inappropriately "doll's eyes" (which refers more accurately to the reflex elevation of the eyelids with flexion of the neck), are normally suppressed in the awake patient. The ability to elicit them therefore indicates a reduced cortical influence on the brainstem. Furthermore, preservation of evoked reflex eye movements signifies the integrity of the brainstem and implies that the origin of unconsciousness lies in the cerebral hemispheres. The opposite, an absence of reflex eye movements, usually signifies damage within the brainstem but can be produced infrequently by profound overdoses of certain drugs. Normal pupillary size and light reaction distinguishes most drug-induced comas from structural brainstem damage.

Thermal, or "caloric," stimulation of the vestibular apparatus (oculovestibular response) provides a more intense stimulus for the oculocephalic reflex but gives fundamentally the same informa-

tion. The test is performed by irrigating the external auditory canal with cool water in order to induce convection currents in the labyrinths. After a brief latency, the result is tonic deviation of both eyes to the side of cool-water irrigation and nystagmus in the opposite direction. (The acronym "COWS" has been used to remind generations of medical students of the direction of nystagmus—"cold water opposite, warm water same.") The loss of conjugate ocular movements indicates brainstem damage. The absence of nystagmus despite conjugate deviation of the globes indicates that the cerebral hemispheres are damaged or metabolically suppressed.

By touching the cornea with a wisp of cotton, a response consisting of brief bilateral lid closure is normally observed. The corneal reflexes depend on the integrity of pontine pathways between the fifth (afferent) and both seventh (efferent) cranial nerves; although rarely useful alone, in conjunction with reflex eye movements they are important clinical tests of pontine function. CNS depressant drugs diminish or eliminate the corneal responses soon after reflex eye movements are paralyzed but before the pupils become unreactive to light. The corneal (and pharyngeal) response may be lost for a time on the side of an acute hemiplegia.

Respiratory Patterns These are of less localizing value in comparison to other brainstem signs. Shallow, slow, but regular breathing suggests metabolic or drug depression. Cheyne-Stokes respiration in its classic cyclic form, ending with a brief apneic period, signifies bihemispheral damage or metabolic suppression and commonly accompanies light coma. Rapid, deep (Kussmaul) breathing usually implies metabolic acidosis but may also occur with pontomesencephalic lesions. Agonal gasps are the result of lower brainstem (medullary) damage and are well known as the terminal respiratory pattern of severe brain damage. A number of other cyclic breathing variations have been described but are of lesser significance.

LABORATORY STUDIES AND IMAGING

The studies that are most useful in the diagnosis of coma are: chemical-toxicologic analysis of blood and urine, cranial CT or MRI, EEG, and CSF examination. Arterial blood-gas analysis is helpful in patients with lung disease and acid-base disorders. The metabolic aberrations commonly encountered in clinical practice require measurements of electrolytes, glucose, calcium, osmolarity, and renal (blood urea nitrogen) and hepatic (NH_3) function. Toxicologic analysis is necessary in any case of coma where the diagnosis is not immediately clear. However, the presence of exogenous drugs or toxins, especially alcohol, does not exclude the possibility that other factors, particularly head trauma, are also contributing to the clinical state. An ethanol level of 43 mmol/L (0.2 g/dL) in nonhabituated patients generally causes impaired mental activity and of >65 mmol/L (0.3 g/dL) is associated with stupor. The development of tolerance may allow the chronic alcoholic to remain awake at levels >87 mmol/L (0.4 g/dL).

The availability of CT and MRI has focused attention on causes of coma that are radiologically detectable (e.g., hemorrhages, tumors, or hydrocephalus). Resorting primarily to this approach, although at times expedient, is imprudent because most cases of coma (and confusion) are metabolic or toxic in origin. The notion that a normal CT scan excludes anatomic lesions as the cause of coma is also erroneous. Bilateral hemisphere infarction, acute brainstem infarction, encephalitis, meningitis, mechanical shearing of axons as a result of closed head trauma, sagittal sinus thrombosis, and subdural hematomas that are isodense to adjacent brain are some of the disorders that may not be detected. Nevertheless, if the source of coma remains unknown, a scan should be obtained.

The EEG is useful in metabolic or drug-induced states but is rarely diagnostic, except when coma is due to clinically unrecognized seizures, to herpesvirus encephalitis, or to prion (Creutzfeldt-Jakob) disease. The amount of background slowing of the EEG is a reflection of the severity of any diffuse encephalopathy. Predominant high-voltage slowing (δ or triphasic waves) in the frontal regions is typical of metabolic coma, as from hepatic failure, and widespread fast (β) activity implicates sedative drugs (e.g., diazepines, barbiturates). A special pattern of "alpha coma," defined by widespread, variable 8- to 12-Hz activity, superficially resembles the normal α rhythm of waking but is unresponsive to environmental stimuli. It results from pontine or diffuse cortical damage and is associated with a poor prognosis. Most importantly, EEG recordings may reveal clinically inapparent epileptic discharges in a patient with coma. Normal α activity on the EEG, which is suppressed by stimulating the patient, also alerts the clinician to the locked-in syndrome or to hysteria or catatonia.

Lumbar puncture is performed less frequently than in the past for coma diagnosis because neuroimaging effectively excludes intracerebral and extensive subarachnoid hemorrhage. However, examination of the CSF remains indispensable in the diagnosis of meningitis and encephalitis. Lumbar puncture should therefore not be deferred if meningitis is a possibility.

DIFFERENTIAL DIAGNOSIS OF COMA

(Table 268-1) The causes of coma can be divided into three broad categories: those without focal neurologic signs (e.g., metabolic encephalopathies); meningitis syndromes, characterized by fever or stiff neck and an excess of cells in the spinal fluid (e.g., bacterial meningitis, subarachnoid hemorrhage); and conditions associated with prominent focal signs (e.g., stroke, cerebral hemorrhage). In most instances coma is part of an obvious medical problem such as drug ingestion, hypoxia, stroke, trauma, or liver or kidney failure. Conditions that cause sudden coma include drug ingestion, cerebral hemorrhage, trauma, cardiac arrest, epilepsy, or basilar artery embolism. Coma that appears subacutely is usually related to a preceding medical or neurologic problem, including the secondary brain swelling of a mass lesion such as tumor or cerebral infarction.

TABLE 268-1 DIFFERENTIAL DIAGNOSIS OF COMA

1. Diseases that cause no focal or lateralizing neurologic signs, usually with normal brainstem functions; CT scan and cellular content of the CSF are normal
   a. Intoxications: alcohol, sedative drugs, opiates, etc.
   b. Metabolic disturbances: anoxia, hyponatremia, hypernatremia, hypercalcemia, diabetic acidosis, nonketotic hyperosmolar hyperglycemia, hypoglycemia, uremia, hepatic coma, hypercarbia, addisonian crisis, hypo- and hyperthyroid states, profound nutritional deficiency
   c. Severe systemic infections: pneumonia, septicemia, typhoid fever, malaria, Waterhouse-Friderichsen syndrome
   d. Shock from any cause
   e. Postseizure states, status epilepticus, subclinical epilepsy
   f. Hypertensive encephalopathy, eclampsia
   g. Severe hyperthermia, hypothermia
   h. Concussion
   i. Acute hydrocephalus
2. Diseases that cause meningeal irritation with or without fever, and with an excess of WBCs or RBCs in the CSF, usually without focal or lateralizing cerebral or brainstem signs; CT or MRI shows no mass lesion
   a. Subarachnoid hemorrhage from ruptured aneurysm, arteriovenous malformation, trauma
   b. Acute bacterial meningitis
   c. Viral encephalitis
   d. Miscellaneous: Fat embolism, cholesterol embolism, carcinomatous and lymphomatous meningitis, etc.
3. Diseases that cause focal brainstem or lateralizing cerebral signs, with or without changes in the CSF; CT and MRI are abnormal
   a. Hemispheral hemorrhage (basal ganglionic, thalamic) or infarction (large middle cerebral artery territory) with secondary brainstem compression
   b. Brainstem infarction due to basilar artery thrombosis or embolism
   c. Brain abscess, subdural empyema
   d. Epidural and subdural hemorrhage, brain contusion
   e. Brain tumor with surrounding edema
   f. Cerebellar and pontine hemorrhage and infarction
   g. Widespread traumatic brain injury
   h. Metabolic coma (see above) with preexisting focal damage
   i. Miscellaneous: cortical vein thrombosis, herpes simplex encephalitis, multiple cerebral emboli due to bacterial endocarditis, acute hemorrhagic leukoencephalitis, acute disseminated (postinfectious) encephalomyelitis, thrombotic thrombocytopenic purpura, cerebral vasculitis, gliomatosis cerebri, pituitary apoplexy, intravascular lymphoma, etc.

Note: CSF, cerebrospinal fluid; WBCs, white blood cells; RBCs, red blood cells.

Cerebrovascular diseases cause the greatest difficulty in coma diagnosis (Chap. 364). The most common categories are: (1) basal ganglia and thalamic hemorrhage (acute but not instantaneous onset, vomiting, headache, hemiplegia, and characteristic eye signs); (2) pontine hemorrhage (sudden onset, pinpoint pupils, loss of reflex eye movements and corneal responses, ocular bobbing, posturing, hyperventilation, and excessive sweating); (3) cerebellar hemorrhage (occipital headache, vomiting, gaze paresis, and inability to stand); (4) basilar artery thrombosis (neurologic prodrome or warning spells, diplopia, dysarthria, vomiting, eye movement and corneal response abnormalities, and asymmetric limb paresis); and (5) subarachnoid hemorrhage (precipitous coma after headache and vomiting). The most common stroke, infarction in the territory of the middle cerebral artery, does not generally cause coma, but edema surrounding large infarcts may expand during the first few days and act as a mass. The syndrome of acute hydrocephalus accompanies many intracranial diseases, particularly subarachnoid hemorrhage. It is characterized by headache and sometimes vomiting that may progress quickly to coma, with extensor posturing of the limbs, bilateral Babinski signs, small unreactive pupils, and impaired oculocephalic movements in the vertical direction.

If the history and examination do not indicate the cause of coma, then information obtained from CT or MRI may be needed. The majority of medical causes of coma can be established without a neuroimaging study.

BRAIN DEATH

This is a state of cessation of cerebral function while somatic function is maintained by artificial means and the heart continues to pump. It is the only type of brain damage that is recognized as equivalent to death. Several similar criteria have been advanced for the diagnosis of brain death, and it is essential to adhere to those standards endorsed by the local medical community. Ideal criteria are simple, can be assessed at the bedside, and allow no chance of diagnostic error. They contain three essential elements of clinical evidence: (1) widespread cortical destruction that is reflected by deep coma and unresponsiveness to all forms of stimulation; (2) global brainstem damage demonstrated by absent pupillary light reaction and by the loss of oculovestibular and corneal reflexes; and (3) destruction of the medulla manifested by complete apnea. The pulse rate is invariant and unresponsive to atropine. Diabetes insipidus is often present but may develop hours or days after the other clinical signs of brain death. The pupils are often enlarged but may be mid-sized; they should not, however, be constricted. The absence of deep tendon reflexes is not required because the spinal cord remains functional. There may or may not be Babinski signs.

Demonstration that apnea is due to irreversible medullary damage requires that the P_{CO_2} be high enough to stimulate respiration during a test of spontaneous breathing. *Apnea testing* can be done safely by the use of diffusion oxygenation prior to removing the ventilator. This is accomplished by preoxygenation with 100% oxygen, which is then sustained during the test by oxygen administered through a tracheal cannula. CO_2 tension increases ~0.3–0.4 kPa/min (2–3 mmHg/min) during apnea. At the end of the period of observation, typically several minutes, arterial P_{CO_2} should be at least >6.6–8.0 kPa (50–60 mmHg) for the test to be valid. Apnea is confirmed if no respiratory effort is observed in the presence of a sufficiently elevated P_{CO_2}.

The possibility of profound drug-induced or hypothermic depression of the nervous system should be excluded, and some period of observation, usually 6–24 h, is desirable during which the signs of brain death are sustained. It is advisable to delay clinical testing for at least 24 h if a cardiac arrest has caused brain death or if the inciting disease is not known. An isoelectric EEG may be used as a confirmatory test for total cerebral damage. Radionuclide brain scanning, cerebral angiography, or transcranial Doppler measurements may also be used to demonstrate the absence of cerebral blood flow but they have not been extensively correlated with pathologic changes.

Although it is largely accepted in western society that the respirator can be disconnected from a brain-dead patient, problems frequently arise because of poor communication and inadequate preparation of the family by the physician. Reasonable medical practice allows the removal of support or transfer out of an intensive care unit of patients who are not brain dead but whose condition is nonetheless hopeless and are likely to live for only a brief time.

Rx COMA

The immediate goal in a comatose patient is prevention of further nervous system damage. Hypotension, hypoglycemia, hypercalcemia, hypoxia, hypercapnia, and hyperthermia should be corrected rapidly. An oropharyngeal airway is adequate to keep the pharynx open in drowsy patients who are breathing normally. Tracheal intubation is indicated if there is apnea, upper airway obstruction, hypoventilation, or emesis, or if the patient is liable to aspirate because of coma. Mechanical ventilation is required if there is hypoventilation or a need to induce hypocapnia in order to lower ICP as described below. IV access is established, and naloxone and dextrose are administered if narcotic overdose or hypoglycemia are even remote possibilities; thiamine is given along with glucose to avoid provoking Wernicke disease in malnourished patients. In cases of suspected basilar thrombosis with brainstem ischemia, IV heparin or a thrombolytic agent is often utilized, after cerebral hemorrhage has been excluded by a neuroimaging study. Physostigmine may awaken patients with anticholinergic-type drug overdose but should be used only by experienced physicians and with careful monitoring; many physicians believe that it should only be used to treat anticholinergic overdose-associated cardiac arrhythmias. The use of benzodiazepine antagonists offers some prospect of improvement after overdoses of soporific drugs and has transient benefit in hepatic encephalopathy. IV administration of hypotonic solutions should be monitored carefully in any serious acute brain illness because of the potential for exacerbating brain swelling. Cervical spine injuries must not be overlooked, particularly prior to attempting intubation or evaluating of oculocephalic responses. Fever and meningismus indicate an urgent need for examination of the CSF to diagnose meningitis. If the lumbar puncture in a case of suspected meningitis is delayed for any reason, an antibiotic such as a third-generation cephalosporin should be administered as soon as possible, preferably after obtaining blood cultures. The management of raised ICP is discussed in Chap. 269.

PROGNOSIS

One hopes to avoid the emotionally painful, hopeless outcome of a patient who is left severely disabled or vegetative. The uniformly poor outcome of the persistent vegetative state has already been mentioned. Children and young adults may have ominous early clinical findings such as abnormal brainstem reflexes and yet recover, so that temporization in offering a prognosis in this group of patients is wise. Metabolic comas have a far better prognosis than traumatic ones. All systems for estimating prognosis in adults should be taken as approximations, and medical judgments must be tempered by factors such as age, underlying systemic disease, and general medical condition. In an attempt to collect prognostic information from large numbers of patients with head injury, the Glasgow Coma Scale was devised; empirically it has predictive value in cases of brain trauma (Table 373-2). For anoxic and metabolic coma, clinical signs such as the pupillary and motor responses after 1 day, 3 days, and 1 week have been shown to have predictive value (Fig. 269-4). The absence of the cortical waves of the somatosensory evoked potentials has also proved a strong indicator of poor outcome in coma from any cause.

269 Neurologic Critical Care, Including Hypoxic-Ischemic Encephalopathy and Subarachnoid Hemorrhage

J. Claude Hemphill III, Wade S. Smith

Life-threatening neurologic illness may be caused by a primary disorder affecting any region of the neuraxis or may occur as a consequence of a systemic disorder such as hepatic failure, multisystem organ failure, or cardiac arrest (Table 269-1). Neurologic critical care focuses on preservation of neurologic tissue and prevention of secondary brain injury caused by ischemia, edema, and elevated intracranial pressure (ICP).

PATHOPHYSIOLOGY

Brain Edema Swelling, or edema, of brain tissue occurs with many types of brain injury. The two principal types of edema are vasogenic and cytotoxic. *Vasogenic edema* refers to the influx of fluid and solutes into the brain through an incompetent blood-brain barrier (BBB). In the normal cerebral vasculature, endothelial tight junctions associated with astrocytes create an impermeable barrier (the BBB), through which access into the brain interstitium is dependent upon specific transport mechanisms (Chap. 360). The BBB may be compromised in ischemia, trauma, infection, and metabolic derangements. Typically, vasogenic edema develops rapidly following injury. *Cytotoxic edema* refers to cellular swelling and occurs in a variety of settings including brain ischemia and trauma. Early astrocytic swelling is a hallmark of ischemia. Brain edema that is clinically significant usually represents a combination of vasogenic and cellular components. Edema can lead to increased ICP as well as tissue shifts and brain displacement from focal processes (Chap. 268). These tissue shifts can cause injury by mechanical distraction and compression in addition to the ischemia of impaired perfusion consequent to the elevated ICP.

Ischemic Cascade and Cellular Injury When delivery of substrates, principally oxygen and glucose, is inadequate to sustain cellular function, a series of interrelated biochemical reactions known as the *ischemic cascade* is initiated (see Fig. 364-2). The release of excitatory amino acids, especially glutamate, leads to influx of calcium and sodium ions, which disrupt cellular homeostasis. An increased intracellular calcium concentration may activate proteases and lipases, which then lead to lipid peroxidation and free radical–mediated cell membrane injury. Cytotoxic edema ensues, and ultimately necrotic cell death and tissue infarction occur. This pathway to irreversible cell death is common to ischemic stroke, global cerebral ischemia, and traumatic brain injury. *Penumbra* refers to ischemic brain tissue that has not yet undergone irreversible infarction, implying that the region is potentially salvageable if ischemia can be reversed. Factors that may exacerbate ischemic brain injury include systemic hypotension and hypoxia, which further reduce substrate delivery to vulnerable brain tissue, and fever, seizures, and hyperglycemia, which can increase cellular metabolism outstripping compensatory processes. Clinically, these events are known as *secondary brain insults* because they lead to exacerbation of the primary brain injury. Prevention, identification, and treatment of secondary brain insults are fundamental goals of management.

An alternative pathway of cellular injury is *apoptosis*. This process implies programmed cell death, which may occur in the setting of ischemic stroke, global cerebral ischemia, traumatic brain injury, and possibly intracerebral hemorrhage. Apoptotic cell death can be distinguished histologically from the necrotic cell death of ischemia and is mediated through a different set of biochemical pathways. At present, interventions for prevention and treatment of apoptotic cell death remain less well defined than those for ischemia. **Excitotoxicity and mechanisms of cell death are discussed in more detail in Chap. 360.**

TABLE 269-1 NEUROLOGIC DISORDERS IN CRITICAL ILLNESS

Localization Along Neuroaxis	Syndrome
Central Nervous System	
Brain: Cerebral hemispheres	Global encephalopathy
	Sepsis
	Organ failure—hepatic, renal
	Medication related
	Sedatives/hypnotics/analgesics
	H_2 blockers, antihypertensives
	Drug overdose
	Electrolyte disturbance—hyponatremia, hypoglycemia
	Hypotension/hypoperfusion
	Hypoxia
	Meningitis
	Subarachnoid hemorrhage
	Wernicke's disease
	Seizure—postictal or nonconvulsive status
	Hypertensive encephalopathy
	Hypothyroidism—myxedema
	Focal deficits
	Ischemic stroke
	Tumor
	Abscess, subdural empyema
	Subdural/epidural hematoma
Brainstem	Mass effect and compression
	Ischemic stroke, intraparenchymal hemorrhage
	Hypoxia
Spinal cord	Mass effect and compression
	Disc herniation
	Epidural hematoma
	Ischemia—hypotension/embolic
	Subdural empyema
	Trauma, central cord syndrome
Peripheral Nervous System	
Peripheral nerve	
Axonal	Critical illness polyneuropathy
	Possible neuromuscular blocking agent complication
	Metabolic disturbances, uremia, hyperglycemia
	Medication effects—chemotherapeutic, antiretroviral
Demyelinating	Guillian-Barré syndrome

Cerebral Perfusion and Autoregulation Brain tissue requires constant perfusion in order to ensure adequate delivery of substrate. The hemodynamic response of the brain has the capacity to preserve perfusion across a wide range of systemic blood pressures. Cerebral perfusion pressure (CPP), defined as the mean systemic arterial pressure (MAP) minus the ICP, provides the driving force for circulation across the capillary beds of the brain. *Autoregulation* refers to the physiologic response whereby cerebral blood flow (CBF) remains relatively constant over a wide range of blood pressures as a consequence of alterations of cerebrovascular resistance (Fig. 269-1). If systemic blood pressure drops, cerebral perfusion is preserved through vasodilatation of arterioles in the brain; likewise, arteriolar vasoconstriction occurs at high systemic pressures to prevent hyperperfusion. At the extreme limits of MAP or CPP (high or low), flow becomes directly related to perfusion pressure. These autoregulatory changes occur in the microcirculation

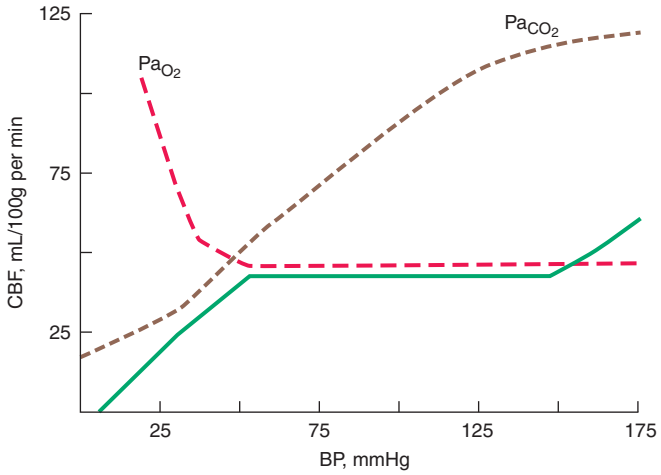

FIGURE 269-1 Autoregulation of cerebral blood flow (solid line). Cerebral perfusion is constant over a wide range of systemic blood pressure. Perfusion is increased in the setting of hypoxia or hypercarbia. BP, blood pressure; CBF, cerebral blood flow. *(Reprinted with permission from Anesthesiology 43:447, 1975. Copyright 1975, Lippincott Company.)*

and are mediated by vessels below the resolution of those seen on angiography. CBF is also strongly influenced by pH and P_{CO_2}. CBF increases with hypercapnia and acidosis and decreases with hypocapnia and alkalosis. This forms the basis for the use of hyperventilation to lower ICP, and this effect on ICP is mediated through a decrease in intracranial blood volume. Cerebral autoregulation is critical to the normal homeostatic functioning of the brain, and this process may be disordered focally and unpredictably in disease states such as traumatic brain injury and severe focal cerebral ischemia.

Cerebrospinal Fluid and Intracranial Pressure The cranial contents consist essentially of brain, cerebrospinal fluid (CSF), and blood. CSF is produced principally in the choroid plexus of each lateral ventricle, exits the brain via the foramina of Luschka and Magendi, and flows over the cortex to be absorbed into the venous system along the superior sagittal sinus. Approximately 150 mL of CSF are contained within the ventricles and surrounding the brain and spinal cord; the cerebral blood volume is also ~150 mL. The bony skull offers excellent protection for the brain but allows little tolerance for additional volume. Significant increases in volume eventually result in increased ICP. Obstruction of CSF outflow, edema of cerebral tissue, or increases in volume from tumor or hematoma may increase ICP. Elevated ICP diminishes cerebral perfusion and can lead to tissue ischemia. Ischemia in turn may lead to vasodilatation via autoregulatory mechanisms designed to restore cerebral perfusion. However, vasodilatation also increases cerebral blood volume, which in turn then increases ICP, lowers CPP, and provokes further ischemia (Fig. 269-2). This vicious cycle is commonly seen in traumatic brain injury, massive intracerebral hemorrhage, and large hemispheric infarcts with significant tissue shifts.

APPROACH TO THE PATIENT: Severe CNS Dysfunction

Critically ill patients with severe central nervous system dysfunction require rapid evaluation and intervention in order to limit primary and secondary brain injury. Initial neurologic evaluation should be performed concurrent with stabilization of basic respiratory, cardiac, and hemodynamic parameters. Significant barriers may exist to neurologic assessment in the critical care unit, including endotracheal intubation and the use of sedative or paralytic agents to facilitate procedures.

An impaired level of consciousness is common in critically ill patients. The essential first task in assessment is to determine whether the cause of dysfunction is related to a diffuse, usually

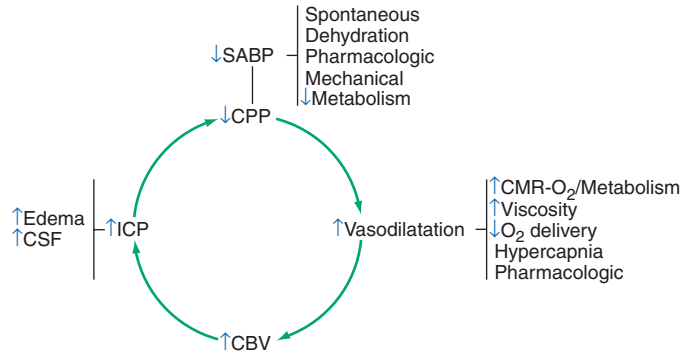

FIGURE 269-2 Ischemia and vasodilatation. Reduced cerebral perfusion pressure (CPP) leads to increased ischemia, vasodilatation, increased intracranial pressure (ICP), and further reductions in CPP, a cycle leading to further neurologic injury. CBV, cerebral blood volume; CMR, cerebral metabolic rate; CSF, cerebrospinal fluid; SABP, systolic arterial blood pressure. *(Adapted from MJ Rosner et al: J Neurosurg 83:949, 1995; with permission.)*

metabolic, process or whether a focal, usually structural, process is implicated. Examples of diffuse processes include metabolic encephalopathies related to organ failure, drug overdose, or hypoxia-ischemia. Focal processes include ischemic and hemorrhagic stroke and traumatic brain injury, especially with intracranial hematomas. Since these two categories of disorders have fundamentally different causes, treatments, and prognoses, the initial focus is on making this distinction rapidly and accurately. **The approach to the comatose patient is discussed in Chap. 268; etiologies are listed in Table 268-1.**

Minor focal deficits may be present on the neurologic examination in patients with metabolic encephalopathies. However, the finding of prominent focal signs such as pupillary asymmetry, hemiparesis, gaze palsy, or paraplegia should suggest the possibility of a structural lesion. All patients with a decreased level of consciousness associated with focal findings should undergo an urgent neuroimaging procedure, as should all patients with coma of unknown etiology. CT scanning is usually the most appropriate initial study because it can be performed quickly in critically ill patients and demonstrates hemorrhage, hydrocephalus, and intracranial tissue shifts well. MRI may provide more specific information in some situations, such as acute ischemic stroke (diffusion-weighted imaging, DWI) and cerebral venous sinus thrombosis (magnetic resonance venography, MRV). Any suggestion of trauma from the history or examination should alert the examiner to the possibility of cervical spine injury and prompt an imaging evaluation using plain x-rays, MRI, or CT.

Other diagnostic studies are best utilized in specific circumstances, usually when neuroimaging studies fail to reveal a structural lesion and the etiology of the altered mental state remains uncertain. Electroencephalography (EEG) can be important in the evaluation of critically ill patients with severe brain dysfunction. The EEG of metabolic encephalopathy typically reveals generalized slowing. One of the most important uses of EEG is to help exclude inapparent seizures, especially nonconvulsive status epilepticus. Untreated continuous or frequently recurrent seizures may cause neuronal injury, making the diagnosis and treatment of seizures crucial in this patient group. Lumbar puncture (LP) may be necessary to exclude infectious processes, and an elevated opening pressure may be an important clue to cerebral venous sinus thrombosis. In patients with coma or profound encephalopathy, it is preferable to perform a neuroimaging study prior to LP. If bacterial meningitis is suspected, an LP may be performed first or antibiotics may be empirically administered before the diagnostic studies are completed. Standard laboratory evaluation of critically ill patients should include assessment of serum electrolytes (especially

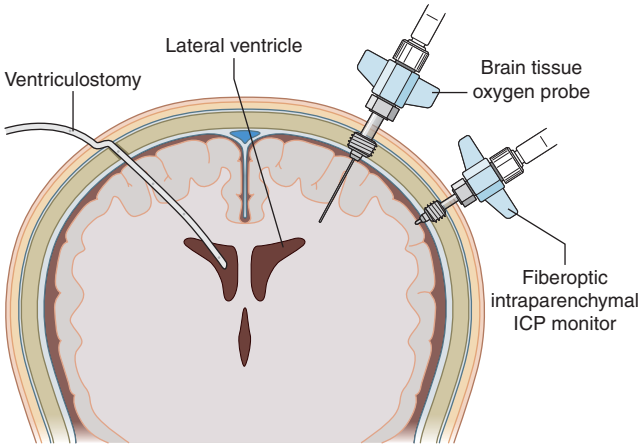

FIGURE 269-3 Intracranial pressure and brain tissue oxygen monitoring. A ventriculostomy allows for drainage of cerebrospinal fluid to treat elevated intracranial pressure (ICP). Fiberoptic ICP and brain tissue oxygen monitors are usually secured using a screwlike skull bolt. Cerebral blood flow and microdialysis probes (not shown) may be placed in a manner similar to the brain tissue oxygen probe.

sodium and calcium), glucose, renal and hepatic function, complete blood count, and coagulation. Serum or urine toxicology screens should be performed in patients with encephalopathy of unknown cause. EEG, LP, and other specific laboratory tests are most useful when the mechanism of the altered level of consciousness is uncertain; they are not routinely performed in clear-cut cases of stroke or traumatic brain injury.

Monitoring of ICP can be an important tool in selected patients. In general, patients who should be considered for ICP monitoring are those with primary neurologic disorders, such as stroke or traumatic brain injury, who are at significant risk for secondary brain injury due to elevated ICP and decreased CPP. Included are patients with the following: severe traumatic brain injury [Glasgow Coma Scale (GCS) score ≤ 8 (Table 373-2)]; large tissue shifts from supratentorial ischemic or hemorrhagic stroke; or hydrocephalus from subarachnoid hemorrhage (SAH), intraventricular hemorrhage, or posterior fossa stroke. An additional disorder in which ICP monitoring can add important information is fulminant hepatic failure, in which elevated ICP may be treated with barbiturates or, eventually, liver transplantation. In general, ventriculostomy is preferable to ICP monitoring devices that are placed in the brain parenchyma, because ventriculostomy allows CSF drainage as a method of treating elevated ICP. However, parenchymal ICP monitoring is most appropriate for patients with diffuse edema and small ventricles (which may make ventriculostomy placement more difficult) or any degree of coagulopathy (in which ventriculostomy carries a higher risk of hemorrhagic complications) (Fig 269-3).

Treatment of Elevated ICP Elevated ICP may occur in a wide range of disorders including head trauma, intracerebral hemorrhage, SAH with hydrocephalus, and fulminant hepatic failure. Because CSF and blood volume can be redistributed initially, by the time elevated ICP occurs intracranial compliance is severely impaired. At this point, any small increase in the volume of CSF, intravascular blood, edema, or a mass lesion may result in a significant increase in ICP and a decrease in cerebral perfusion. This is a fundamental mechanism of secondary ischemic brain injury and constitutes an emergency that requires immediate attention. In general, ICP should be maintained at <20 mmHg and CPP should be maintained at ≤60 mmHg.

Interventions to lower ICP are ideally based on the underlying mechanism responsible for the elevated ICP (Table 269-2). For example, in hydrocephalus from SAH, the principal cause of elevated ICP is impairment of CSF drainage. In this setting, ventricular drainage of CSF is likely to be sufficient and most appropriate. In head trauma and stroke, cytotoxic edema may be most responsible, and the use of osmotic diuretics such as mannitol becomes an appropriate early step. As described above, elevated ICP may cause tissue ischemia, and, if cerebral autoregulation is intact, the resulting vasodilatation can lead to a cycle of worsening ischemia. Paradoxically, administration of vasopressor agents to increase mean arterial pressure may actually lower ICP by improving perfusion, thereby allowing autoregulatory vasoconstriction as ischemia is relieved and ultimately decreasing intracranial blood volume.

Early signs of elevated ICP include drowsiness and a diminished level of consciousness. Neuroimaging studies may reveal evidence of edema and mass effect. Hypotonic IV fluids should be avoided, and elevation of the head of the bed is recommended. Patients must be carefully observed for risk of aspiration and compromise of the airway as the level of alertness declines. Coma and unilateral pupillary changes are late signs and require immediate intervention. Emergent treatment of elevated ICP is most quickly achieved by intubation and hyperventilation, which causes vasoconstriction and reduces cerebral blood volume. In order to avoid provoking or worsening cerebral ischemia, hyperventilation is best used for short periods of time until a more definitive treatment can be instituted. Furthermore, the effects of hyperventilation on ICP are short-lived, often lasting only for several hours because of the buffering capacity of the cerebral interstitium, and rebound elevations of ICP may accompany abrupt discontinuation of hyperventilation. As the level of consciousness declines to coma, the ability to follow the neurologic status of the patient by examination deteriorates and measurement of ICP assumes greater importance. If a ventriculostomy device is in place, direct drainage of CSF to reduce ICP is possible. Finally, high-dose barbiturates, decompressive hemicraniectomy, or hypothermia are sometimes used for refractory elevations of ICP, although these have significant side effects and have not been proven to improve outcome.

Secondary Brain Insults Patients with primary brain injuries, whether due to trauma or stroke, are at risk for ongoing secondary ischemic brain injury. Because secondary brain injury can be a major determinant of a poor outcome, strategies for minimizing secondary brain insults are an integral part of the critical care of all patients. While elevated ICP may lead to secondary ischemia, most

TABLE 269-2 STEPWISE APPROACH TO TREATMENT OF ELEVATED INTRACRANIAL PRESSURE[a]

Insert ICP monitor—ventriculostomy versus parenchymal device
General goals: maintain ICP < 20 mmHg and CPP ≥ 60 mmHg
For ICP > 20–25 mmHg for >5 min:
1. Drain CSF via ventriculostomy (if in place)
2. Elevate head of the bed; midline head position
3. Osmotherapy—mannitol 25–100 g q4h as needed (maintain serum osmolality < 320 mosmol) or hypertonic saline (30 mL, 23.4% NaCl bolus)
4. Glucocorticoids—dexamethasone 4 mg q6h for vasogenic edema from tumor, abscess (avoid glucocorticoids in head trauma, ischemic and hemorrhagic stroke)
5. Sedation (e.g., morphine, propofol, or midazolam); add neuromuscular paralysis if necessary (patient will require endotracheal intubation and mechanical ventilation at this point, if not before)
6. Hyperventilation—to Pa_{CO_2} 30–35 mmHg
7. Pressor therapy—phenylephrine, dopamine, or norepinephrine to maintain adequate MAP to ensure CPP ≥ 60 mmHg (maintain euvolemia to minimize deleterious systemic effects of pressors)
8. Consider second-tier therapies for refractory elevated ICP
   a. High-dose barbiturate therapy ("pentobarb coma")
   b. Aggressive hyperventilation to Pa_{CO_2} < 30 mmHg
   c. Hypothermia
   d. Hemicraniectomy

[a]Throughout ICP treatment algorithm, consider repeat head CT to identify mass lesions amenable to surgical evacuation.
Note: CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; MAP, mean arterial pressure; Pa_{CO_2}, arterial partial pressure of carbon dioxide.

secondary brain injury is mediated through other clinical events that exacerbate the ischemic cascade already initiated by the primary brain injury. Episodes of secondary brain insults are usually not associated with apparent neurologic worsening. Rather, they lead to cumulative injury, which manifests as higher mortality or worsened long-term functional outcome. Thus, close monitoring of vital signs is important, as is early intervention to prevent secondary ischemia. Avoiding hypotension and hypoxia is critical, as significant hypotensive events (systolic blood pressure < 90 mmHg) as short as 10 min in duration have been shown to adversely influence outcome after traumatic brain injury. Even in patients with stroke or head trauma who do not require ICP monitoring, close attention to adequate cerebral perfusion is warranted. Hypoxia (pulse oximetry saturation < 90%), particularly in combination with hypotension, also leads to secondary brain injury. Likewise, fever and hyperglycemia both worsen experimental ischemia and have been associated with worsened clinical outcome after stroke and head trauma. Aggressive control of fever with a goal of normothermia is warranted but may be difficult to achieve with antipyretic medications and cooling blankets. The value of newer surface or intravascular temperature control devices for the management of refractory fever is under investigation. The use of IV insulin infusion is encouraged for control of hyperglycemia as this allows better regulation of serum glucose levels than subcutaneous insulin. A reasonable goal is to maintain the serum glucose level at <7.8 mmol/L (<140 mg/dL), although some have suggested that even tighter control is warranted. New cerebral monitoring tools that allow continuous evaluation of brain tissue oxygen tension, CBF, and metabolism (via microdialysis) may further improve the management of secondary brain injury.

CRITICAL CARE DISORDERS OF THE CENTRAL NERVOUS SYSTEM

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

This occurs from lack of delivery of oxygen to the brain because of hypotension or respiratory failure. Causes include myocardial infarction, cardiac arrest, shock, asphyxiation, paralysis of respiration, and carbon monoxide or cyanide poisoning. In some circumstances, hypoxia may predominate. Carbon monoxide and cyanide poisoning are termed *histotoxic hypoxia* since they cause a direct impairment of the respiratory chain.

Clinical Manifestations Mild degrees of pure hypoxia, such as occur at high altitudes, cause impaired judgment, inattentiveness, motor incoordination, and, at times, euphoria. However, with hypoxia-ischemia, such as occurs with circulatory arrest, consciousness is lost within seconds. If circulation is restored within 3–5 min, full recovery may occur, but if hypoxia-ischemia lasts beyond 3–5 min, some degree of permanent cerebral damage is the rule. Except in extreme cases, it may be difficult to judge the precise degree of hypoxia-ischemia, and some patients make a relatively full recovery after even 8–10 min of global cerebral ischemia. The distinction between pure hypoxia and hypoxia-ischemia is important, since a Pa_{O_2} as low as 20 mmHg (2.7 kPa) can be well tolerated if it develops gradually and normal blood pressure is maintained, but short durations of very low or absent cerebral circulation may result in permanent impairment.

Clinical examination at different time points after a hypoxic-ischemic insult (especially cardiac arrest) is useful in assessing prognosis for long-term neurologic outcome. The prognosis is better for patients with intact brainstem function, as indicated by normal pupillary light responses and intact oculocephalic (doll's-eyes), oculovestibular (caloric), and corneal reflexes (Fig. 269-4). Absence of these reflexes and the presence of persistently dilated pupils that do not react to light are grave prognostic signs. A uniformly dismal prognosis from hypoxic-ischemic coma is conveyed by an absent pupillary light reflex or extensor or absent motor response to pain on day 3 following the injury. Electrophysiologically, the bilateral absence of the N20 component of

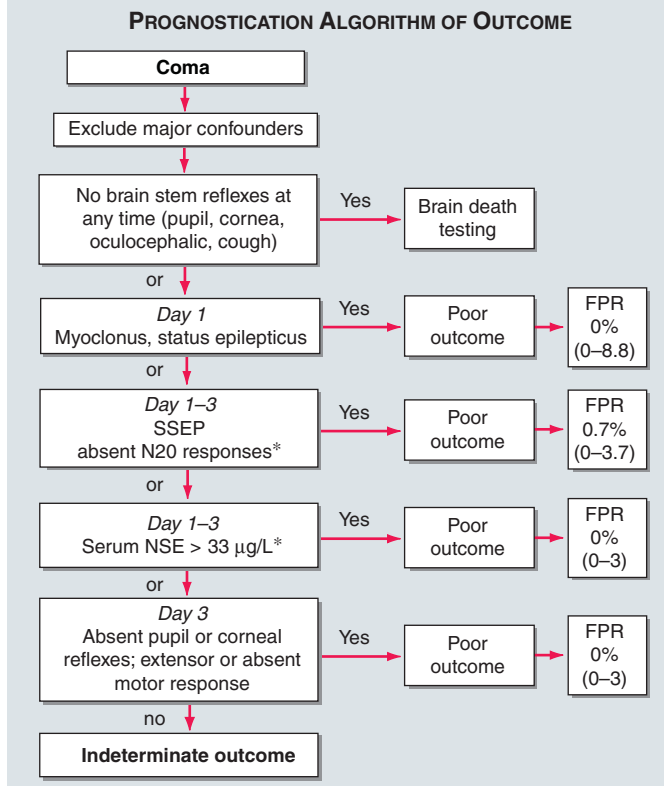

FIGURE 269-4 Prognostication of outcome in comatose survivors of cardiopulmonary resuscitation. Numbers in parentheses are 95% confidence intervals. Confounders could include use of sedatives or neuromuscular blocking agents, hypothermia therapy, organ failure, or shock. Tests denoted with an * may not be available in a timely and standardized manner. SSEP, somatosensory evoked potentials; NSE, neuron-specific enolase; FPR, false-positive rate (Chap. 3). *(From Wijdicks et al, with permission.)*

the somatosensory evoked response (SSEPs) in the first several days also conveys a poor prognosis. A very elevated serum level (>33 µg/L) of the biochemical marker neuron-specific enolase (NSE) is indicative of brain damage after resuscitation from cardiac arrest and predicts a poor outcome. However, at present, SSEPs and NSE levels may be difficult to obtain in a timely fashion, with SSEP testing requiring substantial expertise in interpretation and NSE measurements not yet standardized. Whether administration of mild hypothermia after cardiac arrest (see "Treatment") will alter the usefulness of these clinical and electrophysiologic predictors is unknown. Long-term consequences of hypoxic-ischemic encephalopathy include persistent coma or a vegetative state (Chap. 268), dementia, visual agnosia (Chap. 27), parkinsonism, choreoathetosis, cerebellar ataxia, myoclonus, seizures, and an amnestic state, which may be a consequence of selective damage to the hippocampus.

Pathology Principal histologic findings are extensive multifocal or diffuse laminar cortical necrosis (Fig. 269-5), with almost invariable involvement of the hippocampus. The hippocampal CA1 neurons are vulnerable to even brief episodes of hypoxia-ischemia, perhaps explaining why selective persistent memory deficits may occur after brief cardiac arrest. Scattered small areas of infarction or neuronal loss may be present in the basal ganglia, hypothalamus, or brainstem. In some cases, extensive bilateral thalamic scarring may affect pathways that mediate arousal, and this pathology may be responsible for the persistent vegetative state. A specific form of hypoxic-ischemic encephalopathy, so-called watershed infarcts, occurs at the distal territories between the major cerebral arteries and can cause cognitive deficits, including visual agnosia, and weakness that is greater in proximal than in distal muscle groups.

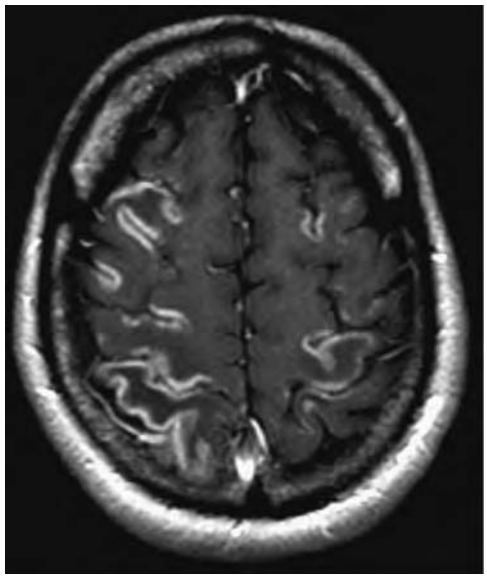

FIGURE 269-5 Cortical laminar necrosis in hypoxic-ischemic encephalopathy. T1-weighted postcontrast MRI shows cortical enhancement in a watershed distribution consistent with laminar necrosis.

Diagnosis Diagnosis is based upon the history of a hypoxic-ischemic event such as cardiac arrest. Blood pressure < 70 mmHg systolic or Pa_{O_2} < 40 mmHg is usually necessary, although both absolute levels as well as duration of exposure are important determinants of cellular injury. Carbon monoxide intoxication can be confirmed by measurement of carboxyhemoglobin and is suggested by a cherry red color of the skin, although the latter is an inconsistent clinical finding.

℞ HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Treatment should be directed at restoration of normal cardiorespiratory function. This includes securing a clear airway, ensuring adequate oxygenation and ventilation, and restoring cerebral perfusion, whether by cardiopulmonary resuscitation, fluid, pressors, or cardiac pacing. Hypothermia may target the neuronal cell injury cascade and has substantial neuroprotective properties in experimental models of brain injury. In two trials, mild hypothermia (33°C) improved functional outcome in patients who remained comatose after resuscitation from a cardiac arrest. Treatment was initiated within minutes of cardiac resuscitation and continued for 12 h in one study and 24 h in the other. Potential complications of hypothermia include coagulopathy and an increased risk of infection. Based upon these studies, the International Liaison Committee on Resuscitation issued the following advisory statement in 2003: "Unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32°–34°C for 12–24 h when the initial rhythm was ventricular fibrillation."

Severe carbon monoxide intoxication may be treated with hyperbaric oxygen. Anticonvulsants may be needed to control seizures, although these are not usually given prophylactically. Posthypoxic myoclonus may respond to oral administration of clonazepam at doses of 1.5–10 mg daily or valproate at doses of 300–1200 mg daily in divided doses. Myoclonic status epilepticus within 24 h after a primary circulatory arrest portends a universally poor prognosis, even if seizures are controlled.

DELAYED POSTANOXIC ENCEPHALOPATHY

Delayed postanoxic encephalopathy is an uncommon phenomenon in which patients appear to make an initial recovery from hypoxic-ischemic insult but then develop a relapse characterized by apathy, confusion, and agitation. Progressive neurologic deficits may include shuffling gait, diffuse rigidity and spasticity, persistent parkinsonism or myoclonus, and, on occasion, coma and death after 1–2 weeks. Widespread cerebral demyelination may be present.

Carbon monoxide and cyanide intoxication can also cause a delayed encephalopathy. Little clinical impairment is evident when the patient first regains consciousness, but a parkinsonian syndrome characterized by akinesia and rigidity without tremor may develop. Symptoms can worsen over months, accompanied by increasing evidence of damage in the basal ganglia as seen on both CT and MRI.

METABOLIC ENCEPHALOPATHIES

Altered mental states, variously described as confusion, delirium, disorientation, and encephalopathy, are present in many patients with severe illness in an intensive care unit (ICU). Older patients are particularly vulnerable to delirium, a confusional state characterized by disordered perception, frequent hallucinations, delusions, and sleep disturbance. This is often attributed to medication effects, sleep deprivation, pain, and anxiety. The term *ICU psychosis* has been used to describe a mental state with profound agitation occurring in this setting. The presence of family members in the ICU may help to calm and orient agitated patients, and in severe cases, low doses of neuroleptics (e.g., haloperidol 0.5–1 mg) can be useful. Ultimately, the psychosis resolves with improvement in the underlying illness and a return to familiar surroundings.

In the ICU setting, several metabolic causes of an altered level of consciousness predominate. Hypercarbic encephalopathy can present with headache, confusion, stupor, or coma. Hypoventilation syndrome occurs most frequently in patients with a history of chronic CO_2 retention who are receiving oxygen therapy for emphysema or chronic pulmonary disease (Chap. 258). The elevated Pa_{CO_2} leading to CO_2 narcosis may have a direct anesthetic effect, and cerebral vasodilatation from increased Pa_{CO_2} can lead to increased ICP. Hepatic encephalopathy is suggested by asterixis and can occur in chronic liver failure or acute fulminant hepatic failure. Both hyperglycemia and hypoglycemia can cause encephalopathy, as can hypernatremia and hyponatremia. Confusion, impairment of eye movements, and gait ataxia are the hallmarks of acute Wernicke's disease (see below).

SEPTIC ENCEPHALOPATHY

Pathogenesis In patients with sepsis, the systemic response to infectious agents leads to the release of circulating inflammatory mediators that appear to contribute to encephalopathy. Critical illness, in association with the systemic inflammatory response syndrome (SIRS), can lead to multisystem organ failure. This syndrome can occur in the setting of apparent sepsis, severe burns, or trauma, even without clear identification of an infectious agent. Many patients with critical illness, sepsis, or SIRS develop encephalopathy without obvious explanation. This condition is broadly termed *septic encephalopathy*. While the specific mediators leading to neurologic dysfunction remain uncertain, it is clear that the encephalopathy is not simply the result of metabolic derangements of multiorgan failure. The cytokines tumor necrosis factor , interleukin (IL) 1, IL-2, and IL-6 are thought to play a role in this syndrome.

Diagnosis Septic encephalopathy presents clinically as a diffuse dysfunction of the brain without prominent focal findings. Confusion, disorientation, agitation, and fluctuations in level of alertness are typical. In more profound cases, especially with hemodynamic compromise, the decrease in level of alertness can be more prominent, at times resulting in coma. Hyperreflexia and frontal release signs such as a grasp or snout reflex (Chap. 27) can be seen. Abnormal movements such as myoclonus, tremor, or asterixis can occur. Septic encephalopathy is quite common, occurring in the majority of patients with sepsis and multisystem organ failure. Diagnosis is often difficult because of the multiple potential causes of neurologic dysfunction in critically ill patients and requires exclusion of structural, metabolic, toxic, and infectious (e.g., meningitis or encephalitis) causes. The mortality of patients with septic encephalopathy severe enough to produce coma approaches 50%, although this principally reflects the severity of the underlying critical illness and is not a singular result of the septic encephalopathy. Patients dying from severe sepsis or septic shock may have elevated levels of the serum brain injury biomarker S-100β and neuropathologic findings of neuronal apoptosis and cerebral ischemic

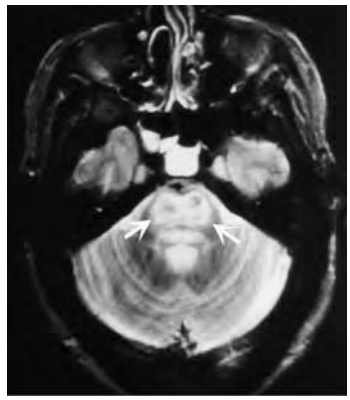

FIGURE 269-6 Central pontine myelinolysis. Axial T2-weighted MR scan through the pons reveals a symmetric area of abnormal high signal intensity within the basis pontis (*arrows*).

injury. However, successful treatment of the underlying critical illness almost always results in complete resolution of the encephalopathy, with profound long-term cognitive disability being uncommon.

CENTRAL PONTINE MYELINOLYSIS

This disorder typically presents in a devastating fashion as quadriplegia and pseudobulbar palsy. Predisposing factors include severe underlying medical illness or nutritional deficiency; most cases are associated with rapid correction of hyponatremia or with hyperosmolar states. The pathology consists of demyelination without inflammation in the base of the pons, with relative sparing of axons and nerve cells. MRI is useful in establishing the diagnosis (Fig. 269-6) and may also identify partial forms that present as confusion, dysarthria, and/or disturbances of conjugate gaze without quadriplegia. Occasional cases present with lesions outside of the brainstem. Therapeutic guidelines for the restoration of severe hyponatremia should aim for gradual correction, i.e., by ≥10 mmol/L (10 meq/L) within 24 h and 20 mmol/L (20 meq/L) within 48 h.

WERNICKE'S DISEASE

Wernicke's disease is a common and preventable disorder due to a deficiency of thiamine (Chap. 71). In the United States, alcoholics account for most cases, but patients with malnutrition due to hyperemesis, starvation, renal dialysis, cancer, AIDS, or rarely gastric surgery are also at risk. The characteristic clinical triad is that of ophthalmoplegia, ataxia, and global confusion. However, only one-third of patients with acute Wernicke's disease present with the classic clinical triad. Most patients are profoundly disoriented, indifferent, and inattentive, although rarely they have an agitated delirium related to ethanol withdrawal. If the disease is not treated, stupor, coma, and death may ensue. Ocular motor abnormalities include horizontal nystagmus on lateral gaze, lateral rectus palsy (usually bilateral), conjugate gaze palsies, and rarely ptosis. Gait ataxia probably results from a combination of polyneuropathy, cerebellar involvement, and vestibular paresis. The pupils are usually spared, but they may become miotic with advanced disease.

Wernicke's disease is usually associated with other manifestations of nutritional disease, such as polyneuropathy. Rarely, amblyopia or myelopathy occurs. Tachycardia and postural hypotension may be related to impaired function of the autonomic nervous system or to the coexistence of cardiovascular beriberi. Patients who recover show improvement in ocular palsies within hours after the administration of thiamine, but horizontal nystagmus may persist. Ataxia improves more slowly than the ocular motor abnormalities. Approximately half recover incompletely and are left with a slow, shuffling, wide-based gait and an inability to tandem walk. Apathy, drowsiness, and confusion improve more gradually. As these symptoms recede, an amnestic state with impairment in recent memory and learning may become more apparent (*Korsakoff's psychosis*). Korsakoff's psychosis is frequently persistent; the residual mental state is characterized by gaps in memory, confabulation, and disordered temporal sequencing.

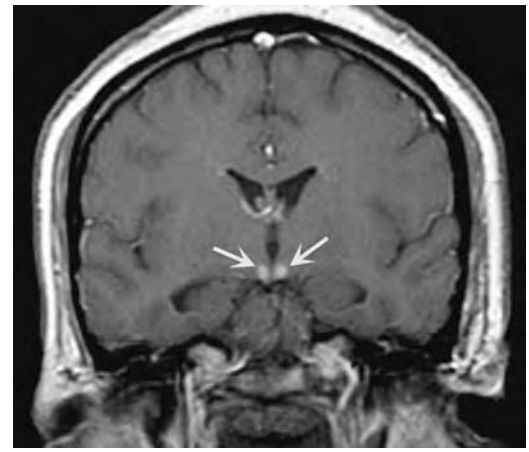

FIGURE 269-7 Wernicke's disease. Coronal T1-weighted postcontrast MRI reveals abnormal enhancement of the mammillary bodies (*arrows*), typical of acute Wernicke's encephalopathy.

Pathology Periventricular lesions surround the third ventricle, aqueduct, and fourth ventricle, with petechial hemorrhages in occasional acute cases and atrophy of the mamillary bodies in most chronic cases. There is frequently endothelial proliferation, demyelination, and some neuronal loss. These changes may be detected by MRI scanning (Fig. 269-7). The amnestic defect is related to lesions in the dorsal medial nuclei of the thalamus.

Pathogenesis Thiamine is a cofactor of several enzymes, including transketolase, pyruvate dehydrogenase, and α-ketoglutarate dehydrogenase. Thiamine deficiency produces a diffuse decrease in cerebral glucose utilization and results in mitochondrial damage. Glutamate accumulates owing to impairment of α-ketoglutarate dehydrogenase activity and, in combination with the energy deficiency, may result in excitotoxic cell damage.

℞ WERNICKE'S DISEASE

Wernicke's disease is a medical emergency and requires immediate administration of thiamine, in a dose of 100 mg either IV or IM. The dose should be given daily until the patient resumes a normal diet and should be begun prior to treatment with IV glucose solutions. Glucose infusions may precipitate Wernicke's disease in a previously unaffected patient or cause a rapid worsening of an early form of the disease. For this reason, thiamine should be administered to all alcoholic patients requiring parenteral glucose.

CRITICAL CARE DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM

Critical illness with disorders of the peripheral nervous system (PNS) arises in two contexts: (1) primary neurologic diseases that require critical care interventions such as intubation and mechanical ventilation, and (2) secondary PNS manifestations of systemic critical illness, often involving multisystem organ failure. The former include acute polyneuropathies such as Guillain-Barré syndrome (Chap. 380), neuromuscular junction disorders including myasthenia gravis (Chap. 381) and botulism (Chap. 134), and primary muscle disorders such as polymyositis (Chap. 383). The latter result either from the systemic disease itself or as a consequence of interventions.

General principles of respiratory evaluation in patients with PNS involvement, regardless of cause, include assessment of pulmonary mechanics, such as maximal inspiratory force (MIF) and vital capacity (VC), and evaluation of strength of bulbar muscles. Regardless of the cause of weakness, endotracheal intubation should be considered

when the MIF falls to <–25 cmH_2O or the VC is <1 L. Also, patients with severe palatal weakness may require endotracheal intubation in order to prevent acute upper airway obstruction or recurrent aspiration. Arterial blood gases and oxygen saturation from pulse oximetry are used to follow patients with potential respiratory compromise from PNS dysfunction. However, intubation and mechanical ventilation should be undertaken based on clinical assessment rather than waiting until oxygen saturation drops or CO_2 retention develops from hypoventilation. Noninvasive mechanical ventilation may be considered initially in lieu of endotracheal intubation but is generally insufficient in patients with severe bulbar weakness or ventilatory failure with hypercarbia. **Principles of mechanical ventilation are discussed in Chap. 263.**

NEUROPATHY

While encephalopathy may be the most obvious neurologic dysfunction in critically ill patients, dysfunction of the PNS is also quite common. It is typically present in patients with prolonged critical illnesses lasting several weeks and involving sepsis; clinical suspicion is aroused when there is failure to wean from mechanical ventilation despite improvement of the underlying sepsis and critical illness. *Critical illness polyneuropathy* refers to the most common PNS complication related to critical illness; it is seen in the setting of prolonged critical illness, sepsis, and multisystem organ failure. Neurologic findings include diffuse weakness, decreased reflexes, and distal sensory loss. Electrophysiologic studies demonstrate a diffuse, symmetric, distal axonal sensorimotor neuropathy, and pathologic studies have confirmed axonal degeneration. The precise mechanism of critical illness polyneuropathy remains unclear, but circulating factors such as cytokines, which are associated with sepsis and SIRS, are thought to play a role. It has been reported that up to 70% of patients with the sepsis syndrome have some degree of neuropathy, although far fewer have a clinical syndrome profound enough to cause severe respiratory muscle weakness requiring prolonged mechanical ventilation or resulting in failure to wean. Recent studies suggest that aggressive glycemic control with insulin infusions decreases the risk of critical illness polyneuropathy. Treatment is supportive, with specific intervention directed at treating the underlying illness. While spontaneous recovery is usually seen, the time course may extend over weeks to months and necessitate long-term ventilatory support and care even after the underlying critical illness has resolved.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

A defect in neuromuscular transmission may be a source of weakness in critically ill patients. Myasthenia gravis may be a consideration; however, persistent weakness secondary to impaired neuromuscular junction transmission is almost always due to administration of drugs. A number of medications impair neuromuscular transmission; these include antibiotics, especially aminoglycosides, and beta-blocking agents. In the ICU, the nondepolarizing neuromuscular blocking agents (nd-NMBAs), also known as muscle relaxants, are most commonly responsible. Included in this group of drugs are such agents as pancuronium, vecuronium, rocuronium, and atracurium. They are often used to facilitate mechanical ventilation or other critical care procedures, but with prolonged use persistent neuromuscular blockade may result in weakness even after discontinuation of these agents hours or days earlier. Risk factors for this prolonged action of neuromuscular blocking agents include female sex, metabolic acidosis, and renal failure.

Prolonged neuromuscular blockade does not appear to produce permanent damage to the PNS. Once the offending medications are discontinued, full strength is restored, although this may take days. In general, the lowest dose of neuromuscular blocking agent should be used to achieve the desired result, and, when these agents are used in the ICU, a peripheral nerve stimulator should be used to monitor neuromuscular junction function.

MYOPATHY

Critically ill patients, especially those with sepsis, frequently develop muscle wasting, often in the face of seemingly adequate nutritional support. The assumption has been that this represents a catabolic myopathy brought about as a result of multiple factors, including elevated cortisol and catecholamine release and other circulating factors induced by the SIRS. In this syndrome, known as *cachectic myopathy*, serum creatine kinase levels and electromyography (EMG) are normal. Muscle biopsy shows type II fiber atrophy. Panfascicular muscle fiber necrosis may also occur in the setting of profound sepsis. This so-called *septic myopathy* is characterized clinically by weakness progressing to a profound level over just a few days. There may be associated elevations in serum creatine kinase and urine myoglobin. Both EMG and muscle biopsy may be normal initially but eventually show abnormal spontaneous activity and panfascicular necrosis with an accompanying inflammatory reaction. Both of these myopathic syndromes may be considered under the broader heading of *critical illness myopathy*.

Acute quadriplegic myopathy describes a clinical syndrome of severe weakness seen in the setting of glucocorticoid and nd-NMBA use. The most frequent scenario in which this is encountered is the asthmatic patient who requires high-dose glucocorticoids and nd-NMBA to facilitate mechanical ventilation. This muscle disorder is not due to prolonged action of nd-NMBAs at the neuromuscular junction but, rather, is an actual myopathy with muscle damage; it has occasionally been described with high-dose glucocorticoid use alone. Clinically this syndrome is most often recognized when a patient fails to wean from mechanical ventilation despite resolution of the primary pulmonary process. Pathologically, there may be vacuolar changes in both type I and type II muscle fibers with evidence of regeneration. Acute quadriplegic myopathy has a good prognosis. If patients survive their underlying critical illness, the myopathy invariably improves and most patients return to normal. However, because this syndrome is a result of true muscle damage, not just prolonged blockade at the neuromuscular junction, this process may take weeks or months, and tracheostomy with prolonged ventilatory support may be necessary. Some patients do have residual long-term weakness, with atrophy and fatigue limiting ambulation. At present, it is unclear how to prevent this myopathic complication, except by avoiding use of nd-NMBAs, a strategy not always possible. Monitoring with a peripheral nerve stimulator can help to avoid the overuse of these agents. However, this is more likely to prevent the complication of prolonged neuromuscular junction blockade than it is to prevent this myopathy.

SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage (SAH) renders the brain critically ill from both primary and secondary brain insults. Excluding head trauma, the most common cause of SAH is rupture of a saccular aneurysm. Other causes include bleeding from a vascular malformation (arteriovenous malformation or dural arterial-venous fistula) and extension into the subarachnoid space from a primary intracerebral hemorrhage. Some idiopathic SAHs are localized to the perimesencephalic cisterns and are benign; they probably have a venous or capillary source, and angiography is unrevealing.

Saccular ("Berry") Aneurysm Autopsy and angiography studies have found that about 2% of adults harbor intracranial aneurysms, for a prevalence of 4 million persons in the United States; the aneurysm will rupture, producing SAH, in 25,000–30,000 cases per year. For patients who arrive alive at hospital, the mortality rate over the next month is about 45%. Of those who survive, more than half are left with major neurologic deficits as a result of the initial hemorrhage, cerebral vasospasm with infarction, or hydrocephalus. If the patient survives but the aneurysm is not obliterated, the rate of rebleeding is about 20% in the first 2 weeks, 30% in the first month, and about 3% per year afterwards. Given these alarming figures, the major therapeutic emphasis is on preventing the predictable early complications of the SAH.

Unruptured, asymptomatic aneurysms are much less dangerous than a recently ruptured aneurysm. The annual risk of rupture for aneurysms <10 mm in size is ~0.1%, and for aneurysms ≥10 mm in size is ~0.5–1%; the surgical morbidity far exceeds these percentages. Because

of the longer length of exposure to risk of rupture, younger patients with aneurysms >10 mm in size may benefit from prophylactic treatment. As with the treatment of asymptomatic carotid stenosis, this risk-benefit strongly depends on the complication rate of treatment.

Giant aneurysms, those >2.5 cm in diameter, occur at the same sites (see below) as small aneurysms and account for 5% of cases. The three most common locations are the terminal internal carotid artery, middle cerebral artery (MCA) bifurcation, and top of the basilar artery. Their risk of rupture is ~6% in the first year after identification and may remain high indefinitely. They often cause symptoms by compressing the adjacent brain or cranial nerves.

Mycotic aneurysms are usually located distal to the first bifurcation of major arteries of the circle of Willis. Most result from infected emboli due to bacterial endocarditis causing septic degeneration of arteries and subsequent dilatation and rupture. Whether these lesions should be sought and repaired prior to rupture or left to heal spontaneously is controversial.

PATHOPHYSIOLOGY Saccular aneurysms occur at the bifurcations of the large to medium-sized intracranial arteries; rupture is into the subarachnoid space in the basal cisterns and often into the parenchyma of the adjacent brain. Approximately 85% of aneurysms occur in the anterior circulation, mostly on the circle of Willis. About 20% of patients have multiple aneurysms, many at mirror sites bilaterally. As an aneurysm develops, it typically forms a neck with a dome. The length of the neck and the size of the dome vary greatly and are factors that are important in planning neurosurgical obliteration or endovascular embolization. The arterial internal elastic lamina disappears at the base of the neck. The media thins, and connective tissue replaces smooth-muscle cells. At the site of rupture (most often the dome) the wall thins, and the tear that allows bleeding is often ≤0.5 mm long. Aneurysm size and site are important in predicting risk of rupture. Those >7 mm in diameter and those at the top of the basilar artery and at the origin of the posterior communicating artery are at greater risk of rupture.

CLINICAL MANIFESTATIONS Most unruptured intracranial aneurysms are completely asymptomatic. Symptoms are usually due to rupture and resultant SAH, although some present with mass effect on cranial nerves or brain parenchyma. At the moment of aneurysmal rupture with major SAH, the ICP suddenly rises. This may account for the sudden transient loss of consciousness that occurs in nearly half of patients. Sudden loss of consciousness may be preceded by a brief moment of excruciating headache, but most patients first complain of headache upon regaining consciousness. In 10% of cases, aneurysmal bleeding is severe enough to cause loss of consciousness for several days. In ~45% of cases, severe headache associated with exertion is the presenting complaint. The patient often calls the headache "the worst headache of my life"; however, the most important characteristic is sudden onset. Occasionally these ruptures may present as headache of only moderate intensity or as a change in the patient's usual headache pattern. The headache is usually generalized, often with neck stiffness, and vomiting is common.

Although sudden headache in the absence of focal neurologic symptoms is the hallmark of aneurysmal rupture, focal neurologic deficits may occur. Anterior communicating artery or MCA bifurcation aneurysms may rupture into the adjacent brain or subdural space and form a hematoma large enough to produce mass effect. The common deficits that result include hemiparesis, aphasia, and abulia.

Occasionally, prodromal symptoms suggest the location of a progressively enlarging unruptured aneurysm. A third cranial nerve palsy, particularly when associated with pupillary dilatation, loss of ipsilateral (but retained contralateral) light reflex, and focal pain above or behind the eye, may occur with an expanding aneurysm at the junction of the posterior communicating artery and the internal carotid artery. A sixth nerve palsy may indicate an aneurysm in the cavernous sinus, and visual field defects can occur with an expanding supraclinoid carotid or anterior cerebral artery aneurysm. Occipital and posterior cervical pain may signal a posterior inferior cerebellar artery or anterior inferior cerebellar artery aneurysm. Pain in or behind the eye and in the low temple can occur with an expanding MCA aneurysm. Thunderclap headache is a variant of migraine that simulates a SAH. Before concluding that a patient with sudden, severe headache has thunderclap migraine, a definitive workup for aneurysm or other intracranial pathology is required.

TABLE 269-3 GRADING SCALES FOR SUBARACHNOID HEMORRHAGE

Grade	Hunt-Hess Scale	World Federation of Neurosurgical Societies (WFNS) Scale
1	Mild headache, normal mental status, no cranial nerve or motor findings	Glasgow Coma Scale[a] (GCS) score 15, no motor deficits
2	Severe headache, normal mental status, may have cranial nerve deficit	GCS 13–14, no motor deficits
3	Somnolent, confused, may have cranial nerve or mild motor deficit	GCS 13–14, with motor deficits
4	Stupor, moderate to severe motor deficit, may have intermittent reflex posturing	GCS 7–12, with or without motor deficits
5	Coma, reflex posturing or flaccid	GCS 3–6, with or without motor deficits

[a]Glasgow Coma Scale: See Fig. 373-2.

Aneurysms can undergo small ruptures and leaks of blood into the subarachnoid space, so-called *sentinel bleeds*. Sudden unexplained headache at any location should raise suspicion of SAH and be investigated, because a major hemorrhage may be imminent.

The initial clinical manifestations of SAH can be graded using the Hunt-Hess or World Federation of Neurosurgical Societies classification schemes (Table 269-3). For ruptured aneurysms, prognosis for good outcomes falls as the grade increases. For example it is unusual for a Hunt-Hess grade 1 patient to die if the aneurysm is treated, but the mortality for grade 4 and 5 patients may be as high as 80%.

DELAYED NEUROLOGIC DEFICITS There are four major causes of delayed neurologic deficits: rerupture, hydrocephalus, vasospasm, and hyponatremia.

1. *Rerupture*. The incidence of rerupture of an untreated aneurysm in the first month following SAH is ~30%, with the peak in the first 7 days. Rerupture is associated with a 60% mortality and poor outcome. Early treatment eliminates this risk.
2. *Hydrocephalus*. Acute hydrocephalus can cause stupor and coma and can be mitigated by placement of an external ventricular drain. More often, subacute hydrocephalus may develop over a few days or weeks and causes progressive drowsiness or slowed mentation (abulia) with incontinence. Hydrocephalus is differentiated from cerebral vasospasm with a CT scan, CT angiogram, transcranial Doppler (TCD) ultrasound, or conventional x-ray angiography. Hydrocephalus may clear spontaneously or require temporary ventricular drainage. Chronic hydrocephalus may develop weeks to months after SAH and manifest as gait difficulty, incontinence, or impaired mentation. Subtle signs may be a lack of initiative in conversation or a failure to recover independence.
3. *Vasospasm*. Narrowing of the arteries at the base of the brain following SAH causes symptomatic ischemia and infarction in ~30% of patients and is the major cause of delayed morbidity and death. Signs of ischemia appear 4–14 days after the hemorrhage, most often at 7 days. The severity and distribution of vasospasm determine whether infarction will occur.

   Delayed vasospasm is believed to result from direct effects of clotted blood and its breakdown products on the arteries within the subarachnoid space. In general, the more blood that surrounds the arteries, the greater the chance of symptomatic vasospasm. Spasm of major arteries produces symptoms referable to the appropriate

vascular territory (Chap. 364). All of these focal symptoms may present abruptly, fluctuate, or develop over a few days. In most cases, focal spasm is preceded by a decline in mental status.

Vasospasm can be detected reliably with conventional x-ray angiography, but this invasive procedure is expensive and carries the risk of stroke and other complications. TCD ultrasound is based on the principle that the velocity of blood flow within an artery will rise as the lumen diameter is narrowed. By directing the probe along the MCA and proximal anterior cerebral artery (ACA), carotid terminus, and vertebral and basilar arteries on a daily or every-other-day basis, vasospasm can be reliably detected and treatments initiated to prevent cerebral ischemia (see below). CT angiography is another method that can detect vasospasm.

Severe cerebral edema in patients with infarction from vasospasm may increase the ICP enough to reduce cerebral perfusion pressure. Treatment may include mannitol, hyperventilation, and hemicraniectomy; moderate hypothermia may have a role as well.

4. *Hyponatremia.* Hyponatremia may be profound and can develop quickly in the first 2 weeks following SAH. There is both natriuresis and volume depletion with SAH, so that patients become both hyponatremic and hypovolemic. Both atrial natriuretic peptide and brain natriuretic peptide have a role in producing this "cerebral salt-wasting syndrome." Typically it clears over the course of 1–2 weeks and, in the setting of SAH, should not be treated with free-water restriction as this may increase the risk of stroke (see below).

LABORATORY EVALUATION AND IMAGING **(Fig. 269-8)** The hallmark of aneurysmal rupture is blood in the CSF. More than 95% of cases have enough blood to be visualized on a high-quality noncontrast CT scan obtained within 72 h. If the scan fails to establish the diagnosis of SAH and no mass lesion or obstructive hydrocephalus is found, a lumbar puncture should be performed to establish the presence of subarachnoid blood. Lysis of the red blood cells and subsequent conversion of hemoglobin to bilirubin stains the spinal fluid yellow within 6–12 h. This xanthochromic spinal fluid peaks in intensity at 48 h and lasts for 1–4 weeks, depending on the amount of subarachnoid blood.

The extent and location of subarachnoid blood on noncontrast CT scan help locate the underlying aneurysm, identify the cause of any neurologic deficit, and predict delayed vasospasm. A high incidence of symptomatic vasospasm in the MCA and ACA has been found when early CT scans show subarachnoid clots >5 × 3 mm in the basal cisterns or layers of blood >1 mm thick in the cerebral fissures. CT scans less reliably predict vasospasm in the vertebral, basilar, or posterior cerebral arteries.

Lumbar puncture prior to an imaging procedure is indicated only if a CT scan is not available at the time of the suspected SAH. Once the diagnosis of hemorrhage from a ruptured saccular aneurysm is suspected, four-vessel conventional x-ray angiography (both carotids and both vertebrals) is generally performed to localize and define the anatomic details of the aneurysm and to determine if other unruptured aneurysms exist (Fig. 269-8*C*). At some centers, the ruptured aneurysm can be treated using endovascular techniques at the time of the initial angiogram as a way to expedite treatment and minimize the number of invasive procedures. CT angiography is an alternative method for locating the aneurysm and may be sufficient to plan definitive therapy.

Close monitoring (daily or twice daily) of electrolytes is important because hyponatremia can occur precipitously during the first 2 weeks following SAH (see above).

The electrocardiogram (ECG) frequently shows ST-segment and T-wave changes similar to those associated with cardiac ischemia. Prolonged QRS complex, increased QT interval, and prominent "peaked" or deeply inverted symmetric T waves are usually secondary to the intracranial hemorrhage. There is evidence that structural myocardial lesions produced by circulating catecholamines and excessive discharge of sympathetic neurons may occur after SAH, causing these ECG changes and a reversible cardiomyopathy sufficient to cause shock or congestive heart failure. Echocardiography reveals a pattern of regional wall motion abnormalities that follow the distribution of sympathetic nerves rather than the major coronary arteries, with relative sparing of the ventricular wall apex. The sympathetic nerves themselves appear to be injured by direct toxicity from the excessive catecholamine release. An asymptomatic troponin elevation is common. Serious ventricular dysrhythmias are unusual.

Rx SUBARACHNOID HEMORRHAGE

Early aneurysm repair prevents rerupture and allows the safe application of techniques to improve blood flow (e.g., induced hypertension and hypervolemia) should symptomatic vasospasm develop. An aneurysm can be "clipped" by a neurosurgeon or "coiled" by an endovascular surgeon. Surgical repair involves placing a metal clip across the aneurysm neck, thereby immediately eliminating the risk of rebleeding. This approach requires craniotomy and brain retraction, which is associated with neurologic morbidity. Endovascular techniques involve placing platinum coils, or other embolic material, within the aneurysm via a catheter that is passed from the femoral artery. The aneurysm is packed tightly to enhance thrombosis and over time is walled-off from the circulation (Fig. 269-8D). The only prospective randomized trial of surgery versus endovascular treatment for ruptured aneurysm, the International Subarachnoid Aneurysm Trial (ISAT), was terminated early when 24% of patients treated with endovascular therapy were dead or dependent at 1 year compared to 31% treated with surgery, a significant 23% relative reduction. Follow-up for these patients, now complete, reveals that the benefit of endovascular therapy is durable. However, some aneurysms have a morphology that is not amenable to endovascular treatment. Thus, surgery remains an important treatment option. Centers that combine both endovascular and neurosurgical expertise likely offer the best outcomes for patients, and there are good data showing that centers that specialize in aneurysm treatment have improved mortality rates.

The medical management of SAH focuses on protecting the airway, managing blood pressure before and after aneurysm treatment, preventing rebleeding prior to treatment, managing vasospasm, treating hydrocephalus, treating hyponatremia, and preventing pulmonary embolus.

Intracranial hypertension following aneurysmal rupture occurs secondary to subarachnoid blood, parenchymal hematoma, acute hydrocephalus, or loss of vascular autoregulation. Patients who are stuporous should undergo emergent ventriculostomy to measure ICP and to treat high ICP in order to prevent cerebral ischemia. Medical therapies designed to combat raised ICP (e.g., mild hyperventilation, mannitol, and sedation) can also be used as needed. High ICP refractory to treatment is a poor prognostic sign.

Prior to definitive treatment of the ruptured aneurysm, care is required to maintain adequate cerebral perfusion pressure while avoiding excessive elevation of arterial pressure. If the patient is alert, it is reasonable to lower the blood pressure to normal using nicardipine, labetolol, or esmolol. If the patient has a depressed level of consciousness, ICP should be measured and the cerebral perfusion pressure targeted to 60–70 mmHg.

Because rebleeding is common, all patients who are not candidates for early aneurysm repair are put on bed rest in a quiet room and are given stool softeners to prevent straining. If headache or neck pain is severe, mild sedation and analgesia are prescribed. Extreme sedation is avoided because it can obscure changes in neurologic status. Adequate hydration is necessary to avoid a decrease in blood volume predisposing to brain ischemia.

Seizures are uncommon at the onset of aneurysmal rupture. The quivering, jerking, and extensor posturing that often accompany loss of consciousness with SAH are probably related to the sharp rise in ICP or, perhaps, acute generalized vasospasm rather than seizure. However, phenytoin is often given as prophylactic therapy since a seizure may promote rebleeding.

Glucocorticoids may help reduce the head and neck ache caused by the irritative effect of the subarachnoid blood. There is no good evidence that they reduce cerebral edema, are neuroprotective, or reduce vascular injury, and their routine use therefore is not recommended.

Antifibrinolytic agents are not routinely prescribed but may be considered in patients in whom aneurysm treatment cannot proceed immediately. They are associated with a reduced incidence of aneurysmal rerupture but may also increase the risk of delayed cerebral infarction and deep vein thrombosis (DVT).

Vasospasm remains the leading cause of morbidity and mortality following aneurysmal SAH. Treatment with the calcium channel antagonist nimodipine (60 mg PO every 4 h) improves outcome, perhaps by preventing ischemic injury rather than reducing the risk of vasospasm. Nimodipine can cause significant hypotension in some patients, which may worsen cerebral ischemia in patients with vasospasm. Symptomatic cerebral vasospasm can also be treated by increasing the cerebral perfusion pressure by raising mean arterial pressure through plasma volume expansion and the judicious use of IV vasopressor agents, usually phenylephrine or norepinephrine. Raised perfusion pressure has been associated with clinical improvement in many patients, but high arterial pressure may promote rebleeding in unprotected aneurysms. Treatment with induced hypertension and hypervolemia generally requires monitoring of arterial and central venous pressures; it is best to infuse pressors through a central venous line as well. Volume expansion helps prevent hypotension, augments cardiac output, and reduces blood viscosity by reducing the hematocrit. This method is called "triple-H" (hypertension, hemodilution, and hypervolemic) therapy.

If symptomatic vasospasm persists despite optimal medical therapy, intraarterial vasodilators and percutaneous transluminal angioplasty are considered. Vasodilatation by direct angioplasty appears to be permanent, allowing triple-H therapy to be tapered sooner. The pharmacologic vasodilators (verapamil and nicardipine) do not last more than 8–24 h, and therefore multiple treatments may be required until the subarachnoid blood is reabsorbed. Although intraarterial papaverine is an effective vasodilator, there is evidence that papaverine may be neurotoxic so its use should be reserved for refractory cases.

Acute hydrocephalus can cause stupor or coma. It may clear spontaneously or require temporary ventricular drainage. When chronic hydrocephalus develops, ventricular shunting is the treatment of choice.

Free-water restriction is contraindicated in patients with SAH at risk for vasospasm because hypovolemia and hypotension may occur and precipitate cerebral ischemia. Many patients continue to experience a decline in serum sodium despite receiving parenteral fluids containing normal saline. Frequently, supplemental oral salt coupled with normal saline will mitigate hyponatremia, but often patients also require hypertonic saline. Care must be taken not to correct serum sodium too quickly in patients with marked hyponatremia of several days' duration, as central pontine myelinolysis may occur.

All patients should have pneumatic compression stockings applied to prevent pulmonary embolism. Unfractionated heparin administered subcutaneously for DVT prophylaxis can be initiated immediately following endovascular treatment and within days following craniotomy and surgical clipping and is a useful adjunct to pneumatic compression stockings. Treatment of pulmonary embolus depends on whether the aneurysm has been treated and whether or not the patient has had a craniotomy. Systemic anticoagulation with heparin is contraindicated in patients with ruptured and untreated aneurysms. It is a relative contraindication following craniotomy for several days or perhaps weeks, and it may delay thrombosis of a coiled aneurysm. Following craniotomy, use of inferior vena cava filters is preferred to prevent further pulmonary emboli, while systemic anticoagulation with heparin is preferred following successful endovascular treatment.

SECTION 4 ONCOLOGIC EMERGENCIES

270 Oncologic Emergencies

Rasim Gucalp, Janice Dutcher

Emergencies in patients with cancer may be classified into three groups: pressure or obstruction caused by a space-occupying lesion, metabolic or hormonal problems (paraneoplastic syndromes, Chap. 96), and treatment-related complications.

STRUCTURAL-OBSTRUCTIVE ONCOLOGIC EMERGENCIES

SUPERIOR VENA CAVA SYNDROME

Superior vena cava syndrome (SVCS) is the clinical manifestation of superior vena cava (SVC) obstruction, with severe reduction in venous return from the head, neck, and upper extremities. Malignant tumors, such as lung cancer, lymphoma, and metastatic tumors, are responsible for the majority of SVCS cases. With the expanding use of intravascular devices (e.g., permanent central venous access catheters, pacemaker/defibrillator leads), the prevalence of benign causes of SVCS is increasing. Lung cancer, particularly of small cell and squamous cell histologies, accounts for approximately 85% of all cases of malignant origin. In young adults, malignant lymphoma is a leading cause of SVCS. Hodgkin's lymphoma involves the mediastinum more commonly than other lymphomas but rarely causes SVCS. When SVCS is noted in a young man with a mediastinal mass, the differential diagnosis is lymphoma vs primary mediastinal germ cell tumor. Metastatic cancers to the mediastinum, such as testicular and breast carcinomas, account for a small proportion of cases. Other causes include benign tumors, aortic aneurysm, thyromegaly, thrombosis, and fibrosing mediastinitis from prior irradiation or histoplasmosis.

Patients with SVCS usually present with neck and facial swelling (especially around the eyes), dyspnea, and cough. Other symptoms include hoarseness, tongue swelling, headaches, nasal congestion, epistaxis, hemoptysis, dysphagia, pain, dizziness, syncope, and lethargy. Bending forward or lying down may aggravate the symptoms. The characteristic physical findings are dilated neck veins, an increased number of collateral veins covering the anterior chest wall, cyanosis, and edema of the face, arms, and chest. More severe cases include proptosis, glossal and laryngeal edema, and obtundation. The clinical picture is milder if the obstruction is located above the azygos vein.

Signs and symptoms of cerebral and/or laryngeal edema, though rare, are associated with a poorer prognosis and require urgent evaluation. Seizures are more likely related to brain metastases than to cerebral edema from venous occlusion. Patients with small cell lung cancer and SVCS have a higher incidence of brain metastases than those without SVCS.

Cardiorespiratory symptoms at rest, particularly with positional changes, suggest significant airway and vascular obstruction and limited physiologic reserve. Cardiac arrest or respiratory failure can occur, particularly in patients receiving sedatives or undergoing general anesthesia.

The diagnosis of SVCS is a clinical one. The most significant chest radiographic finding is widening of the superior mediastinum, most commonly on the right side. Pleural effusion occurs in only 25% of patients, often on the right side. However, a normal chest radiograph is still compatible with the diagnosis if other characteristic findings are present. CT provides the most reliable view of the mediastinal anatomy. The diagnosis of SVCS requires diminished or absent opacification of central venous structures with prominent collateral venous circulation. MRI has no advantages over CT. Invasive procedures, including bronchoscopy, percutaneous needle biopsy, mediastinoscopy, and even thoracotomy, can be performed by a skilled clinician without any major risk of bleeding. For patients with a known cancer, a detailed workup usually is not necessary, and appropriate treatment may be started after obtaining a CT scan of the thorax. For those with no history of malignancy, a detailed evaluation is essential to rule out benign causes and determine a specific diagnosis to direct the appropriate therapy.

Rx SUPERIOR VENA CAVA SYNDROME

The one potentially life-threatening complication of a superior mediastinal mass is tracheal obstruction. Upper airway obstruction demands emergent therapy. Diuretics with a low-salt diet, head elevation, and oxygen may produce temporary symptomatic relief. Glucocorticoids may be useful at shrinking lymphoma masses; they are of no benefit in patients with lung cancer.

Radiation therapy is the primary treatment for SVCS caused by non-small cell lung cancer and other metastatic solid tumors. Chemotherapy is effective when the underlying cancer is small cell carcinoma of the lung, lymphoma, or germ cell tumor. SVCS recurs in 10–30% of patients; it may be palliated with the use of intravascular self-expanding stents **(Fig. 270-1)**. Early stenting may be necessary in patients with severe symptoms; however, the prompt increase in venous return after stenting may precipitate heart failure and pulmonary edema. Surgery may provide immediate relief for patients in whom a benign process is the cause.

Clinical improvement occurs in most patients, although this improvement may be due to the development of adequate collateral circulation. The mortality associated with SVCS does not relate to caval obstruction, but rather to the underlying cause.

SVCS AND CENTRAL VENOUS CATHETERS IN ADULTS The use of long-term central venous catheters has become common practice in patients with cancer. Major vessel thrombosis may occur. In these cases, catheter removal should be combined with anticoagulation to prevent embolization. SVCS in this setting, if detected early, can be treated by fibrinolytic therapy without sacrificing the catheter. The routine use of low-dose warfarin or low molecular weight heparin to prevent thrombosis related to permanent central venous access catheters in cancer patients is not recommended.

PERICARDIAL EFFUSION/TAMPONADE

Malignant pericardial disease is found at autopsy in 5–10% of patients with cancer, most frequently with lung cancer, breast cancer, leukemias, and lymphomas. Cardiac tamponade as the initial presentation of extrathoracic malignancy is rare. The origin is not malignancy in about 50% of cancer patients with symptomatic pericardial disease, but it can be related to irradiation, drug-induced pericarditis, hypothyroidism, idiopathic pericarditis, infection, or autoimmune diseases. Two types of radiation pericarditis occur: an acute inflammatory, effusive pericarditis occurring within months of irradiation, which usually resolves spontaneously, and a chronic effusive pericarditis that may appear up to 20 years after radiation therapy and is accompanied by a thickened pericardium.

Most patients with pericardial metastasis are asymptomatic. However, the common symptoms are dyspnea, cough, chest pain, orthopnea, and weakness. Pleural effusion, sinus tachycardia, jugular venous distension, hepatomegaly, peripheral edema, and cyanosis are the most frequent physical findings. Relatively specific diagnostic findings, such as paradoxical pulse, diminished heart sounds, pulsus alternans (pulse waves alternating between those of greater and lesser amplitude with successive beats), and friction rub are less common than with nonmalignant pericardial disease. Chest radiographs and ECG reveal abnormalities in 90% of patients, but half of these abnormalities are nonspecific. Echocardiography is the most helpful diagnostic test. Pericardial fluid may be serous, serosanguineous, or hemorrhagic, and cytologic examination of pericardial fluid is diagnostic in most pa-

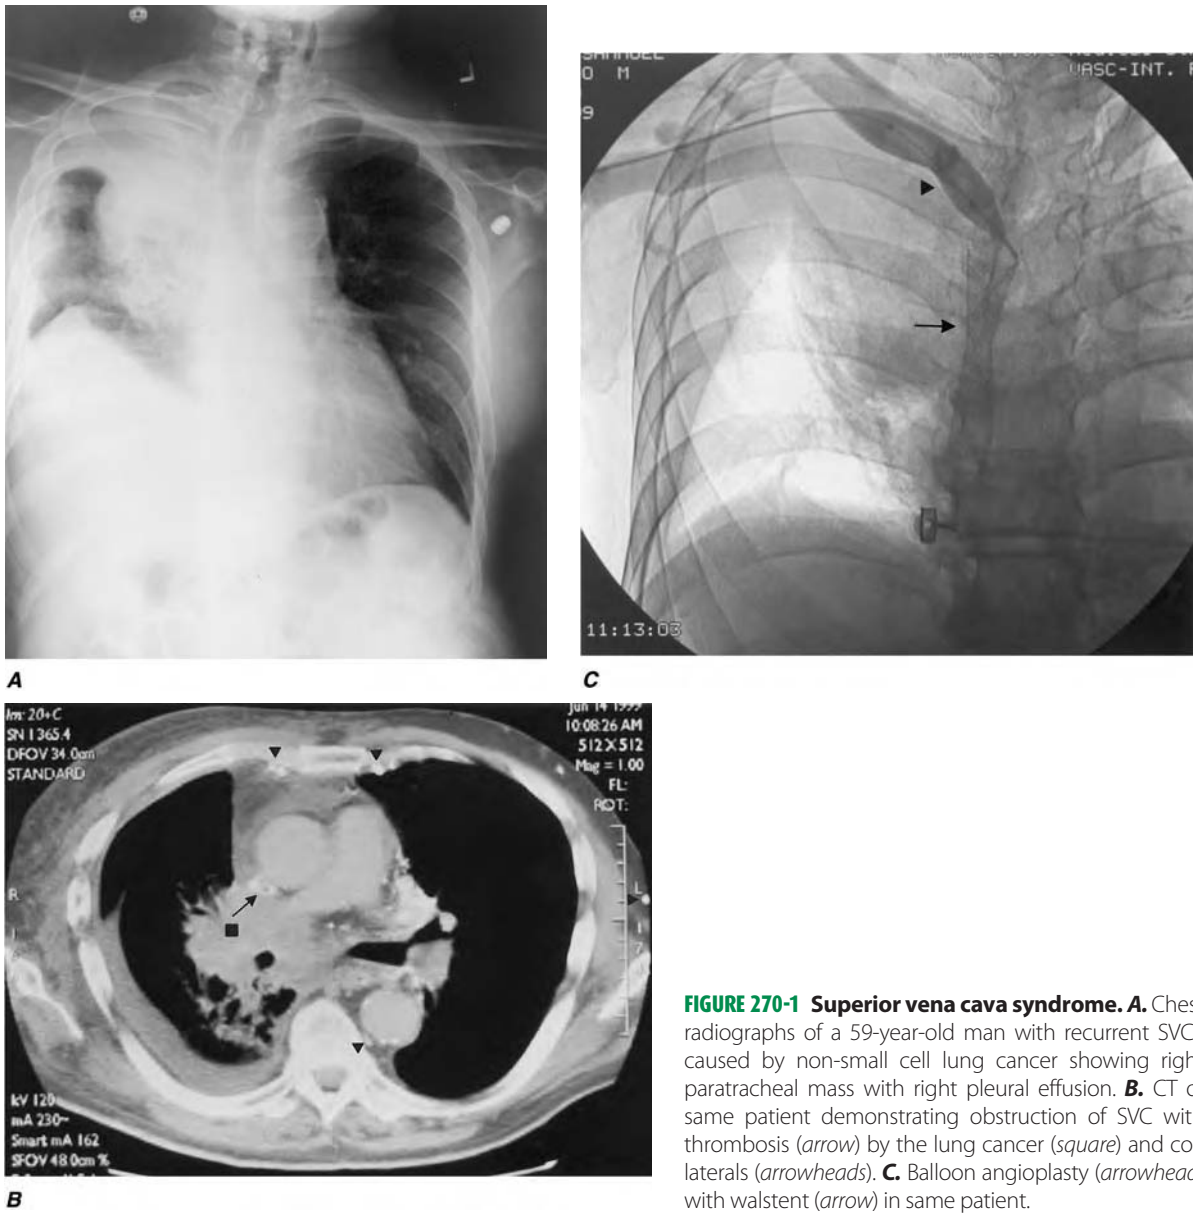

FIGURE 270-1 Superior vena cava syndrome. ***A.*** Chest radiographs of a 59-year-old man with recurrent SVCS caused by non-small cell lung cancer showing right paratracheal mass with right pleural effusion. ***B.*** CT of same patient demonstrating obstruction of SVC with thrombosis (*arrow*) by the lung cancer (*square*) and collaterals (*arrowheads*). ***C.*** Balloon angioplasty (*arrowhead*) with walstent (*arrow*) in same patient.

tients. Cancer patients with pericardial effusion containing malignant cells on cytology have a very poor survival, about 7 weeks.

℞ PERICARDIAL EFFUSION/TAMPONADE

Pericardiocentesis with or without the introduction of sclerosing agents, the creation of a pericardial window, complete pericardial stripping, cardiac irradiation, or systemic chemotherapy are effective treatments. Acute pericardial tamponade with life-threatening hemodynamic instability requires immediate drainage of fluid. This can be quickly achieved by pericardiocentesis. The recurrence rate after percutaneous catheter drainage is around 20%. Sclerotherapy (pericardial instillation of bleomycin, mitomycin C, or tetracycline) may decrease recurrences. Alternatively, subxiphoid pericardiotomy can be performed in 45 min under local anesthesia. Thoracoscopic pericardial fenestration can be employed for benign causes; however, 60% of malignant pericardial effusions recur after this procedure.

INTESTINAL OBSTRUCTION

Intestinal obstruction and reobstruction are common problems in patients with advanced cancer, particularly colorectal or ovarian carcinoma. However, other cancers, such as lung or breast cancer and melanoma, can metastasize within the abdomen, leading to intestinal obstruction. Typically, obstruction occurs at multiple sites. Melanoma has a predilection to involve the small bowel; this involvement may be isolated and resection may result in prolonged survival. Intestinal pseudoobstruction is caused by infiltration of the mesentery or bowel muscle by tumor, involvement of the celiac plexus, or paraneoplastic neuropathy in patients with small cell lung cancer. Paraneoplastic neuropathy is associated with IgG antibodies reactive to neurons of the myenteric and submucosal plexuses of the jejunum and stomach. Ovarian cancer can lead to authentic luminal obstruction or to pseudoobstruction that results when circumferential invasion of a bowel segment arrests the forward progression of peristaltic contractions.

The onset of obstruction is usually insidious. Pain is the most common symptom and is usually colicky in nature. Pain can also be due to abdominal distention, tumor masses, or hepatomegaly. Vomiting can be intermittent or continuous. Patients with complete obstruction usually have constipation. Physical examination may reveal abdominal distention with tympany, ascites, visible peristalsis, high-pitched bowel sounds, and tumor masses. Erect plain abdominal films may reveal multiple air-fluid levels and dilation of the small or large bowel. Acute cecal dilation to >12–14 cm is considered a surgical emergency because of the high likelihood of rupture. CT scan is useful in differentiating benign from malignant causes of obstruction in patients who have undergone surgery for malignancy. Malignant obstruction is suggested by a mass at the site of obstruction or prior surgery, adenopathy, or an abrupt transition zone and irregular bowel thickening at the obstruction site. Benign obstruction is more likely when CT shows mesenteric vascular changes,

a large volume of ascites, or a smooth transition zone and smooth bowel thickening at the obstruction site. The prognosis for the patient with cancer who develops intestinal obstruction is poor; median survival is 3–4 months. About 25–30% of patients are found to have intestinal obstruction due to causes other than cancer. Adhesions from previous operations are a common benign cause. Ileus induced by vincristine or other drugs is another reversible cause.

Rx INTESTINAL OBSTRUCTION

The management of intestinal obstruction in patients with advanced malignancy depends on the extent of the underlying malignancy and the functional status of the major organs. The initial management should include surgical evaluation. Operation is not always successful and may lead to further complications with a substantial mortality rate (10–20%). Laparoscopy can diagnose and treat malignant bowel obstruction in some cases. Self-expanding metal stents placed in the gastric outlet, duodenum, proximal jejunum, colon, or rectum may palliate obstructive symptoms at those sites without major surgery. Patients known to have advanced intra-abdominal malignancy should receive a prolonged course of conservative management, including nasogastric decompression. Treatment with antiemetics, antispasmodics, and analgesics may allow patients to remain outside the hospital. Octreotide may relieve obstructive symptoms through its inhibitory effect on gastrointestinal secretion.

URINARY OBSTRUCTION

Urinary obstruction may occur in patients with prostatic or gynecologic malignancies, particularly cervical carcinoma; metastatic disease from other primary sites such as carcinomas of the breast, stomach, lung, colon, and pancreas; or lymphomas. Radiation therapy to pelvic tumors may cause fibrosis and subsequent ureteral obstruction. Bladder outlet obstruction is usually due to prostate and cervical cancers and may lead to bilateral hydronephrosis and renal failure.

Flank pain is the most common symptom. Persistent urinary tract infection, persistent proteinuria, or hematuria in patients with cancer should raise suspicion of ureteral obstruction. Total anuria and/or anuria alternating with polyuria may occur. A slow, continuous rise in the serum creatinine level necessitates immediate evaluation. Renal ultrasound is the safest and cheapest way to identify hydronephrosis. The function of an obstructed kidney can be evaluated by a nuclear scan. CT scan can reveal the point of obstruction and identify a retroperitoneal mass or adenopathy.

Rx URINARY OBSTRUCTION

Obstruction associated with flank pain, sepsis, or fistula formation is an indication for immediate palliative urinary diversion. Internal ureteral stents can be placed under local anesthesia. Percutaneous nephrostomy offers an alternative approach for drainage. In the case of bladder outlet obstruction due to malignancy, a suprapubic cystostomy can be used for urinary drainage.

MALIGNANT BILIARY OBSTRUCTION

This common clinical problem can be caused by a primary carcinoma arising in the pancreas, ampulla of Vater, bile duct, or liver or by metastatic disease to the periductal lymph nodes or liver parenchyma. The most common metastatic tumors causing biliary obstruction are gastric, colon, breast, and lung cancers. Jaundice, light-colored stools, dark urine, pruritus, and weight loss due to malabsorption are usual symptoms. Pain and secondary infection are uncommon in malignant biliary obstruction. Ultrasound, CT scan, or percutaneous transhepatic or endoscopic retrograde cholangiography will identify the site and nature of the biliary obstruction.

Rx MALIGNANT BILIARY OBSTRUCTION

Palliative intervention is indicated only in patients with disabling pruritus resistant to medical treatment, severe malabsorption, or infection. Stenting under radiographic control, surgical bypass, or radiation therapy with or without chemotherapy may alleviate the obstruction. The choice of therapy should be based on the site of obstruction (proximal versus distal), the type of tumor (sensitive to radiotherapy, chemotherapy, or neither), and the general condition of the patient. In the absence of pruritus, biliary obstruction may be a largely asymptomatic cause of death.

SPINAL CORD COMPRESSION

Malignant spinal cord compression (MSCC) is defined as compression of the spinal cord and/or cauda equina by an extradural tumor mass. The minimum radiologic evidence for cord compression is indentation of the theca at the level of clinical features. Spinal cord compression occurs in 5–10% of patients with cancer. Epidural tumor is the first manifestation of malignancy in about 10% of patients. The underlying cancer is usually identified during the initial evaluation; lung cancer is the most common cause of MSCC.

Metastatic tumor involves the vertebral column more often than any other part of the bony skeleton. Lung, breast, and prostate cancer are the most frequent offenders. Multiple myeloma also has a high incidence of spine involvement. Lymphomas, melanoma, renal cell cancer, and genitourinary cancers also cause cord compression. The thoracic spine is the most common site (70%), followed by the lumbosacral spine (20%) and the cervical spine (10%). Involvement of multiple sites is most frequent in patients with breast and prostate carcinoma. Cord injury develops when metastases to the vertebral body or pedicle enlarge and compress the underlying dura. Another cause of cord compression is direct extension of a paravertebral lesion through the intervertebral foramen. These cases usually involve a lymphoma, myeloma, or pediatric neoplasm. Parenchymal spinal cord metastasis due to hematogenous spread is rare.

Expanding extradural tumors induce injury through several mechanisms. Obstruction of the epidural venous plexus leads to edema. Local production of inflammatory cytokines enhances blood flow and edema formation. Compression compromises blood flow leading to ischemia. Production of vascular endothelial growth factor is associated with spinal cord hypoxia and has been implicated as a potential cause of damage after spinal cord injury.

The most common initial symptom in patients with spinal cord compression is localized back pain and tenderness due to involvement of vertebrae by tumor. Pain is usually present for days or months before other neurologic findings appear. It is exacerbated by movement and by coughing or sneezing. It can be differentiated from the pain of disc disease by the fact that it worsens when the patient is supine. Radicular pain is less common than localized back pain and usually develops later. Radicular pain in the cervical or lumbosacral areas may be unilateral or bilateral. Radicular pain from the thoracic roots is often bilateral and is described by patients as a feeling of tight, band-like constriction around the thorax and abdomen. Typical cervical radicular pain radiates down the arm; in the lumbar region, the radiation is down the legs. *Lhermitte's sign*, a tingling or electric sensation down the back and upper and lower limbs upon flexing or extending the neck, may be an early sign of cord compression. Loss of bowel or bladder control may be the presenting symptom but usually occurs late in the course.

On physical examination, pain induced by straight leg raising, neck flexion, or vertebral percussion may help to determine the level of cord compression. Patients develop numbness and paresthesias in the extremities or trunk. Loss of sensibility to pinprick is as common as loss of sensibility to vibration or position. The upper limit of the zone of sensory loss is often one or two vertebrae below the site of compression. Motor findings include weakness, spasticity, and abnormal muscle stretching. An extensor plantar reflex reflects significant compression. Deep tendon reflexes may be brisk. Motor and sensory loss usually precedes sphincter disturbance. Patients with autonomic dysfunction may present with decreased anal tonus, decreased perineal sensibility, and a distended bladder. The absence of the anal wink reflex or the bulbocavernosus reflex confirms cord involvement. In doubtful cases, evaluation of post-voiding urinary residual volume can be helpful. A residual volume of >150 mL suggests bladder dysfunction. Autonomic dysfunction is an unfavorable prognostic factor. Patients with progressive neurologic symptoms should

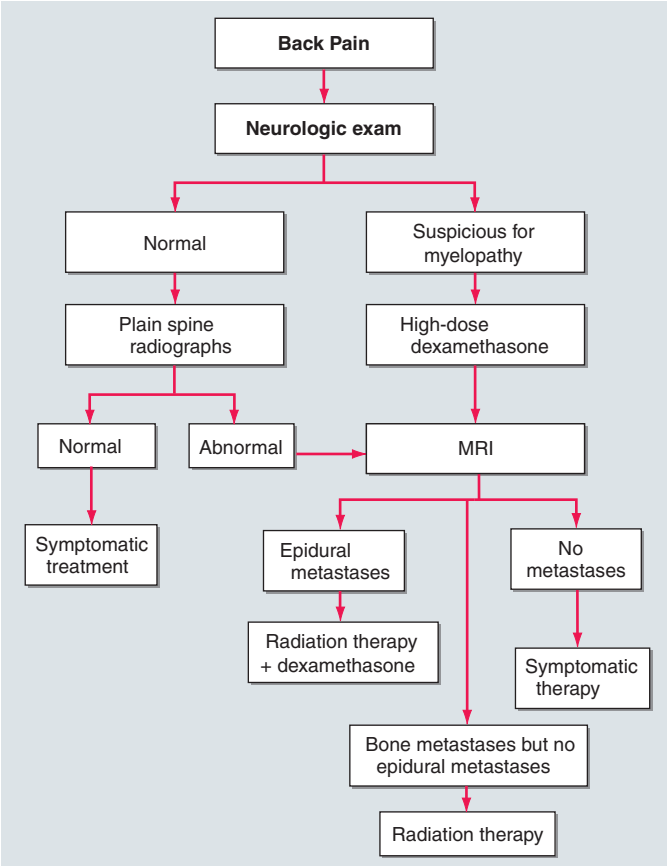

FIGURE 270-2 Management of cancer patients with back pain.

have frequent neurologic examinations and rapid therapeutic intervention. Other illnesses that may mimic cord compression include osteoporotic vertebral collapse, disc disease, pyogenic abscess or vertebral tuberculosis, radiation myelopathy, neoplastic leptomeningitis, benign tumors, epidural hematoma, and spinal lipomatosis.

Cauda equina syndrome is characterized by low back pain; diminished sensation over the buttocks; posterior-superior thighs; perineal area in a saddle distribution; rectal and bladder dysfunction; sexual impotence; absent bulbocavernous, patellar, and Achilles' reflexes; and variable amount of lower-extremity weakness. This reflects compression of nerve roots as they form the cauda equina after leaving the spinal cord.

Patients with cancer who develop back pain should be evaluated for spinal cord compression as quickly as possible (Fig. 270-2). Treatment is more often successful in patients who are ambulatory and still have sphincter control at the time treatment is initiated. Patients should have a neurologic examination and plain films of the spine. Those whose physical examination suggests cord compression should receive dexamethasone (24 mg intravenously every 6 h), starting immediately.

Erosion of the pedicles (the "winking owl" sign) is the earliest radiologic finding of vertebral tumor. Other radiographic changes include increased intrapedicular distance, vertebral destruction, lytic or sclerotic lesions, scalloped vertebral bodies, and vertebral body collapse. Vertebral collapse is not a reliable indicator of the presence of tumor; about 20% of cases of vertebral collapse, particularly those in older patients and postmenopausal women, are due not to cancer but to osteoporosis. Also, a normal appearance on plain films of the spine does not exclude the diagnosis of cancer. The role of bone scans in the detection of cord compression is not clear; this method is sensitive but less specific than spinal radiography.

The full-length image of the cord provided by MRI is useful. Multiple epidural metastases are noted in 25% of patients with cord compression, and their presence influences treatment plans. On T1-weighted images, good contrast is noted between the cord, cerebrospinal fluid, and extradural lesions. Owing to its sensitivity in demonstrating the replacement of bone marrow by tumor, MRI can show which parts of a vertebra are involved by tumor. MRI also visualizes intraspinal extradural masses compressing the cord. T2-weighted images are most useful for the demonstration of intramedullary pathology. Gadolinium-enhanced MRI can help to delineate intramedullary disease. MRI is as good as or better than myelography plus postmyelogram CT scan in detecting metastatic epidural disease with cord compression. Myelography should be reserved for patients who have poor MR images or who cannot undergo MRI promptly. CT scan in conjunction with myelography enhances the detection of small areas of spinal destruction.

In patients with cord compression and an unknown primary tumor, a simple workup including chest radiography, mammography, measurement of prostate-specific antigen, and abdominal CT usually reveals the underlying malignancy.

Rx SPINAL CORD COMPRESSION

The treatment of patients with spinal cord compression is aimed at relief of pain and restoration/preservation of neurologic function (Fig. 270-2).

Radiation therapy plus glucocorticoids is generally the initial treatment of choice for most patients with spinal cord compression. Up to 75% of patients treated when still ambulatory remain ambulatory, but only 10% of patients with paraplegia recover walking capacity. Indications for surgical intervention include unknown etiology, failure of radiation therapy, a radioresistant tumor type (e.g., melanoma or renal cell cancer), pathologic fracture dislocation, and rapidly evolving neurologic symptoms. Laminectomy is done for tissue diagnosis and for the removal of posteriorly localized epidural deposits in the absence of vertebral body disease. Because most cases of epidural spinal cord compression are due to anterior or anterolateral extradural disease, resection of the anterior vertebral body along with the tumor, followed by spinal stabilization, has achieved good results. A randomized trial showed that patients who underwent an operation followed by radiotherapy (within 14 days) retained the ability to walk significantly longer than those treated with radiotherapy alone. Surgically treated patients also maintained continence and neurologic function significantly longer than patients in the radiation group. The length of survival was not significantly different in the two groups, although there was a trend toward longer survival in the surgery group. The study drew some criticism for the poorer than expected results in the patients who did not go to surgery. However, patients should be evaluated for surgery. Conventional radiotherapy has a role after surgery. Chemotherapy may have a role in patients with chemosensitive tumors who have had prior radiotherapy to the same region and who are not candidates for surgery. Most patients with prostate cancer who develop cord compression have already had hormonal therapy; however, for those who have not, androgen deprivation is combined with surgery and radiotherapy.

Patients with metastatic vertebral tumors may benefit from percutaneous vertebroplasty, the injection of acrylic cement into a collapsed vertebra to stabilize the fracture. Pain palliation is common, and local antitumor effects have been noted. Cement leakage may cause symptoms in about 10% of patients.

The histology of the tumor is an important determinant of both recovery and survival. Rapid onset and progression of signs and symptoms are poor prognostic features.

INCREASED INTRACRANIAL PRESSURE

About 25% of patients with cancer die with intracranial metastases. The cancers that most often metastasize to the brain are lung and breast cancers and melanoma. Brain metastases often occur in the presence of systemic disease, and they frequently cause major symptoms, disability, and early death. The initial presentation of brain metastases from a previously unknown primary cancer is common. Lung cancer is most commonly the primary malignancy. Chest CT scans and brain MRI as the initial diagnostic studies can identify a biopsy site in most patients.

The signs and symptoms of a metastatic brain tumor are similar to those of other intracranial expanding lesions: headache, nausea, vomiting, behavioral changes, seizures, and focal, progressive neurologic changes. Occasionally the onset is abrupt, resembling a stroke, with the

sudden appearance of headache, nausea, vomiting, and neurologic deficits. This picture is usually due to hemorrhage into the metastasis. Melanoma, germ cell tumors, and renal cell cancers have a particularly high incidence of intracranial bleeding. The tumor mass and surrounding edema may cause obstruction of the circulation of cerebrospinal fluid, with resulting hydrocephalus. Patients with increased intracranial pressure may have papilledema with visual disturbances and neck stiffness. As the mass enlarges, brain tissue may be displaced through the fixed cranial openings, producing various herniation syndromes.

CT scan and MRI are equally effective in the diagnosis of brain metastases. CT scan with contrast should be used as a screening procedure. The CT scan shows brain metastases as multiple enhancing lesions of various sizes with surrounding areas of low-density edema. If a single lesion or no metastases are visualized by contrast-enhanced CT, MRI of the brain should be performed. Gadolinium-enhanced MRI is more sensitive than CT at revealing meningeal involvement and small lesions, particularly in the brainstem or cerebellum.

Intracranial hypertension secondary to tretinoin therapy has been reported.

Rx INCREASED INTRACRANIAL PRESSURE

If signs and symptoms of brain herniation (particularly headache, drowsiness, and papilledema) are present, the patient should be intubated and hyperventilated to maintain P_{CO_2} between 25 and 30 mmHg and should receive infusions of mannitol (1–1.5 g/kg) every 6 h. Dexamethasone is the best initial treatment for all symptomatic patients with brain metastases (see above). Patients with multiple lesions should receive whole-brain radiation therapy. Patients with a single brain metastasis and with controlled extracranial disease may be treated with surgical excision followed by whole-brain radiation therapy, especially if they are younger than 60 years. Radioresistant tumors should be resected if possible. Stereotactic radiosurgery is an effective treatment for inaccessible or recurrent lesions. With a gamma knife or linear accelerator, multiple small, well-collimated beams of ionizing radiation destroy lesions seen on MRI. Some patients with increased intracranial pressure associated with hydrocephalus may benefit from shunt placement. If neurological deterioration is not reversed with medical therapy, ventriculotomy to remove cerebrospinal fluid (CSF) or craniotomy to remove tumors or hematomas may be necessary.

NEOPLASTIC MENINGITIS

Tumor involving the leptomeninges is a complication of both primary central nervous system (CNS) tumors and tumors that metastasize to the CNS. The incidence is estimated at 3–8% of patients with cancer. Melanoma, breast and lung cancer, lymphoma (including AIDS-associated), and acute leukemia are the most common causes. Synchronous intraparenchymal brain metastases are evident in 11–31% of patients with neoplastic meningitis.

Patients typically present with multifocal neurologic signs and symptoms, including headache, gait abnormality, mental changes, nausea, vomiting, seizures, back or radicular pain, and limb weakness. Signs include cranial nerve palsies, extremity weakness, paresthesia, and decreased deep tendon reflexes.

Diagnosis is made by demonstrating malignant cells in the CSF; however, up to 40% of patients may have false negative CSF cytology. An elevated CSF protein level is nearly always present (except in HTLV-1–associated adult T cell leukemia). Patients with neurologic signs and symptoms consistent with neoplastic meningitis who have a negative CSF cytology but an elevated CSF protein level should have the spinal tap repeated at least three times for cytologic examination before the diagnosis is rejected. MRI findings suggestive of neoplastic meningitis include leptomeningeal, subependymal, dural, or cranial nerve enhancement; superficial cerebral lesions; and communicating hydrocephalus. Spinal cord imaging by MRI is a necessary component of the evaluation of nonleukemia neoplastic meningitis as ~20% of patients have cord abnormalities, including intradural enhancing nodules that are diagnostic for leptomeningeal involvement. Cauda equina lesions are common, but lesions may be seen anywhere in the spinal canal. Radiolabeled CSF flow studies are abnormal in up to 70% of patients with neoplastic meningitis; ventricular outlet obstruction, abnormal flow in the spinal canal, or impaired flow over the cerebral convexities may affect distribution of intrathecal chemotherapy resulting in decreased efficacy or increased toxicity. Radiation therapy may correct CSF flow abnormalities before use of intrathecal chemotherapy. Neoplastic meningitis can also lead to intracranial hypertension and hydrocephalus. Placement of a ventriculoperitoneal shunt may effectively palliate symptoms in these patients.

The development of neoplastic meningitis usually occurs in the setting of uncontrolled cancer outside the CNS; thus, prognosis is poor (median survival 10–12 weeks). However, treatment of the neoplastic meningitis may successfully alleviate symptoms and control the CNS spread.

Rx NEOPLASTIC MENINGITIS

Intrathecal chemotherapy, usually methotrexate, cytarabine, or thiotepa, is delivered by lumbar puncture or by an intraventricular reservoir (Ommaya) three times a week until the CSF is free of malignant cells. Injections are given twice a week for a month and then weekly for a month. An extended release preparation of cytarabine (Depocyte) has a longer half-life and is more effective than other formulations. Among solid tumors, breast cancer responds best to therapy. Patients with neoplastic meningitis from either acute leukemia or lymphoma may be cured of their CNS disease if the systemic disease can be eliminated.

SEIZURES

Seizures occurring in a patient with cancer can be caused by the tumor itself, by metabolic disturbances, by radiation injury, by cerebral infarctions, by chemotherapy-related encephalopathies, or by CNS infections. Metastatic disease to the CNS is the most common cause of seizures in patients with cancer. However, seizures occur more frequently in primary brain tumors than in metastatic brain lesions. Seizures are a presenting symptom of CNS metastasis in 6–29% of cases. Approximately 10% of patients with CNS metastasis eventually develop seizures. The presence of frontal lesions correlates with early seizures, and the presence of hemispheric symptoms increases the risk for late seizures. Both early and late seizures are uncommon in patients with posterior fossa lesions. Seizures are also common in patients with CNS metastases from melanoma. Very rarely, cytotoxic drugs such as etoposide, busulfan, and chlorambucil cause seizures.

Rx SEIZURES

Patients in whom seizures due to CNS metastases have been demonstrated should receive anticonvulsive treatment with diphenylhydantoin. Prophylactic anticonvulsant therapy is not recommended unless the patient is at a high risk for late seizures (melanoma primary, hemorrhagic metastases, treatment with radiosurgery). In those patients, serum diphenylhydantoin levels should be monitored closely and the dosage adjusted according to serum levels. Phenytoin induces the hepatic metabolism of dexamethasone, reducing its half-life, while dexamethasone may decrease phenytoin levels. Most antiseizure medications induce CYP450, which alters the metabolism of antitumor agents, including irinotecan, taxanes, and etoposide as well as molecular targeted agents including imatinib, gefitinib, and tipifarnib.

PULMONARY AND INTRACEREBRAL LEUKOCYTOSTASIS

Hyperleukocytosis and the leukostasis syndrome associated with it is a potentially fatal complication of acute leukemia (particularly myeloid leukemia) that can occur when the peripheral blast cell count is >100,000/mL. The frequency of hyperleukocytosis is 5–13% in AML and 10–30% in acute lymphoid leukemia; however, leukostasis is rare in lymphoid leukemia. At such high blast cell counts, blood viscosity is increased, blood flow is slowed by aggregates of tumor cells, and the primitive myeloid leukemic cells are capable of invading through endothelium and causing hemorrhage. Brain and lung are most commonly affected. Patients with brain leukostasis may experience stupor,

headache, dizziness, tinnitus, visual disturbances, ataxia, confusion, coma, or sudden death. Administration of 600 cGy of whole-brain irradiation can protect against this complication and can be followed by rapid institution of antileukemic therapy. Pulmonary leukostasis may present as respiratory distress, hypoxemia, and progress to respiratory failure. Chest radiographs may be normal but usually show interstitial or alveolar infiltrates. Arterial blood gas results should be interpreted cautiously. Rapid consumption of plasma oxygen by the markedly increased number of white blood cells can cause spuriously low arterial oxygen tension. Pulse oximetry is the most accurate way of assessing oxygenation in patients with hyperleukocytosis. Leukapheresis may be helpful in decreasing circulating blast counts. Treatment of the leukemia can result in pulmonary hemorrhage from lysis of blasts in the lung, called *leukemic cell lysis pneumopathy*. Intravascular volume depletion and unnecessary blood transfusions may increase blood viscosity and worsen the leukostasis syndrome. Leukostasis is not a feature of the high white cell counts associated with chronic lymphoid or chronic myeloid leukemia.

When acute promyelocytic leukemia is treated with differentiating agents like tretinoin and arsenic trioxide, cerebral or pulmonary leukostasis may occur as tumor cells differentiate into mature neutrophils. This complication can be largely avoided by using cytotoxic chemotherapy together with the differentiating agents.

HEMOPTYSIS

Hemoptysis may be caused by nonmalignant conditions, but lung cancer accounts for a large proportion of cases. Up to 20% of patients with lung cancer have hemoptysis some time in their course. Endobronchial metastases from carcinoid tumors, breast cancer, colon cancer, kidney cancer, and melanoma may also cause hemoptysis. The volume of bleeding is often difficult to gauge. Massive hemoptysis is defined as >600 mL of blood produced in 24 h. However, any hemoptysis should be considered massive if it threatens life. When respiratory difficulty occurs, hemoptysis should be treated emergently. The first priorities are to maintain the airway, optimize oxygenation, and stabilize the hemodynamic status. Often patients can tell where the bleeding is occurring. They should be placed bleeding side down and given supplemental oxygen. If large-volume bleeding continues or the airway is compromised, the patient should be intubated and undergo emergency bronchoscopy. If the site of bleeding is detected, either the patient undergoes a definitive surgical procedure or the lesion is treated with a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. The surgical option is preferred. Bronchial artery embolization may control brisk bleeding in 75–90% of patients, permitting the definitive surgical procedure to be done more safely. Embolization without definitive surgery is associated with rebleeding in 20–50% of patients. Recurrent hemoptysis usually responds to a second embolization procedure. A post-embolization syndrome characterized by pleuritic pain, fever, dysphagia, and leukocytosis may occur; it lasts 5–7 days and resolves with symptomatic treatment. Bronchial or esophageal wall necrosis, myocardial infarction, and spinal cord infarction are rare complications.

Pulmonary hemorrhage with or without hemoptysis in hematologic malignancies is often associated with fungal infections, particularly *Aspergillus* sp. After granulocytopenia resolves, the lung infiltrates in aspergillosis may cavitate and cause massive hemoptysis. Thrombocytopenia and coagulation defects should be corrected, if possible. Surgical evaluation is recommended in patients with aspergillosis-related cavitary lesions.

AIRWAY OBSTRUCTION

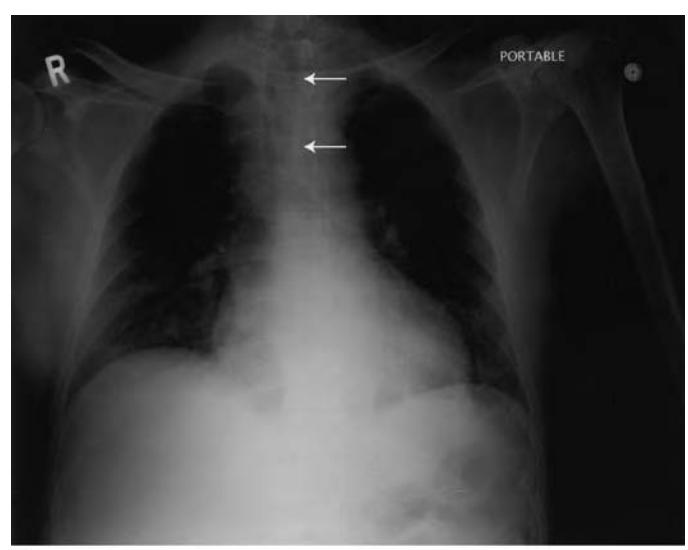
Airway obstruction refers to a blockage at the level of the mainstem bronchi or above. It may result either from intraluminal tumor growth or from extrinsic compression of the airway. The most common cause of malignant upper airway obstruction is invasion from an adjacent primary tumor, most commonly lung cancer, followed by esophageal, thyroid, and mediastinal malignancies. Extrathoracic primary tumors such as renal, colon, or breast cancer can cause airway obstruction through endobronchial and/or mediastinal lymph node metastases. Patients may present with dyspnea, hemoptysis, stridor, wheezing, intractable cough, postobstructive pneumonia, or hoarseness. Chest radiographs usually demonstrate obstructing lesions. CT scans reveal the extent of tumor. Cool, humidified oxygen, glucocorticoids, and ventilation with a mixture of helium and oxygen (Heliox) may provide temporary relief. If the obstruction is proximal to the larynx, a tracheostomy may be lifesaving. For more distal obstructions, particularly intrinsic lesions incompletely obstructing the airway, bronchoscopy with laser treatment, photodynamic therapy, or stenting can produce immediate relief in most patients (Fig. 270-3). However, radiation therapy (either external-beam irradiation or brachytherapy) given together with glucocorticoids may also open the airway. Symptomatic extrinsic compression may be palliated by stenting. Patients with primary airway tumors such as squamous cell carcinoma, carcinoid tumor, adenocystic carcinoma, or non-small cell lung cancer should have surgery.

METABOLIC EMERGENCIES

HYPERCALCEMIA

Hypercalcemia is the most common paraneoplastic syndrome. **Its pathogenesis and management are fully discussed in Chaps. 96 and 347.**

A



B

FIGURE 270-3 Airway obstruction. *A.* CT scan of a 62-year-old-man with tracheal obstruction caused by renal carcinoma showing paratracheal mass (*A*) with tracheal invasion/obstruction (*arrow*). ***B.*** Chest x-ray of same patient after stent (*arrows*) placement.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE (SIADH)

Hyponatremia is a common electrolyte abnormality in cancer patients, and SIADH is the most common cause of hyponatremia among patients with cancer. **SIADH is discussed fully in Chaps. 96 and 334.**

LACTIC ACIDOSIS

Lactic acidosis is a rare and potentially fatal metabolic complication of cancer. Lactic acidosis associated with sepsis, and circulatory failure is a common preterminal event in many malignancies. Lactic acidosis in the absence of hypoxemia may occur in patients with leukemia, lymphoma, or solid tumors. Extensive involvement of the liver by tumor is present in most cases. Alteration of liver function may be responsible for the lactate accumulation. HIV-infected patients have an increased risk of aggressive lymphoma; lactic acidosis that occurs in such patients may be related either to the rapid growth of the tumor or from toxicity of nucleoside reverse transcriptase inhibitors. Symptoms of lactic acidosis include tachypnea, tachycardia, change of mental status, and hepatomegaly. The serum level of lactic acid may reach 10–20 meq/L (90–180 mg/dL). Treatment is aimed at the underlying disease. The danger from lactic acidosis is from the acidosis, not the lactate. Sodium bicarbonate should be added if acidosis is very severe or if hydrogen ion production is very rapid and uncontrolled. The prognosis is poor.

HYPOGLYCEMIA

Persistent hypoglycemia is occasionally associated with tumors other than pancreatic islet cell tumors. Usually these tumors are large; tumors of mesenchymal origin, hepatomas, or adrenocortical tumors may cause hypoglycemia. Mesenchymal tumors are usually located in the retroperitoneum or thorax. Obtundation, confusion, and behavioral aberrations occur in the postabsorptive period and may precede the diagnosis of the tumor. These tumors often secrete incompletely processed insulin-like growth factor II (IGF-II), a hormone capable of activating insulin receptors and causing hypoglycemia. Tumors secreting incompletely processed big IGF-II are characterized by an increased IGF-II to IGF-I ratio, suppressed insulin and C peptide level, and inappropriately low growth hormone and β-hydroxybutyrate concentrations. Rarely, hypoglycemia is due to insulin secretion by a non-islet cell carcinoma. The development of hepatic dysfunction from liver metastases and increased glucose consumption by the tumor can contribute to hypoglycemia. If the tumor cannot be resected, hypoglycemia symptoms may be relieved by the administration of glucose, glucocorticoids, or glucagon.

Hypoglycemia can be artifactual; hyperleukocytosis from leukemia, myeloproliferative diseases, leukemoid reactions, or colony stimulating factor treatment can increase glucose consumption in the test tube after blood is drawn, leading to pseudohypoglycemia.

ADRENAL INSUFFICIENCY

In patients with cancer, adrenal insufficiency may go unrecognized because the symptoms, such as nausea, vomiting, anorexia, and orthostatic hypotension, are nonspecific and may be mistakenly attributed to progressive cancer or to therapy. Primary adrenal insufficiency may develop owing to replacement of both glands by metastases (lung, breast, colon, or kidney cancer; lymphoma), to removal of both glands, or to hemorrhagic necrosis in association with sepsis or anticoagulation. Impaired adrenal steroid synthesis occurs in patients being treated for cancer with mitotane, ketoconazole, or aminoglutethimide or undergoing rapid reduction in glucocorticoid therapy. Rarely, metastatic replacement causes primary adrenal insufficiency as the first manifestation of an occult malignancy. Metastasis to the pituitary or hypothalamus is found at autopsy in up to 5% of patients with cancer, but associated secondary adrenal insufficiency is rare. Megesterol acetate, used to manage cancer and HIV-related cachexia, may suppress plasma levels of cortisol and adrenocorticotropic hormone (ACTH). Patients taking megesterol may develop adrenal insufficiency, and even those whose adrenal dysfunction is not symptomatic may have inadequate adrenal reserve if they become seriously ill. Cranial irradiation for childhood brain tumors may affect the hypothalamus-pituitary-adrenal axis, resulting in secondary adrenal insufficiency.

Acute adrenal insufficiency is potentially lethal. Treatment of suspected adrenal crisis is initiated after the sampling of serum cortisol and ACTH levels (Chap. 336).

TREATMENT-RELATED EMERGENCIES

TUMOR LYSIS SYNDROME

Tumor lysis syndrome (TLS) is characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia and is caused by the destruction of a large number of rapidly proliferating neoplastic cells. Acidosis may also develop. Acute renal failure occurs frequently.

TLS is most often associated with the treatment of Burkitt's lymphoma, acute lymphoblastic leukemia, and other high-grade lymphomas, but it also may be seen with chronic leukemias and, rarely, with solid tumors. This syndrome has been seen in patients with chronic lymphocytic leukemia after treatment with nucleosides. TLS has been observed with administration of glucocorticoids, hormonal agents such as letrozole and tamoxifen, and monoclonal antibodies such as rituximab and gemtuzumab. TLS usually occurs during or shortly (1–5 days) after chemotherapy. Rarely, spontaneous necrosis of malignancies causes TLS.

Hyperuricemia may be present at the time of chemotherapy. Effective treatment kills malignant cells and leads to increased serum uric acid levels from the turnover of nucleic acids. Owing to the acidic local environment, uric acid can precipitate in the tubules, medulla, and collecting ducts of the kidney, leading to renal failure. Lactic acidosis and dehydration may contribute to the precipitation of uric acid in the renal tubules. The finding of uric acid crystals in the urine is strong evidence for uric acid nephropathy. The ratio of urinary uric acid to urinary creatinine is >1 in patients with acute hyperuricemic nephropathy and <1 in patients with renal failure due to other causes.

Hyperphosphatemia, which can be caused by the release of intracellular phosphate pools by tumor lysis, produces a reciprocal depression in serum calcium, which causes severe neuromuscular irritability and tetany. Deposition of calcium phosphate in the kidney and hyperphosphatemia may cause renal failure. Potassium is the principal intracellular cation, and massive destruction of malignant cells may lead to hyperkalemia. Hyperkalemia in patients with renal failure may rapidly become life-threatening by causing ventricular arrhythmias and sudden death.

The likelihood that TLS will occur in patients with Burkitt's lymphoma is related to the tumor burden and renal function. Hyperuricemia and high serum levels of lactate dehydrogenase (LDH >1500 U/L), both of which correlate with total tumor burden, also correlate with the risk of TLS. In patients at risk for TLS, pretreatment evaluations should include a complete blood count, serum chemistry evaluation, and urine analysis. High leukocyte and platelet counts may artificially elevate potassium levels ("pseudohyperkalemia") due to lysis of these cells after the blood is drawn. In these cases, plasma potassium instead of serum potassium should be followed. In pseudohyperkalemia, no electrocardiographic abnormalities are present. In patients with abnormal baseline renal function, the kidneys and retroperitoneal area should be evaluated by sonography and/or CT to rule out obstructive uropathy. Urine output should be watched closely.

℞ TUMOR LYSIS SYNDROME

Recognition of risk and prevention are the most important steps in the management of this syndrome **(Fig. 270-4)**. The standard preventive approach consists of allopurinol, urinary alkalinization, and aggressive hydration. Intravenous allopurinol may be given in patients who cannot tolerate oral therapy. In some cases, uric acid levels cannot be lowered sufficiently with the standard preventive approach. Rasburicase can be effective in these instances. Urate oxidase is missing from primates and catalyzes the conversion of poorly soluble uric acid to readily soluble allantoin. Rasburicase acts rapidly, decreasing uric acid levels within hours; however, it may cause hypersensitivity reactions such as bronchospasm, hypoxemia, and hypotension. Rasburicase is contraindicated in patients with glucose-

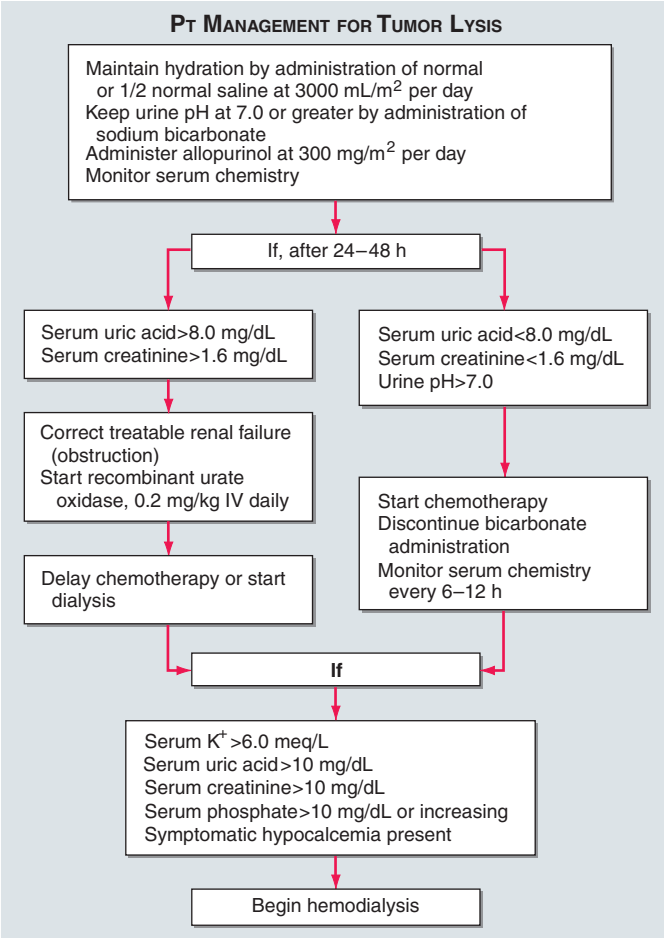


FIGURE 270-4 Management of patients at high risk for the tumor lysis syndrome.

6-phosphate dehydrogenase deficiency who are unable to break down hydrogen peroxide, an end product of the urate oxidase reaction. Despite aggressive prophylaxis, TLS and/or oliguric or anuric renal failure may occur. Care should be taken to prevent worsening of symptomatic hypocalcemia by induction of alkalosis during bicarbonate infusion. Administration of sodium bicarbonate may also lead to urinary precipitation of calcium phosphate, which is less soluble at alkaline pH. Dialysis is often necessary and should be considered early in the course. Hemodialysis is preferred. Hemofiltration offers a gradual, continuous method of removing cellular byproducts and fluid. The prognosis is excellent, and renal function recovers after the uric acid level is lowered to ≤10 mg/dL.

HUMAN ANTIBODY INFUSION REACTIONS

The initial infusion of human or humanized antibodies (e.g., rituximab, gemtuzumab, trastuzumab) is associated with fever, chills, nausea, asthenia, and headache in up to half of treated patients. Bronchospasm and hypotension occur in 1% of patients. The pathogenesis is thought to be activation of immune effector processes (cells and complement). In the presence of high levels of circulating lymphoid tumor cells, thrombocytopenia, a rapid fall in circulating tumor cells, and mild electrolyte evidence of TLS may also occur. In addition, increased liver enzymes, D-dimer, LDH, and prolongation of the prothrombin time may occur. This syndrome is related to release of inflammatory cytokines, such as tumor necrosis factor α and interleukin 6. Diphenhydramine and acetaminophen can often prevent or suppress the symptoms. If they occur, the infusion is stopped and restarted at half the initial infusion rate after the symptoms have abated.

HEMOLYTIC-UREMIC SYNDROME

Hemolytic-uremic syndrome (HUS) and, less commonly, thrombotic thrombocytopenic purpura (TTP) occurring after treatment with antineoplastic drugs have been described. Mitomycin is by far the most common agent causing this peculiar syndrome. Other chemotherapeutic agents, including cisplatin, bleomycin, and gemcitabine, have also been reported to be associated with this syndrome. It occurs most often in patients with gastric, colorectal, pancreatic, and breast carcinoma. In one series, 35% of patients were without evident cancer at the time this syndrome appeared. Secondary HUS/TTP has also been reported as a rare but sometimes fatal complication of bone marrow transplantation.

HUS usually has its onset 4–8 weeks after the last dose of chemotherapy, but it is not rare to detect it several months later. HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Dyspnea, weakness, fatigue, oliguria, and purpura are also common initial symptoms and findings. Systemic hypertension and pulmonary edema frequently occur. Severe hypertension, pulmonary edema, and rapid worsening of hemolysis and renal function may occur after a blood or blood product transfusion. Cardiac findings include atrial arrhythmias, pericardial friction rub, and pericardial effusion. Raynaud's phenomenon is part of the syndrome in patients treated with bleomycin.

Laboratory findings include severe to moderate anemia associated with red blood cell fragmentation and numerous schistocytes on peripheral smear. Reticulocytosis, decreased plasma haptoglobin, and an LDH level document hemolysis. The serum bilirubin level is usually normal or slightly elevated. The Coombs' test is negative. The white cell count is usually normal, and thrombocytopenia (<100,000/μL) is almost always present. Most patients have a normal coagulation profile, although some have mild elevations in thrombin time and in level of fibrin degradation products. The serum creatinine level is elevated at presentation and shows a pattern of subacute worsening within weeks of the initial azotemia. The urinalysis reveals hematuria, proteinuria, and granular or hyaline casts; and circulating immune complexes may be present.

The basic pathologic lesion appears to be deposition of fibrin in the walls of capillaries and arterioles, and these deposits are similar to those seen in HUS due to other causes. These microvascular abnormalities involve mainly the kidneys and rarely occur in other organs. The pathogenesis of chemotherapy-related HUS is unknown. Other forms of HUS/TTP are related to a decrease in processing of von Willebrand factor by a protease called ADAMTS13.

The case fatality rate is high; most patients die within a few months. Plasmapheresis and plasma exchange may normalize the hematologic abnormalities, but renal failure is not reversed in most patients. Immunoperfusion over a staphylococcal protein A column is the most successful treatment. About half of the patients treated with immunoperfusion respond with resolution of thrombocytopenia, improvement in anemia, and stabilization of renal failure. Treatment is well tolerated. It is not clear how the treatment works.

NEUTROPENIA AND INFECTION

These remain the most common serious complications of cancer therapy. They are covered in detail in Chap. 82.

PULMONARY INFILTRATES

Patients with cancer may present with dyspnea associated with diffuse interstitial infiltrates on chest radiographs. Such infiltrates may be due to progression of the underlying malignancy, treatment-related toxicities, infection, and/or unrelated diseases. The cause may be multifactorial; however, most commonly they occur as a consequence of treatment. Infiltration of the lung by malignancy has been described in patients with leukemia, lymphoma, and breast and other solid cancers. Pulmonary lymphatics may be involved diffusely by neoplasm (pulmonary lymphangitic carcinomatosis), resulting in a diffuse increase in interstitial markings on chest radiographs. The patient is often mildly dyspneic at the onset, but pulmonary failure develops over a period of weeks. In some patients, dyspnea precedes changes on the chest radiographs and is accompanied by a nonproductive cough. This syndrome is characteristic of solid tumors. In patients with leukemia,

diffuse microscopic neoplastic peribronchial and peribronchiolar infiltration is frequent but may be asymptomatic. However, some patients present with diffuse interstitial infiltrates, an alveolar capillary block syndrome, and respiratory distress. In these situations, glucocorticoids can provide symptomatic relief, but specific chemotherapy should always be started promptly.

Several cytotoxic agents, such as bleomycin, methotrexate, busulfan, and the nitrosoureas, may cause pulmonary damage. The most frequent presentations are interstitial pneumonitis, alveolitis, and pulmonary fibrosis. Some cytotoxic agents, including methotrexate and procarbazine, may cause an acute hypersensitivity reaction. Cytosine arabinoside has been associated with noncardiogenic pulmonary edema. Administration of multiple cytotoxic drugs, as well as radiotherapy and preexisting lung disease, may potentiate the pulmonary toxicity. Supplemental oxygen may potentiate the effects of drugs and radiation injury. Patients should always be managed with the lowest FI_{O_2} that is sufficient to maintain hemoglobin saturation.

The onset of symptoms may be insidious, with symptoms including dyspnea, nonproductive cough, and tachycardia. Patients may have bibasilar crepitant rales, end-inspiratory crackles, fever, and cyanosis. The chest radiograph generally shows an interstitial and sometimes an intraalveolar pattern that is strongest at the lung bases and may be symmetric. A small effusion may occur. Hypoxemia with decreased carbon monoxide diffusing capacity is always present. Glucocorticoids may be helpful in patients in whom pulmonary toxicity is related to radiation therapy or to chemotherapy. Treatment is otherwise supportive.

Molecular targeted agents, imatinib, erlotinib, and gefitinib are potent inhibitors of tyrosine kinases. These drugs may cause interstitial lung disease. In the case of gefitinib, preexisting fibrosis, poor performance status, and prior thoracic irradiation are independent risk factors; this complication has high fatality rate. In Japan, incidence of interstitial lung disease associated with gefitinib was about 4.5%.

Radiation pneumonitis and/or fibrosis is a relatively frequent side effect of thoracic radiation therapy. It may be acute or chronic. Radiation-induced lung toxicity is a function of the irradiated lung volume, dose per fraction, and radiation dose. The larger the irradiated lung field, the higher the risk for radiation pneumonitis. Radiation pneumonitis usually develops from 2 to 6 months after completion of radiotherapy. The clinical syndrome, which varies in severity, consists of dyspnea, cough with scanty sputum, low-grade fever, and an initial hazy infiltrate on chest radiographs. The infiltrate and tissue damage usually are confined to the radiation field. The patients subsequently may develop a patchy alveolar infiltrate and air bronchograms, which may progress to acute respiratory failure that is sometimes fatal. A lung biopsy may be necessary to make the diagnosis. Asymptomatic infiltrates found incidentally after radiation therapy need not be treated. However, prednisone should be administered to patients with fever or other symptoms. The dosage should be tapered slowly after the resolution of radiation pneumonitis, as abrupt withdrawal of glucocorticoids may cause an exacerbation of pneumonia. Delayed radiation fibrosis may occur years after radiation therapy and is signaled by dyspnea on exertion. Often it is mild, but it can progress to chronic respiratory failure. Therapy is supportive.

Classical radiation pneumonitis that leads to pulmonary fibrosis is due to radiation-induced production of local cytokines such as platelet-derived growth factor β, tumor necrosis factor, and transforming growth factor β in the radiation field. An immunologically mediated sporadic radiation pneumonitis occurs in about 10% of patients; bilateral alveolitis mediated by T cells results in infiltrates outside the radiation field. This form of radiation pneumonitis usually resolves without sequelae.

Pneumonia is a common problem in patients undergoing treatment for cancer. Bacterial pneumonia typically causes a localized infiltrate on chest radiographs. Therapy is tailored to the causative organism. When diffuse interstitial infiltrates appear in a febrile patient, the differential diagnosis is extensive and includes pneumonia due to infection with *Pneumocystis carinii*; viral infections including cytomegalovirus, adenovirus, herpes simplex virus, herpes zoster, respiratory syncytial virus, or intracellular pathogens such as *Mycoplasma* and *Legionella*; effects of drugs or radiation; tumor progression; nonspecific pneumonitis; and fungal disease. Detection of opportunistic pathogens in pulmonary infections is still a challenge. Diagnostic tools include chest radiographs, CT scans, bronchoscopy with bronchoalveolar lavage, brush cytology, transbronchial biopsy, fine-needle aspiration, and open lung biopsy. In addition to the culture, evaluation of bronchoalveolar lavage fluid for *P. carinii* by polymerase chain reaction (PCR) and aspergillus antigen improve the diagnostic yield. Patients with cancer who are neutropenic and have fever and local infiltrates on chest radiograph should be treated initially with broad spectrum antibiotics, such as ceftazidime or imipenem. A new or persistent focal infiltrate not responding to broad spectrum antibiotics argues for initiation of empiric antifungal therapy. When diffuse bilateral infiltrates develop in patients with febrile neutropenia, broad spectrum antibiotics plus trimethoprim-sulfamethoxazole, with or without erythromycin, should be initiated. Addition of an antiviral agent is necessary in some settings, such as patients undergoing allogeneic hematopoietic stem cell transplantation. The empiric administration of trimethoprim-sulfamethoxazole plus erythromycin to patients without neutropenia and these antibiotics plus ceftazidime to patients with neutropenia covers nearly every treatable diagnosis (except tumor progression) and gives as good overall survival as a strategy based on early invasive intervention with bronchoalveolar lavage or open lung biopsy. If the patient does not improve in 4 days, open lung biopsy is the procedure of choice. Bronchoscopy with bronchoalveolar lavage may be used in patients who are poor candidates for surgery.

In patients with pulmonary infiltrates who are afebrile, heart failure and multiple pulmonary emboli are in the differential diagnosis.

NEUTROPENIC ENTEROCOLITIS

Neutropenic enterocolitis (typhlitis) is the inflammation and necrosis of the cecum and surrounding tissues that may complicate the treatment of acute leukemia. This complication has also been seen in patients with other forms of cancer treated with taxanes and in patients receiving high-dose chemotherapy (Fig. 270-5). The patient develops right lower quadrant abdominal pain, often with rebound tenderness and a tense, distended abdomen, in a setting of fever and neutropenia. Watery diarrhea (often containing sloughed mucosa) and bacteremia are common, and bleeding may occur. Plain abdominal films are generally of little value in the diagnosis; CT scan may show marked bowel wall thickening, particularly in the cecum, with bowel wall edema. Patients with bowel wall thickness >10 mm on ultrasonogram have higher mortality rates. However, bowel wall thickening is significantly more prominent in patients with *Clostridium difficile* colitis. Pneumatosis intestinalis is a more specific finding, seen only in those with neutropenic enterocolitis and ischemia. The combined involvement of the small and large bowel suggests a diagnosis of neutropenic enterocolitis. Rapid institution of broad-spectrum antibiotics and nasogastric suction may reverse the process. Surgical intervention should be considered if no improvement is seen by 24 h after the start of antibiotic treatment. If the localized abdominal findings become diffuse, the prognosis is poor.

C. difficile colitis is increasing in incidence. Newer strains of *C. difficile* produce about 20 times more of toxins A and B compared to previously studied strains. *C. difficile* risk is also increased with chemotherapy. Antibiotic coverage for *C. difficile* should be added if pseudomembranous colitis cannot be excluded.

HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis can develop in patients receiving cyclophosphamide or ifosfamide. Both drugs are metabolized to acrolein, which is a strong chemical irritant that is excreted in the urine. Prolonged contact or high concentrations may lead to bladder irritation and hemorrhage. Symptoms include gross hematuria, frequency, dysuria, burning, urgency, incontinence, and nocturia. The best management is prevention. Maintaining a high rate of urine flow minimizes exposure. In addition, 2-mercaptoethanesulfonate (mesna) detoxifies

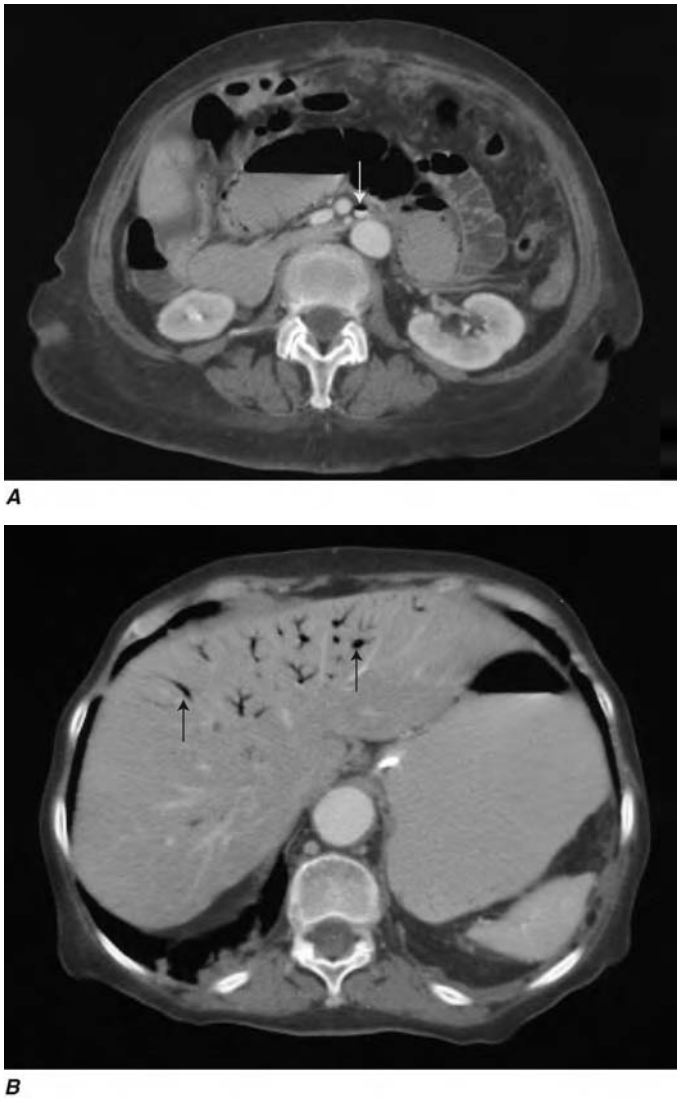

FIGURE 270-5 Abdominal CT scans of a 72-year-old woman with neutropenic enterocolitis secondary to chemotherapy. *A.* Air in inferior mesenteric vein (*arrow*) and bowel wall with pneumatosis intestinalis. ***B.*** CT scans of upper abdomen demonstrating air in portal vein (*arrows*).

the metabolites and can be coadministered with the instigating drugs. Mesna usually is given three times on the day of ifosfamide administration in doses that are each 20% of the total ifosfamide dose. If hemorrhagic cystitis develops, the maintenance of a high urine flow may be sufficient supportive care. If conservative management is not effective, irrigation of the bladder with a 0.37–0.74% formalin solution for 10 min stops the bleeding in most cases. *N*-acetylcysteine may also be an effective irrigant. Prostaglandins (carboprost) can inhibit the process. In extreme cases, ligation of the hypogastric arteries, urinary diversion, or cystectomy may be necessary.

Hemorrhagic cystitis also occurs in patients who undergo bone marrow transplantation (BMT). In the BMT setting, early-onset hemorrhagic cystitis is related to drugs in the treatment regimen (e.g., cyclophosphamide) and late-onset hemorrhagic cystitis is usually due to the polyoma virus BKV or adenovirus type 11. BKV load in urine alone or in combination with acute graft-versus-host disease correlate with development of hemorrhagic cystitis. Viral causes are usually detected by PCR-based diagnostic tests. Treatment of viral hemorrhagic cystitis is largely supportive, with reduction in doses of immunosuppressive agents, if possible. No antiviral therapy is approved, though cidofovir is being tested.

HYPERSENSITIVITY REACTIONS TO ANTINEOPLASTIC DRUGS

Many antineoplastic drugs may cause hypersensitivity reaction (HSR). These reactions are unpredictable and potentially life-threatening. Most reactions occur during or within hours of parenteral drug administration. Taxanes; platinum compounds; asparginase; etoposide; and biologic agents including rituximab, bevacizumab, trastuzumab, gemtuzumab, cetuximab, and alemtuzumab are more commonly associated with acute HSR than are other agents. Acute hypersensitivity reactions to some drugs, such as taxanes, occur during the first or second dose administered. HSR from platinum compounds occurs after prolonged exposure. Skin testing may identify patients with high risk for HSR after carboplatin exposure. Premedication with histamine H1 and H2 receptor antagonists and glucocorticoids reduce the incidence of hypersensitivity reaction to taxanes, particularly paclitaxel. Despite premedication, HSR may still occur. In these cases, retreatment may be attempted with care, but use of alternative agents may be required.

271 Cellular and Molecular Biology of the Kidney

Alfred L. George, Jr., Eric G. Neilson

The kidney is one of the most highly differentiated organs in the body. Nearly 30 different cell types can be found in the renal interstitium or along segmented nephrons, blood vessels, and filtering capillaries at the conclusion of embryological development. This panoply of cells modulates a variety of complex physiologic processes. Endocrine functions, the regulation of blood pressure and intraglomerular hemodynamics, solute and water transport, acid-base balance, and removal of fuel or drug metabolites are all accomplished by intricate mechanisms of renal response. This breadth of physiology hinges on the clever ingenuity of nephron architecture that evolved as complex organisms came out of water to live on land.

EMBRYOLOGICAL DEVELOPMENT

The kidney develops from within the intermediate mesoderm under the timed or sequential control of a growing number of genes, described in Fig. 271-1. The transcription of these genes is guided by morphogenic cues that invite ureteric buds to penetrate the metanephric blastema, where they induce primary mesenchymal cells to form early nephrons. This induction involves a number of complex signaling pathways mediated by c-Met, fibroblast growth factor, transforming growth factor β, glial cell–derived neurotrophic factor, hepatocyte growth factor, epithelial growth factor, and the Wnt family of proteins. The ureteric buds derive from the posterior nephric ducts and mature into collecting ducts that eventually funnel to a renal pelvis and ureter. Induced mesenchyme undergoes mesenchymal-epithelia transitions to form comma-shape bodies at the proximal end of each ureteric bud leading to the formation of S-shape nephrons that cleft and enjoin with penetrating endothelial cells derived from sprouting angioblasts. Under the influence of vascular endothelial growth factor A, these penetrating cells form capillaries with surrounding mesangial cells that differentiate into a glomerular filter for plasma water and solute. The ureteric buds branch, and each branch produces a new set of nephrons. The number of branching events ultimately determines the total number of nephrons in each kidney. There are approximately 900,000 glomeruli in each kidney in normal-birth-weight adults and as few as 225,000 in low-birth-weight adults. In the latter case, a failure to complete the last one or two rounds of branching leads to smaller kidneys and increased risk for hypertension and cardiovascular disease later in life.

Glomeruli evolved as complex capillary filters with fenestrated endothelia. Outlining each capillary is a basement membrane covered by epithelial podocytes. Podocytes attach by special foot processes and share a slit-pore membrane with their neighbor. The slit-pore membrane is formed by the interaction of nephrin, annexin-4, CD2AP, FAT, ZO-1, P-cadherin, podocin, and neph 1–3 proteins. These glomerular capillaries seat in a mesangial matrix shrouded by parietal and proximal tubular epithelia forming Bowman's capsule. Mesangial cells have an embryonic lineage consistent with arteriolar or juxtaglomerular cells and contain contractile actin-myosin fibers. These cells make contact with glomerular capillary loops, and their matrix holds them in condensed arrangement. Between nephrons lies the renal interstitium. This region forms the functional space surrounding glomeruli and their downstream tubules, which are home to resident and trafficking cells, such as fibroblasts, dendritic cells, occasional lymphocytes, and lipid-laden macrophages. The cortical and medullary capillaries, which siphon off solute and water following tubular reclamation of glomerular filtrate, are also part of the interstitial fabric as well as a web of connective tissue that supports the kidney's emblematic architecture of folding tubules. The relational precision of these structures determines the unique physiology of the kidney.

Each nephron segments during embryological development into a proximal tubule, descending and ascending limbs of the loop of Henle, distal tubule, and the collecting duct. These classic tubular segments have subsegments recognized by highly unique epithelia serving regional physiology. All nephrons have the same structural components, but there are two types whose structure depends on their location within the kidney. The majority of nephrons are cortical, with glomeruli located in the mid-to-outer cortex. Fewer nephrons are juxtamedullary, with glomeruli at the boundary of the cortex and outer medulla. Cortical nephrons have short loops of Henle, whereas juxtamedullary nephrons have long loops of Henle. There are critical differences in blood supply as well. The peritubular capillaries surrounding cortical nephrons are shared among adjacent nephrons. By contrast, juxtamedullary nephrons use separate capillaries called *vasa recta*. Cortical nephrons

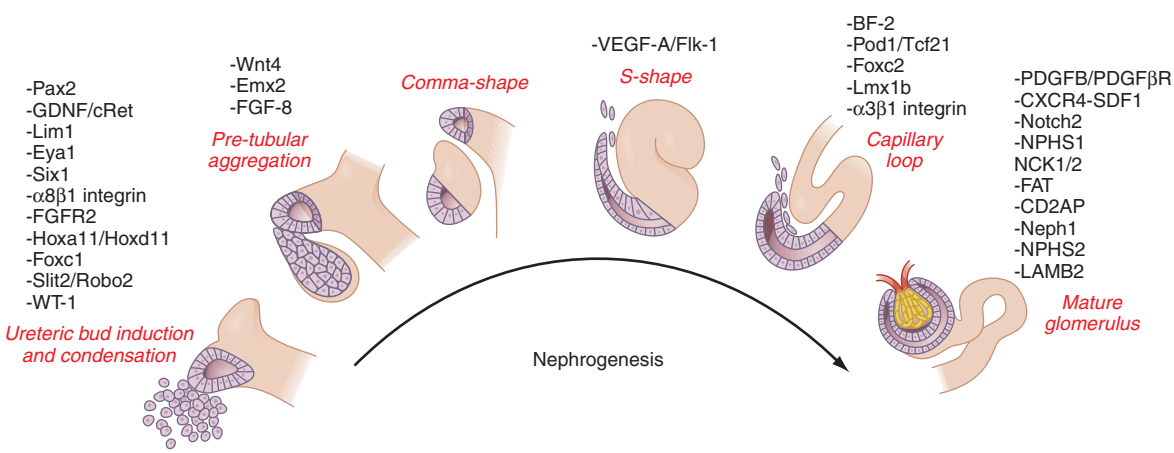

FIGURE 271-1 Genes controlling renal nephrogenesis. A growing number of genes have been identified at various stages of glomerulotubular development in mammalian kidney. The genes listed have been tested in various genetically modified mice, and their location corresponds to the classical stages of kidney development postulated by Saxen in 1987. GDNF, giant cell line–derived neutrophilic factor; FGFR2, fibroblast growth factor receptor 2; WT-1, Wilms tumor gene 1; FGF-8, fibroblast growth factor 8; VEGF–A/Flk-1, vascular endothelial growth factor–A/fetal liver kinase-1; PDGFB, platelet-derived growth factor B; PDGFβR, PDGFβ receptor; SDF-1, stromal-derived factor 1; NPHS1, nephrin; NCK1/2, NCK-adaptor protein; CD2AP, CD2-associated protein; NPHS2, podocin; LAMB2, laminin beta-2.

perform most of the glomerular filtration because there are more of them and because their afferent arterioles are larger than their respective efferent arterioles. The juxtamedullary nephrons, with longer loops of Henle, create a hyperosmolar gradient that allows for the production of concentrated urine. How developmental instructions specify the differentiation of all these unique epithelia among various tubular segments is still unknown.

DETERMINANTS AND REGULATION OF GLOMERULAR FILTRATION

Renal blood flow drains approximately 20% of the cardiac output, or 1000 mL/min. Blood reaches each nephron through the afferent arteriole leading into a glomerular capillary where large amounts of fluid and solutes are filtered as tubular fluid. The distal ends of the glomerular capillaries coalesce to form an efferent arteriole leading to the first segment of a second capillary network (peritubular capillaries) surrounding the cortical tubules (Fig. 271-2*A*). Thus, the cortical nephron has two capillary beds arranged in series separated by the efferent arteriole that regulates the hydrostatic pressure in both capillary beds. The peritubular capillaries empty into small venous branches, which coalesce into larger veins to eventually form the renal vein.

The hydrostatic pressure gradient across the glomerular capillary wall is the primary driving force for glomerular filtration. Oncotic pressure within the capillary lumen, determined by the concentration of unfiltered plasma proteins, partially offsets the hydrostatic pressure gradient and opposes filtration. As the oncotic pressure rises along the length of the glomerular capillary, the driving force for filtration falls to zero before reaching the efferent arteriole. Approximately 20% of the renal plasma flow is filtered into Bowman's space, and the ratio of glomerular filtration rate (GFR) to renal plasma flow determines the filtration fraction. Several factors, mostly hemodynamic, contribute to the regulation of filtration under physiologic conditions.

Although glomerular filtration is affected by renal artery pressure, this relationship is not linear across the range of physiologic blood pressures. Autoregulation of glomerular filtration is the result of three major factors that modulate either afferent or efferent arteriolar tone: these include an autonomous vasoreactive (myogenic) reflex in the afferent arteriole, *tubuloglomerular feedback,* and angiotensin II–mediated vasoconstriction of the efferent arteriole. The myogenic reflex is a first line of defense against fluctuations in renal blood flow. Acute changes in renal perfusion pressure evoke reflex constriction or dilatation of the afferent arteriole in response to increased or decreased pressure, respectively. This phenomenon helps protect the glomerular capillary from sudden elevations in systolic pressure.

Tubuloglomerular feedback changes the rate of filtration and tubular flow by reflex vasoconstriction or dilatation of the afferent arteriole. Tubuloglomerular feedback is mediated by specialized cells in the thick ascending limb of the loop of Henle called the *macula densa* that act as sensors of solute concentration and flow of tubular fluid. With high tubular flow rates, a proxy for an inappropriately high filtration rate, there is increased solute delivery to the macula densa (Fig. 271-2*B*), which evokes vasoconstriction of the afferent arteriole causing the GFR to return to normal. One component of the soluble signal from the macula densa is adenosine triphosphate (ATP), which is released by the cells during increased NaCl reabsorption. ATP is metabolized in the extracellular space by ecto-5′-nucleotidase to generate adenosine, a potent vasoconstrictor of the afferent arteriole. Direct release of adenosine by macula densa cells also occurs. During conditions associated with a fall in filtration rate, reduced solute delivery to the macula densa attenuates the tubuloglomerular response, allowing afferent arteriolar dilatation and restoring glomerular filtration to normal levels. Loop diuretics block tubuloglomerular feedback by interfering with NaCl reabsorption by macula densa cells. Angiotensin II and reactive oxygen species enhance, while nitric oxide blunts tubuloglomerular feedback.

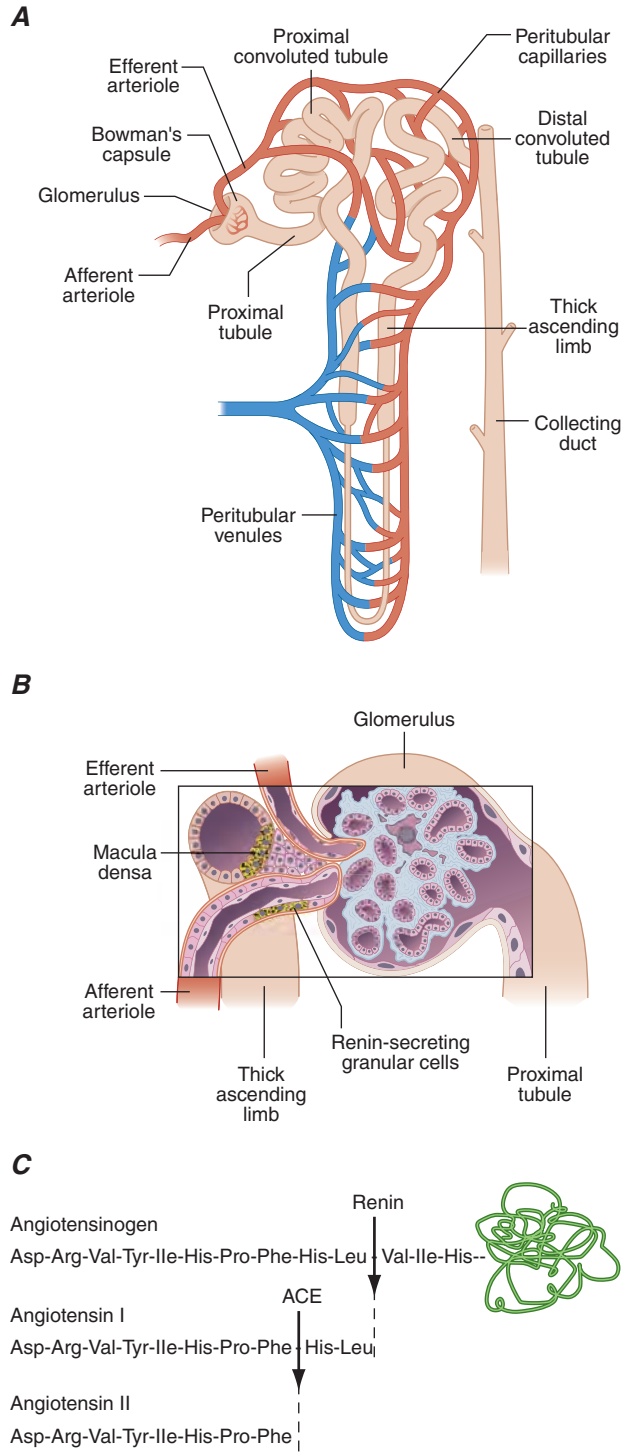

FIGURE 271-2 Renal microcirculation and the renin-angiotensin system. *A.* Diagram illustrating relationships of the nephron with glomerular and peritubular capillaries. ***B.*** Expanded view of the glomerulus with its juxtaglomerular apparatus including the macula densa and adjacent afferent arteriole. ***C.*** Proteolytic processing steps in the generation of angiotensin II.

The third component underlying autoregulation of filtration rate involves angiotensin II. During states of reduced renal blood flow, renin is released from granular cells within the wall of the afferent arteriole near the macula densa in a region called the juxtaglomerular apparatus (Fig. 271-2*B*). Renin, a proteolytic enzyme, catalyzes the conversion of angiotensinogen to angiotensin I, which is subsequently converted to angiotensin II by angiotensin-converting enzyme (ACE) (Fig. 271-2*C*). Angiotensin II evokes vasoconstriction of the efferent

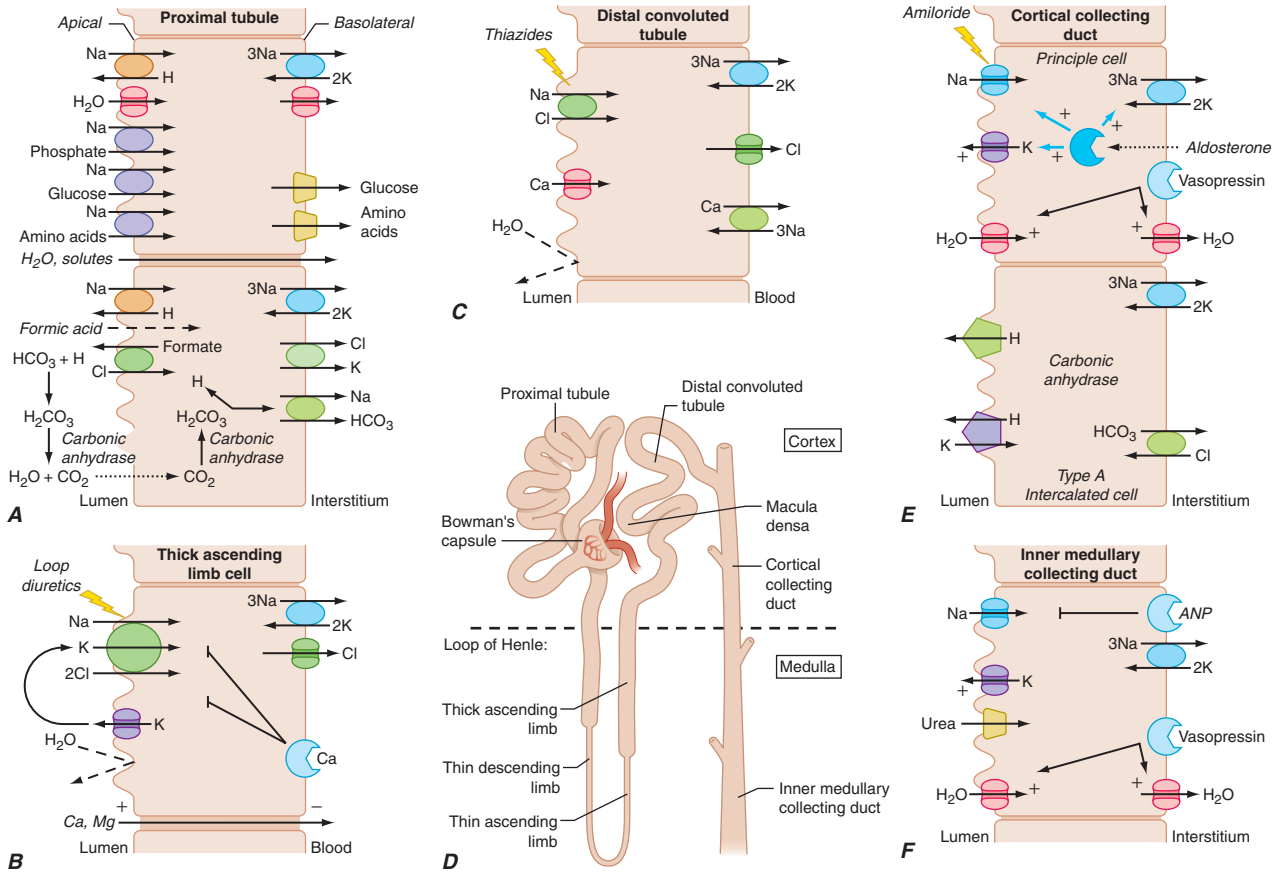

FIGURE 271-3 Transport activities of the major nephron segments. Representative cells from five major tubular segments are illustrated with the lumen side (apical membrane) facing left and interstitial side (basolateral membrane) facing right. ***A.*** Proximal tubular cells. ***B.*** Typical cell in the thick ascending limb of the loop of Henle. ***C.*** Distal convoluted tubular cell. ***D.*** Overview of entire nephron. ***E.*** Cortical collecting duct cells. ***F.*** Typical cell in the inner medullary collecting duct. The major membrane transporters, channels, and pumps are drawn with arrows indicating the direction of solute or water movement. For some events, the stoichiometry of transport is indicated by numerals preceding the solute. Targets for major diuretic agents are labeled. The actions of hormones are illustrated by arrows with plus signs for stimulatory effects and lines with perpendicular ends for inhibitory events. Dotted lines indicate free diffusion across cell membranes. The dashed line indicates water impermeability of cell membranes in the thick ascending limb and distal convoluted tubule.

arteriole, and the resulting increased glomerular hydrostatic pressure elevates filtration to normal levels.

MECHANISMS OF RENAL TUBULAR TRANSPORT

The renal tubules are composed of highly differentiated epithelia that vary dramatically in morphology and function along the nephron (Fig. 271-3). The cells lining the various tubular segments form monolayers connected to one another by a specialized region of the adjacent lateral membranes called the *tight junction*. Tight junctions form an occlusive barrier that separates the lumen of the tubule from the interstitial spaces surrounding the tubule. These specialized junctions also divide the cell membrane into discrete domains: the apical membrane faces the tubular lumen, and the basolateral membrane faces the interstitium. This physical separation of membranes allows cells to allocate membrane proteins and lipids asymmetrically to different regions of the membrane. Owing to this feature, renal epithelial cells are said to be *polarized*. The asymmetrical assignment of membrane proteins, especially proteins mediating transport processes, provides the structural machinery for directional movement of fluid and solutes by the nephron.

EPITHELIAL SOLUTE TRANSPORT

There are two types of epithelial transport. The movement of fluid and solutes sequentially across the apical and basolateral cell membranes (or vice versa) mediated by transporters, channels, or pumps is called *cellular transport.* By contrast, movement of fluid and solutes through the narrow passageway between adjacent cells is called *paracellular transport.* Paracellular transport occurs through tight junctions, indicating that they are not completely "tight." Indeed, some epithelial cell layers allow rather robust paracellular transport to occur (*leaky epithelia*), whereas other epithelia have more effective tight junctions (*tight epithelia*). In addition, because the ability of ions to flow through the paracellular pathway determines the electrical resistance across the epithelial monolayer, leaky and tight epithelia are also referred to as low- and high-resistance epithelia, respectively. The proximal tubule contains leaky epithelia, whereas distal nephron segments, such as the collecting duct, contain tight epithelia. Leaky epithelia are most well suited for bulk fluid reabsorption, whereas tight epithelia allow for more refined control and regulation of transport.

MEMBRANE TRANSPORT

Cell membranes are composed of hydrophobic lipids that repel water and aqueous solutes. The movement of solutes and water across cell membranes is made possible by discrete classes of integral membrane proteins, including channels, pumps, and transporters. These different components mediate specific types of transport activities, including *active transport* (pumps), *passive transport* (channels), *facilitated diffusion* (transporters), and *secondary active transport* (co-transporters). Different cell types in the mammalian nephron are endowed with distinct combinations of proteins that serve specific transport functions. Active transport requires metabolic energy generated by the hydrolysis

of ATP. The classes of protein that mediate active transport ("pumps") are ion-translocating ATPases, including the ubiquitous Na^+/K^+-ATPase, the H^+-ATPases, and Ca^{2+}-ATPases. Active transport can create asymmetrical ion concentrations across a cell membrane and can move ions against a chemical gradient. The potential energy stored in a concentration gradient of an ion such as Na^+ can be utilized to drive transport through other mechanisms (secondary active transport). Pumps are often *electrogenic*, meaning they can create an asymmetrical distribution of electrostatic charges across the membrane and establish a voltage or membrane potential. The movement of solutes through a membrane protein by simple diffusion is called passive transport. This activity is mediated by channels created by selectively permeable membrane proteins, and it allows solute or water to move across a membrane driven by favorable *concentration gradients* or *electrochemical potential.* Examples in the kidney include water channels (aquaporins), K^+ channels, epithelial Na^+ channels, and Cl^- channels. Facilitated diffusion is a specialized type of passive transport mediated by simple transporters called *carriers* or *uniporters*. For example, a family of hexose transporters (GLUTs 1–13) mediates glucose uptake by cells. These transporters are driven by the concentration gradient for glucose, which is highest in extracellular fluids and lowest in the cytoplasm due to rapid metabolism. Many transporters operate by translocating two or more ions/solutes in concert either in the same direction (*symporters* or *co-transporters*) or in opposite directions (*antiporters* or *exchangers*) across the cell membrane. The movement of two or more ions/solutes may produce no net change in the balance of electrostatic charges across the membrane (*electroneutral*), or a transport event may alter the balance of charges (*electrogenic*). Several inherited disorders of renal tubular solute and water transport occur as a consequence of mutations in genes encoding a variety of channels, transporter proteins, and their regulators (Table 271-1).

TABLE 271-1 INHERITED DISORDERS AFFECTING RENAL TUBULAR ION AND SOLUTE TRANSPORT

Disease or Syndrome	Gene	OMIM[a]
Disorders Involving the Proximal Tubule		
Proximal renal tubular acidosis	Sodium bicarbonate co-transporter (*SLC4A4*, 4q21)	604278
Faconi-Bickel syndrome	Glucose transporter-2 (*SLC2A2* 3q26.1-q26.3)	227810
Isolated renal glycosuria	Sodium glucose co-transporter (*SLC5A2*,16p11.2)	233100
Cystinuria, type I	Cystine, dibasic and neutral amino acid transporter (*SLC3A1*, 2p16.3)	220100
Cystinuria, non-type I	Amino acid transporter, light subunit (*SLC7A9*, 19q13.1)	600918
Lysinuric protein intolerance	Amino acid transporter (*SLC7A7*, 4q11.2)	222700
Hereditary hypophosphatemic rickets with hypercalcemia	Sodium phosphate co-transporter (*SLC34A3*, 9q34)	241530
Renal hypouricemia	Urate-anion exchanger (*SLC22A12*, 11q13)	220150

SEGMENTAL NEPHRON FUNCTIONS

Each anatomic segment of the nephron has unique characteristics and specialized functions that enable selective transport of solutes and water (Fig. 271-3). Through sequential events of reabsorption and secretion along the nephron, tubular fluid is progressively conditioned into final urine for excretion. Knowledge of the major tubular mechanisms responsible for solute and water transport is critical for understanding hormonal regulation of kidney function and the pharmacologic manipulation of renal excretion.

PROXIMAL TUBULE

The proximal tubule is responsible for reabsorbing ~60% of filtered NaCl and water, as well as ~90% of filtered bicarbonate and most critical nutrients such as glucose and amino acids. The proximal tubule utilizes both cellu-

lar and paracellular transport mechanisms. The apical membrane of proximal tubular cells has an expanded surface area available for reabsorptive work created by a dense array of microvilli called the *brush border*, and comparatively leaky tight junctions further enable high-capacity fluid reabsorption.

Solute and water pass through these tight junctions to enter the lateral intercellular space where absorption by the peritubular capillaries occurs. Bulk fluid reabsorption by the proximal tubule is driven by high oncotic pressure and low hydrostatic pressure within the peritubular capillaries. Physiologic adjustments in GFR made by changing efferent arteriolar tone cause proportional changes in reabsorption, a phenomenon known as *glomerulotubular balance.* For example, vasoconstriction of the efferent arteriole by angiotensin II will increase glomerular capillary hydrostatic pressure but lower pressure in the peritubular capillaries. At the same time, increased GFR and filtration fraction cause a rise in oncotic pressure near the end of the glomerular capillary. These changes, a lowered hydrostatic and increased oncotic pressure, increase the driving force for fluid absorption by the peritubular capillaries.

Cellular transport of most solutes by the proximal tubule is coupled to the Na^+ concentration gradient established by the activity of a basolateral Na^+/K^+-ATPase (Fig. 271-3*A*). This active transport mechanism maintains a steep Na^+ gradient by keeping intracellular Na^+ concentrations low. Solute reabsorption is coupled to the Na^+ gradient by Na^+-dependent co-transporters such as Na^+-glucose and the Na^+-phosphate. In addition to the paracellular route, water reabsorption also occurs through the cellular pathway enabled by constitutively active water channels (aquaporin-1) present on both apical and basolateral membranes. In addition, small, local *osmotic gradients* close to plasma membranes generated by cellular Na^+ reabsorption are likely responsible for driving directional water movement across proximal tubule cells.

Proximal tubular cells reclaim bicarbonate by a mechanism dependent on carbonic anhydrases. Filtered bicarbonate is first titrated by protons delivered to the lumen by Na^+/H^+ exchange. The resulting carbonic acid is metabolized by brush border carbonic anhydrase to water and carbon dioxide. Dissolved carbon dioxide then diffuses into the cell, where it is enzymatically hydrated by cytoplasmic carbonic anhydrase to reform carbonic acid. Finally, intracellular carbonic acid dissociates into free protons and bicarbonate anions, and bicarbonate exits the cell through a basolateral Na^+/HCO_3^- co-transporter. This process is saturable, resulting in renal bicarbonate excretion when plasma levels exceed the physiologically normal range (24–26 meq/L). Carbonic anhydrase inhibitors such as acetazolamide, a class of weak diuretic agents, block proximal tubule reabsorption of bicarbonate and are useful for alkalinizing the urine.

Chloride is poorly reabsorbed throughout the first segment of the proximal tubule, and a rise in Cl^- concentration counterbalances the removal of bicarbonate anion from tubular fluid. In later proximal tubular segments, cellular Cl^- reabsorption is initiated by apical exchange of cellular formate for higher luminal concentrations of Cl^-. Once in the lumen, formate anions are titrated by H^+ (provided by Na^+/H^+ exchange) to generate neutral formic acid, which can diffuse passively across the apical membrane back into the cell where it dissociates a proton and is recycled. Basolateral Cl^- exit is mediated by a K^+/Cl^- co-transporter.

Reabsorption of glucose is nearly complete by the end of the proximal tubule. Cellular transport of glucose is mediated by apical Na^+-glucose co-transport coupled with basolateral, facilitated diffusion by a glucose transporter. This process is also saturable, leading to glycosuria when plasma levels exceed 180–200 mg/dL, as seen in untreated diabetes mellitus.

The proximal tubule possesses specific transporters capable of secreting a variety of organic acids (carboxylate anions) and bases (mostly primary amine cations). Organic anions transported by these systems include urate, ketoacid anions, and several protein-bound drugs not filtered at the glomerulus (penicillins, cephalosporins, and salicylates). Probenecid inhibits renal organic anion secretion and can be clinically useful for raising plasma concentrations of certain drugs like penicillin and oseltamivir. Organic cations secreted by the proximal tubule include various biogenic amine neurotransmitters (dopamine, acetylcholine, epinephrine, norepinephrine, and histamine) and creatinine. Certain drugs like cimetidine and trimethoprim compete with endogenous compounds for transport by the organic cation pathways. These drugs elevate levels of serum creatinine, but this change does not reflect changes in the GFR.

The proximal tubule, through distinct classes of Na^+-dependent and Na^+-independent transport systems, reabsorbs amino acids efficiently. These transporters are specific for different groups of amino acids. For example, cystine, lysine, arginine, and ornithine are transported by a system comprising two proteins encoded by the *SLC3A1* and *SLC7A9* genes. Mutations in either *SLC3A1* or *SLC7A9* impair reabsorption of these amino acids and cause the disease cystinuria. Peptide hormones, such as insulin and growth hormone, β_2-microglobulin, and other small proteins, are taken up by the proximal tubule through a process of absorptive endocytosis and are degraded in acidified endocytic vesicles or lysosomes. Acidification of these vesicles depends on a "proton pump" (vacuolar H^+-ATPase) and a Cl^- channel. Impaired acidification of endocytic vesicles because of mutations in a Cl^- channel gene (*CLCN5*) causes low-molecular-weight proteinuria in Dent's disease. Renal ammoniagenesis from glutamine in the proximal tubule provides a major tubular fluid buffer to ensure excretion of secreted H^+ ion as NH_4^+ by the collecting duct. Cellular K^+ levels inversely modulate ammoniagenesis, and in the setting of high serum K^+ from hypoaldosteronism, reduced ammoniagenesis facilitates the appearance of Type IV renal tubular acidosis.

LOOP OF HENLE

The loop of Henle consists of three major segments: descending thin limb, ascending thin limb, and ascending thick limb. These divisions are based on cellular morphology and anatomic location, but also correlate well with specialization of function. Approximately 15–25% of filtered NaCl is reabsorbed in the loop of Henle, mainly by the thick ascending limb. The loop of Henle has a critically important role in urinary concentrating ability by contributing to the generation of a hypertonic medullary interstitium in a process called *countercurrent multiplication.* The loop of Henle is the site of action for the most potent class of diuretic agents (loop diuretics) and contributes to reabsorption of calcium and magnesium ions.

The descending thin limb is highly water-permeable owing to dense expression of constitutively active aquaporin-1 water channels. By contrast, water permeability is negligible in the ascending limb. In the thick ascending limb, there is a high level of secondary active salt transport enabled by the $Na^+/K^+/2Cl^-$ co-transporter on the apical membrane in series with basolateral Cl^- channels and Na^+/K^+-ATPase (Fig. 271-3*B*). The $Na^+/K^+/2Cl^-$ co-transporter is the primary target for loop diuretics. Tubular fluid K^+ is the limiting substrate for this co-transporter (tubular concentration of K^+ is similar to plasma, about 4 meq/L), but it is maintained by K^+ recycling through an apical potassium channel. An inherited disorder of the thick ascending limb, Bartter's syndrome, results in a salt-wasting renal disease associated with hypokalemia and metabolic alkalosis. Loss-of-function mutations in one of four distinct genes encoding components of the $Na^+/K^+/2Cl^-$ co-transporter (*NKCC2*), apical K^+ channel (*KCNJ1*), or basolateral Cl^- channel (*CLCNKB, BSND*) can cause the syndrome.

Potassium recycling also contributes to a positive electrostatic charge in the lumen relative to the interstitium, which promotes divalent cation (Mg^{2+} and Ca^{2+}) reabsorption through the paracellular pathway. A Ca^{2+}-sensing, G-protein coupled receptor (CaSR) on basolateral membranes regulates NaCl reabsorption in the thick ascending limb through dual signaling mechanisms utilizing either cyclic AMP or eicosanoids. This receptor enables a steep relationship between plasma Ca^{2+} levels and renal Ca^{2+} excretion. Loss-of-function mutations in CaSR cause familial hypercalcemic hypocalciuria because of a blunted response of the thick ascending limb to exocellular Ca^{2+}. Mutations in *CLDN16* encoding paracellin-1, a transmembrane protein located within the tight junction complex, leads to familial hypo-

magnesemia with hypercalcuria and nephrocalcinosis, suggesting that the ion conductance of the paracellular pathway in the thick limb is regulated. Mutations in *TRPM6* encoding a Mg^{2+} permeable ion channel also cause familial hypomagnesemia with hypocalcemia. A molecular complex of TRPM6 and TRPM7 proteins is critical for Mg^{2+} reabsorption in the thick ascending limb of Henle.

The loop of Henle contributes to urine concentrating ability by establishing a *hypertonic medullary interstitium,* which promotes water reabsorption by a more distal nephron segment, the inner medullary collecting duct. *Countercurrent multiplication* produces a hypertonic medullary interstitium using two countercurrent systems: the loop of Henle (opposing descending and ascending limbs) and the vasa recta (medullary peritubular capillaries enveloping the loop). The countercurrent flow in these two systems helps maintain the hypertonic environment of the inner medulla, but NaCl reabsorption by the thick ascending limb is the primary initiating event. Reabsorption of NaCl without water dilutes the tubular fluid and adds new osmoles to the interstitial fluid surrounding the thick ascending limb. Because the descending thin limb is highly water permeable, osmotic equilibrium occurs between the descending-limb tubular fluid and the interstitial space, leading to progressive solute trapping in the inner medulla. Maximum medullary interstitial osmolality also requires partial recycling of urea from the collecting duct.

DISTAL CONVOLUTED TUBULE

The distal convoluted tubule reabsorbs ~5% of the filtered NaCl. This segment is composed of a tight epithelium with little water permeability. The major NaCl transporting pathway utilizes an apical membrane, electroneutral thiazide-sensitive Na^+/Cl^- co-transporter in tandem with basolateral Na^+/K^+-ATPase and Cl^- channels (Fig. 271-3*C*). Apical Ca^{2+}-selective channels (TRPV5) and basolateral Na^+/Ca^{2+} exchange mediate calcium reabsorption in the distal convoluted tubule. Ca^{2+} reabsorption is inversely related to Na^+ reabsorption and is stimulated by parathyroid hormone. Blocking apical Na^+/Cl^- co-transport will reduce intracellular Na^+, favoring increased basolateral Na^+/Ca^{2+} exchange and passive apical Ca^{2+} entry. Loss-of-function mutations of *SLC12A3* encoding the apical Na^+/Cl^- co-transporter cause Gitelman's syndrome, a salt-wasting disorder associated with hypokalemic alkalosis and hypocalciuria. Mutations in genes encoding WNK kinases, WNK-1 and WNK-4, cause pseudohypoaldosteronism type II or Gordon's syndrome characterized by familial hypertension with hyperkalemia. WNK kinases influence the activity of several tubular ion transporters. Mutations in this disorder lead to overactivity of the apical Na^+/Cl^- co-transporter in the distal convoluted tubule as the primary stimulus for increased salt reabsorption, extracellular volume expansion, and hypertension. Hyperkalemia may be caused by diminished activity of apical K^+ channels in the collecting duct, a primary route for K^+ secretion.

COLLECTING DUCT

The collecting duct regulates the final composition of the urine. The two major divisions, the cortical collecting duct and inner medullary collecting duct, contribute to reabsorbing ~4–5% of filtered Na^+ and are important for hormonal regulation of salt and water balance. The cortical collecting duct contains a *high-resistance epithelia* with two cell types. Principal cells are the main Na^+ reabsorbing cells and the site of action of aldosterone, K^+-sparing diuretics, and spironolactone. The other cells are type A and B intercalated cells. Type A intercalated cells mediate acid secretion and bicarbonate reabsorption. Type B intercalated cells mediate bicarbonate secretion and acid reabsorption.

Virtually all transport is mediated through the cellular pathway for both principal cells and intercalated cells. In principal cells, passive apical Na^+ entry occurs through the amiloride-sensitive, epithelial Na^+ channel with basolateral exit via the Na^+/K^+-ATPase (Fig. 271-3*E*). This Na^+ reabsorptive process is tightly regulated by aldosterone. Aldosterone enters the cell across the basolateral membrane, binds to a cytoplasmic mineralocorticoid receptor, and then translocates into the nucleus, where it modulates gene transcription, resulting in increased sodium reabsorption. Activating mutations in this epithelial Na^+ channel increase Na^+ reclamation and produce hypokalemia, hypertension, and metabolic alkalosis (Liddle's syndrome). The potassium-sparing diuretics amiloride and triamterene block the epithelial Na^+ channel causing reduced Na^+ reabsorption.

Principal cells secrete K^+ through an apical membrane potassium channel. Two forces govern the secretion of K^+. First, the high intracellular K^+ concentration generated by Na^+/K^+-ATPase creates a favorable concentration gradient for K^+ secretion into tubular fluid. Secondly, with reabsorption of Na^+ without an accompanying anion, the tubular lumen becomes negative relative to the cell interior, creating a favorable electrical gradient for secretion of cations. When Na^+ reabsorption is blocked, the electrical component of the driving force for K^+ secretion is blunted. K^+ secretion is also promoted by fast tubular fluid flow rates (which might occur during volume expansion or diuretics acting "upstream" of the cortical collecting duct), and the presence of relatively nonreabsorbable anions (including bicarbonate and penicillins) that contribute to the lumen-negative potential. Principal cells also participate in water reabsorption by increased water permeability in response to vasopressin; this effect is explained more fully below for the inner medullary collecting duct.

Intercalated cells do not participate in Na^+ reabsorption but instead mediate acid-base secretion. These cells perform two types of transport: active H^+ transport mediated by H^+-ATPase ("proton pump") and Cl^-/HCO_3^- exchanger. Intercalated cells arrange the two transport mechanisms on opposite membranes to enable either acid or base secretion. Type A intercalated cells have an apical proton pump that mediates acid secretion and a basolateral anion exchanger for mediating bicarbonate reabsorption (Fig. 271-3*E*). By contrast, type B intercalated cells have the anion exchanger on the apical membrane to mediate bicarbonate secretion while the proton pump resides on the basolateral membrane to enable acid reabsorption. Under conditions of acidemia, the kidney preferentially uses type A intercalated cells to secrete the excess H^+ and generate more HCO_3^-. The opposite is true in states of bicarbonate excess with alkalemia where the type B intercalated cells predominate. An extracellular protein called *hensin* mediates this adaptation.

Inner medullary collecting duct cells share many similarities with principal cells of the cortical collecting duct. They have apical Na^+ and K^+ channels that mediate Na^+ reabsorption and K^+ secretion, respectively (Fig. 271-3*F*). Inner medullary collecting duct cells also have vasopressin-regulated water channels (aquaporin-2 on the apical membrane, aquaporin-3 and 4 on the basolateral membrane). The antidiuretic hormone vasopressin binds to the V2 receptor on the basolateral membrane and triggers an intracellular signaling cascade through G-protein–mediated activation of adenylyl cyclase, resulting in an increase in levels of cyclic AMP. This signaling cascade ultimately stimulates the insertion of water channels into the apical membrane of the inner medullary collecting duct cells to promote increased water permeability. This increase in permeability enables water reabsorption and production of concentrated urine. In the absence of vasopressin, inner medullary collecting duct cells are water-impermeable, and urine remains dilute. Thus, the nephron separates NaCl from water so that considerations of volume or tonicity can determine whether to retain or excrete water.

Sodium reabsorption by inner medullary collecting duct cells is also inhibited by the natriuretic peptides called *atrial natriuretic peptide* or *renal natriuretic peptide* (urodilatin); the same gene encodes both peptides but uses different posttranslational processing of a common preprohormone to generate different proteins. Atrial natriuretic peptides are secreted by atrial myocytes in response to volume expansion, whereas urodilatin is secreted by renal tubular epithelia. Natriuretic peptides interact with either apical (urodilatin) or basolateral (atrial natriuretic peptides) receptors on inner medullary collecting duct cells to stimulate guanylyl cyclase and increase levels of cytoplasmic cGMP. This effect in turn reduces the activity of the apical Na^+ channel in these cells and attenuates net Na^+ reabsorption producing natriuresis. The inner medullary collecting duct is permeable to urea, allowing

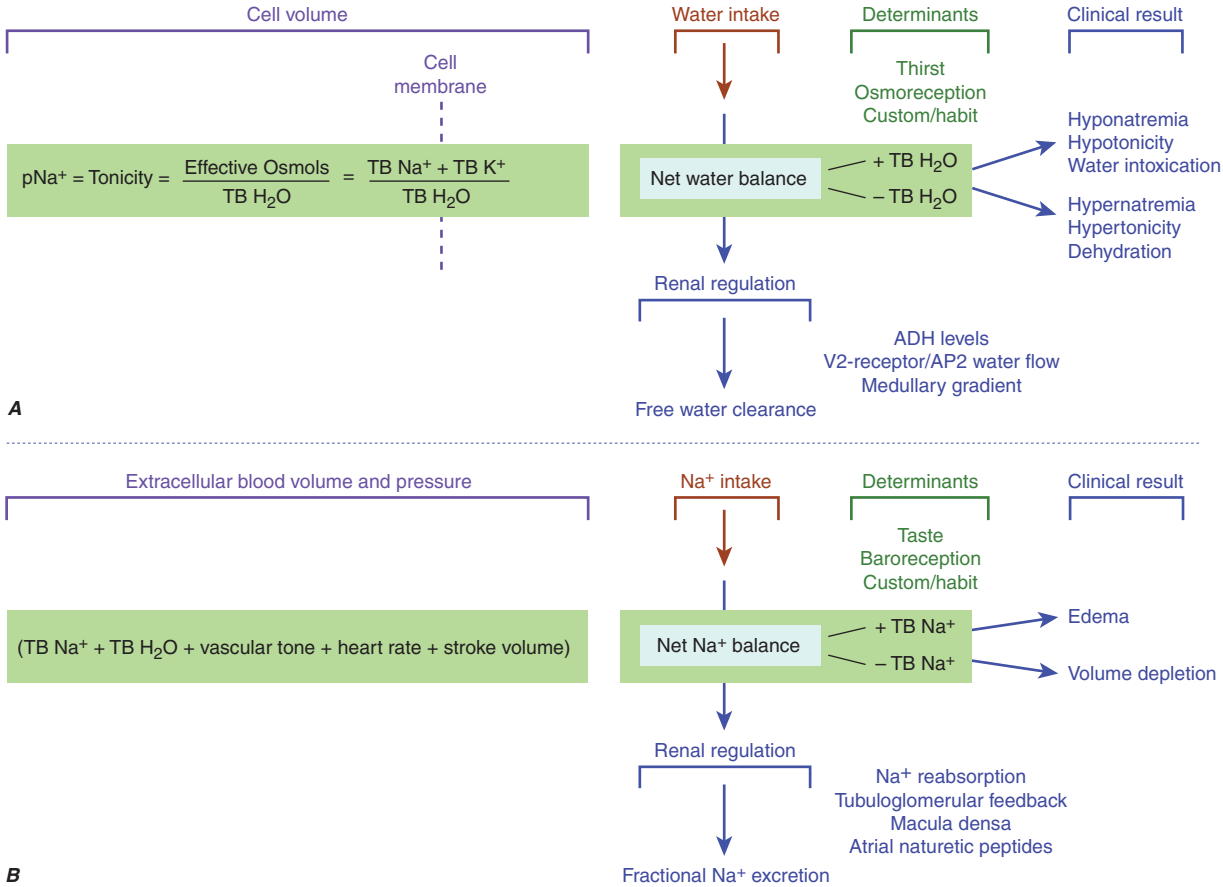

FIGURE 271-4 Determinants of sodium and water balance. ***A.*** Plasma Na^+ concentration is a surrogate marker for plasma tonicity, the volume behavior of cells in a solution. Tonicity is determined by the number of effective osmols in the body divided by the total body H_2O (TB H_20), which translates simply into the total body Na (TB Na^+) and anions outside the cell separated from the total body K (TB K^+) inside the cell by the cell membrane. Net water balance is determined by the integrated functions of thirst, osmoreception, Na reabsorption, vasopressin release, and the strength of the medullary gradient in the kidney, keeping tonicity within a narrow range of osmolality around 280 mosmol. When water metabolism is disturbed and total-body water increases, hyponatremia, hypotonicity, and water intoxication occurs; when total-body water decreases, hypernatremia, hypertonicity, and dehydration occurs. ***B.*** Extracellular blood volume and pressure are an integrated function of total body Na^+ (TB Na^+), total body H_20 (TB H_2O), vascular tone, heart rate, and stroke volume that modulates volume and pressure in the vascular tree of the body. This extracellular blood volume is determined by net Na balance under the control of taste, baroreception, habit, Na^+ reabsorption, macula densa/tubuloglomerular feedback, and naturetic peptides. When Na^+ metabolism is disturbed and total body Na^+ increases, edema occurs; when total body Na^+ is decreased, volume depletion occurs. ADH, antidiuretic hormone; AP2, aquaporin-2.

urea to diffuse into the interstitium, where it contributes to the hypertonicity of the medullary interstitium. Urea is recycled by diffusing from the interstitium into the descending and ascending limbs of the loop of Henle.

HORMONAL REGULATION OF SODIUM AND WATER BALANCE

The balance of solute and water in the body is determined by the amounts ingested, distributed to various fluid compartments, and excreted by skin, bowel, and kidneys. *Tonicity,* the osmolar state determining the volume behavior of cells in a solution, is regulated by water balance (Fig. 271-4*A*), and *extracellular blood volume* is regulated by Na^+ balance (Fig. 271-4*B*). The kidney is a critical modulator for both of these physiologic processes.

WATER BALANCE

Tonicity depends on the variable concentration of *effective osmoles* inside and outside the cell that cause water to move in either direction across its membrane. Classic effective osmoles, like Na^+, K^+, and their anions, are solutes trapped on either side of a cell membrane, where they collectively partition and obligate water to move and find equilibrium in proportion to retained solute; Na^+/K^+-ATPase keeps most K^+ inside cells and most Na^+ outside. Normal tonicity (~280 mosmol/L) is rigorously defended by osmoregulatory mechanisms that control water balance to protect tissues from inadvertent *dehydration* (cell shrinkage) or *water intoxication* (cell swelling), both of which are deleterious to cell function (Fig. 271-4*A*).

The mechanisms that control osmoregulation are distinct from those governing extracellular volume, although there is some shared physiology in both processes. While cellular concentrations of K^+ have a determinant role in reaching any level of tonicity, the routine surrogate marker for assessing clinical tonicity is the concentration of serum Na^+. Any reduction in total body water, which raises the Na^+ concentration, triggers a brisk sense of thirst and conservation of water by decreasing renal water excretion mediated by release of vasopressin from the posterior pituitary. Conversely, a decrease in plasma Na^+ concentration triggers an increase in renal water excretion by suppressing the secretion of vasopressin. While all cells expressing mechanosensitive TRPV4 channels respond to changes in tonicity by altering their volume and Ca^{2+} concentration, only $TRPV4^+$ neuronal cells connected to the supraoptic and paraventricular nuclei in the hypothalamus are *osmoreceptive*; that is, they alone, because of their neural connectivity, modulate the release of vasopressin by the posterior lobe of the pituitary gland. Secretion is stimulated primarily by changing

tonicity and secondarily by other nonosmotic signals, such as variable blood volume, stress, pain, and some drugs. The release of vasopressin by the posterior pituitary increases linearly as plasma tonicity rises above normal, although this varies depending on the perception of extracellular volume (one form of cross-talk between mechanisms that adjudicate blood volume and osmoregulation). Changing the intake or excretion of water provides a means for adjusting plasma tonicity; thus, osmoregulation governs water balance.

The kidneys play a vital role in maintaining water balance through their regulation of renal water excretion. The ability to concentrate urine to an osmolality exceeding that of plasma enables water conservation, while the ability to produce urine more dilute than plasma promotes excretion of excess water. Cell membranes are composed of lipids and other hydrophobic substances that are intrinsically impermeable to water. In order for water to enter or exit a cell, the cell membrane must express water channel aquaporins. In the kidney, aquaporin 1 is constitutively active in all water-permeable segments of the proximal and distal tubules, while aquaporins 2, 3, and 4 are regulated by vasopressin in the collecting duct. Vasopressin interacts with the V2 receptor on basolateral membranes of collecting duct cells and signals the insertion of new water channels into apical membranes to promote water permeability. Net water reabsorption is ultimately driven by the osmotic gradient between dilute tubular fluid and a hypertonic medullary interstitium.

SODIUM BALANCE

The perception of *extracellular blood volume* is determined, in part, by the integration of arterial tone, cardiac stroke volume, heart rate, and the water and solute content of the extracellular volume. Na^+ and its anions are the most abundant extracellular effective osmoles, and together they support a blood volume around which pressure is generated. Under normal conditions, this volume is regulated by sodium balance (Fig. 271-4*B*), and the balance between daily Na^+ intake and excretion is under the influence of *baroreceptors* in regional blood vessels and vascular hormone-sensors modulated by atrial naturetic peptides, the renin-angiotensin-aldosterone system, Ca^{2+} signaling, adenosine, vasopressin, and the neural adrenergic axis. If Na^+ intake exceeds Na^+ excretion (positive Na^+ balance), then an increase in blood volume will trigger a proportional increase in urinary Na^+ excretion. Conversely, when Na^+ intake is less than urinary excretion (negative Na^+ balance), blood volume will decrease and trigger enhanced renal Na^+ reabsorption, leading to decreased urinary Na^+ excretion.

The renin-angiotensin-aldosterone system is the best-understood hormonal system modulating renal Na^+ excretion. Renin is synthesized and secreted by granular cells in the wall of the afferent arteriole. Its secretion is controlled by several factors, including β_1-adrenergic stimulation to the afferent arteriole, input from the macula densa, and prostaglandins. Renin and ACE activity eventually produce angiotensin II, which directly or indirectly promotes renal Na^+ and water reabsorption. Stimulation of proximal tubular Na^+/H^+ exchange by angiotensin II directly increases Na^+ reabsorption. Angiotensin II also promotes Na^+ reabsorption along the collecting duct by stimulating aldosterone secretion by the adrenal cortex. Constriction of the efferent glomerular arteriole by angiotensin II indirectly increases the filtration fraction and raises peritubular capillary oncotic pressure to promote Na^+ reabsorption. Finally, angiotensin II inhibits renin secretion through a negative feedback loop.

Aldosterone is synthesized and secreted by granulosa cells in the adrenal cortex. It binds to cytoplasmic mineralocorticoid receptors in principal cells of the collecting duct that increase the activity of the apical membrane Na^+ channel, apical membrane K^+ channel, and basolateral Na^+/K^+-ATPase. These effects are mediated in part by aldosterone-stimulated transcription of the gene encoding serum/glucocorticoid-induced kinase 1 (SGK1). The activity of epithelial Na^+ channel is increased by SGK1-mediated phosphorylation of Nedd4-2, a protein that promotes recycling of the Na^+ channel from the plasma membrane. Phosphorylated Nedd4-2 has impaired interactions with epithelial Na^+ channel, leading to increased channel density at the plasma membrane and increased capacity for Na^+ reabsorption by the collecting duct.

Chronic overexpression of aldosterone causes a decrease in urinary Na^+ excretion lasting only a few days, after which Na^+ excretion returns to previous levels. This phenomenon, called *aldosterone escape,* is explained by decreased proximal tubular Na^+ reabsorption following blood volume expansion. Excess Na^+ that is not reabsorbed by the proximal tubule overwhelms the reabsorptive capacity of more distal nephron segments. This escape may be facilitated by atrial naturetic peptides, which lose their effectiveness in the clinical settings of heart failure, nephrotic syndrome, and cirrhosis, leading to severe Na^+ retention and volume overload.

272 Adaptation of the Kidney to Renal Injury

Raymond C. Harris, Eric G. Neilson

The size of a kidney and the number of nephrons formed late in embryological development depend on the frequency with which the ureteric bud undergoes branching morphogenesis. Humans have between 225,000 and 900,000 nephrons in each kidney, a number that mathematically hinges on whether ureteric branching goes to completion or is prematurely terminated by one or two cycles. Although the signaling mechanism regulating cycle number is unknown, these final rounds of branching likely determine how well the kidney will adapt to the physiologic demands of blood pressure and body size, various environmental stresses, or unwanted inflammation leading to chronic renal failure.

One of the intriguing generalities made in the course of studying chronic renal failure is that residual nephrons hyperfunction to compensate for the loss of those nephrons falling to primary disease. This compensation depends on adaptive changes produced by renal hypertrophy and adjustments in *tubuloglomerular feedback* and *glomerulotubular balance,* as advanced in the *intact nephron hypothesis* by Neal Bricker in 1969. Some physiologic adaptations to nephron loss also produce unintended clinical consequences explained by Bricker's *trade-off hypothesis* in 1972, and eventually some adaptations accelerate the deterioration of residual nephrons, as described by Barry Brenner in his *hyperfiltration hypothesis* in 1982. These three important notions regarding chronic renal failure form a conceptual foundation for understanding common pathophysiology leading to uremia.

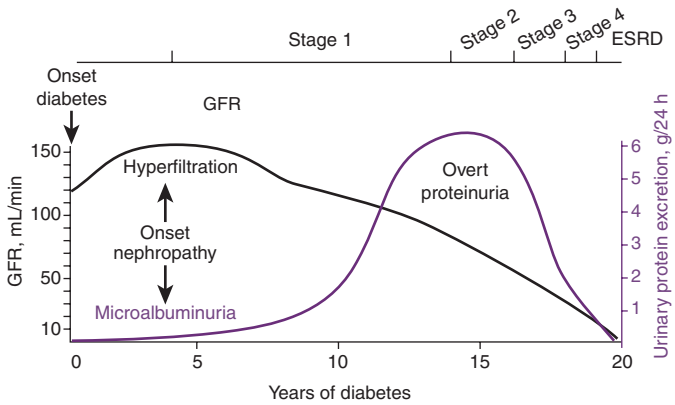

FIGURE 272-1 Progression of chronic renal injury. Although various types of renal injury have their own unique rates of progression, one of the best understood is that associated with type I diabetic nephropathy. Notice the early increase in glomerular filtration rate (GFR), followed by inexorable decline associated with increasing proteinuria. Also indicated is the National Kidney Foundation K/DOQI classification of the stages of chronic kidney disease. ESRD, end-stage renal disease.

COMMON MECHANISMS OF PROGRESSIVE RENAL DISEASE

When the initial complement of nephrons is reduced by a sentinel event, like unilateral nephrectomy, the remaining kidney adapts by enlarging and increasing its glomerular filtration rate (GFR). If the kidneys were initially normal, the GFR usually returns to 80% of normal for two kidneys. The remaining kidney grows by *compensatory renal hypertrophy* with very little cellular proliferation. This unique event is accomplished by increasing the size of each cell along the nephron, which is accommodated by the elasticity or growth of interstitial spaces and the renal capsule. The mechanism of this compensatory renal hypertrophy is only partially understood, but the signals for the remaining kidney to hypertrophy may rest with the local expression of angiotensin II; transforming growth factor β (TGF-β); $p27^{kip1}$, a cell cycle protein that prevents tubular cells exposed to angiotensin II from proliferating; and epidermal growth factor (EGF), which induces the mammalian target of rapamycin (mTOR) to engage a transcriptome supporting new protein synthesis.

Hyperfiltration during pregnancy, or in humans born with one kidney or who lose one to trauma or transplantation, generally leads to no ill consequences. By contrast, experimental animals who undergo resection of 80% of their renal mass, or humans who have persistent injury that destroys a comparable amount of renal tissue, progress to end-stage disease (Fig. 272-1). Clearly there is a critical amount of primary nephron loss that produces a maladaptive deterioration in the remaining nephrons. This maladaptive response is referred to clinically as *renal progression,* and the pathologic correlate of renal progression is *relentless tubular atrophy* and *tissue fibrosis*. The mechanism for this maladaptive response has been the focus of intense investigation. A unified theory of renal progression is just starting to emerge, and, most importantly, this progression follows a final common pathway regardless of whether renal injury begins in glomeruli or within the tubulointerstitium.

There are six mechanisms that hypothetically unify this final common pathway. If injury begins in glomeruli, these sequential steps build on each other: (1) Persistent glomerular injury produces local hypertension in capillary tufts, increases their single-nephron GFR, and engenders protein leak into the tubular fluid. (2) Significant glomerular proteinuria, accompanied by increases in the local production of angiotensin II, facilitates (3) a downstream cytokine bath that induces an accumulation of interstitial mononuclear cells. (4) The initial appearance of interstitial neutrophils is quickly replaced by gathering macrophages and T lymphocytes that form a nephritogenic immune response producing interstitial nephritis. (5) Some tubular epithelia respond to this inflammation by disaggregating from their basement membrane and adjacent sister cells to undergo *epithelial-mesenchymal transitions* forming new interstitial fibroblasts. (6) Finally, surviving fibroblasts lay down a collagenous matrix that disrupts adjacent capillaries and tubular nephrons, eventually leaving an acellular scar. The details of these complex events are outlined below (Fig. 272-2).

Significant ablation of renal mass results in *hyperfiltration* characterized by an increase in the rate of *single-nephron glomerular filtration.* The remaining nephrons lose their ability to autoregulate, and systemic hypertension is transmitted to the glomerulus. Both the hyperfiltration and *intraglomerular hypertension* stimulate the eventual appearance of glomerulosclerosis. Angiotensin II acts as an essential mediator of increased *intraglomerular capillary pressure* by selectively increasing efferent arteriolar vasoconstriction relative to afferent arteriolar tone. Angiotensin II impairs glomerular size-selectivity, induces protein ultrafiltration, and increases intracellular Ca^{2+} in podocytes, which alters podocyte function. Diverse vasoconstrictor mechanisms, including blockade of nitric oxide synthase and activation of angiotensin II and thromboxane receptors, can also induce oxidative stress in surrounding renal tissue. Finally, the effects of aldosterone on increasing renal vascular resistance and glomerular capillary pressure, or stimulating plasminogen activator inhibitor-1, facilitate fibrogenesis and complement the detrimental activity of angiotensin II.

On occasion, inflammation that begins in the renal interstitium disables tubular reclamation of filtered protein, producing mild nonselective proteinuria. Renal inflammation that initially damages glomerular capillaries often spreads to the tubulointerstitium in association with heavier proteinuria. Many clinical observations support the association of worsening *glomerular proteinuria* with renal progression. The simplest explanation for this expansion is that increasingly severe proteinuria triggers a downstream inflammatory cascade around epithelia that line the nephron, producing interstitial nephritis, fibrosis, and tubular atrophy. As albumin is an abundant polyanion in plasma and can bind a variety of cytokines, chemokines, and lipid mediators, it might be that these small molecules carried by albumin initiate the tubular inflammation brought on by proteinuria. Furthermore, glomerular injury either adds activated mediators to the proteinuric filtrate or alters the balance of cytokine inhibitors and activators such that attainment of a critical level of activated cytokines eventually damages downstream tubular epithelia.

Tubular epithelia bathed in these complex mixtures of proteinuric cytokines respond by increasing their secretion of chemokines and relocating nuclear factor κB to the nucleus to induce proinflammatory release of TGF-β, platelet-derived growth factor B (PDGF-BB), and fibroblast growth factor 2 (FGF-2). Inflammatory cells are drawn into the renal interstitium by this cytokine milieu. This interstitial spreading reduces the likelihood that the kidney will survive. The immunologic mechanisms for spreading include loss of tolerance to parenchymal self, immune deposits that share cross-reactive epitopes in either compartment, or glomerular injury that reveals a new interstitial epitope. Drugs, infection, and metabolic defects may also induce autoimmunity through Toll-like receptors that bind to moieties with an immunologically distinct molecular pattern. Bacterial and viral ligands do so, but, interestingly, so do Tamm-Horsfall protein, bacterial CpG repeats, and RNA that is released nonspecifically from injured tubular cells. Dendritic cells and macrophages are subsequently activated, and circulating T cells engage in the formal cellular immunologic response.

Nephritogenic interstitial T cells are a mix of $CD4^+$ helper and $CD8^+$ cytotoxic lymphocytes. Presumptive evidence of antigen-driven T cells found by examining the DNA sequence of T cell receptors suggests a polyclonal expansion that responds to multiple epitopes. Some experimental interstitial lesions are histologically analogous to a cutaneous delayed-type hypersensitivity reaction, and more intense reactions sometimes induce granuloma formation. The cytotoxic activity of antigen-reactive T cells probably accounts for tubular cell destruction and atrophy. Cytotoxic T cells synthesize proteins with serine esterase activity as well as pore-forming proteins, which can affect membrane damage much like the activated membrane attack complex of the complement cascade. Such enzymatic activity provides a structural explanation for target cell lysis.

One long-term consequence of tubular epithelia exposed to cytokines is the profibrotic activation of *epithelial-mesenchymal transition.* Persis-

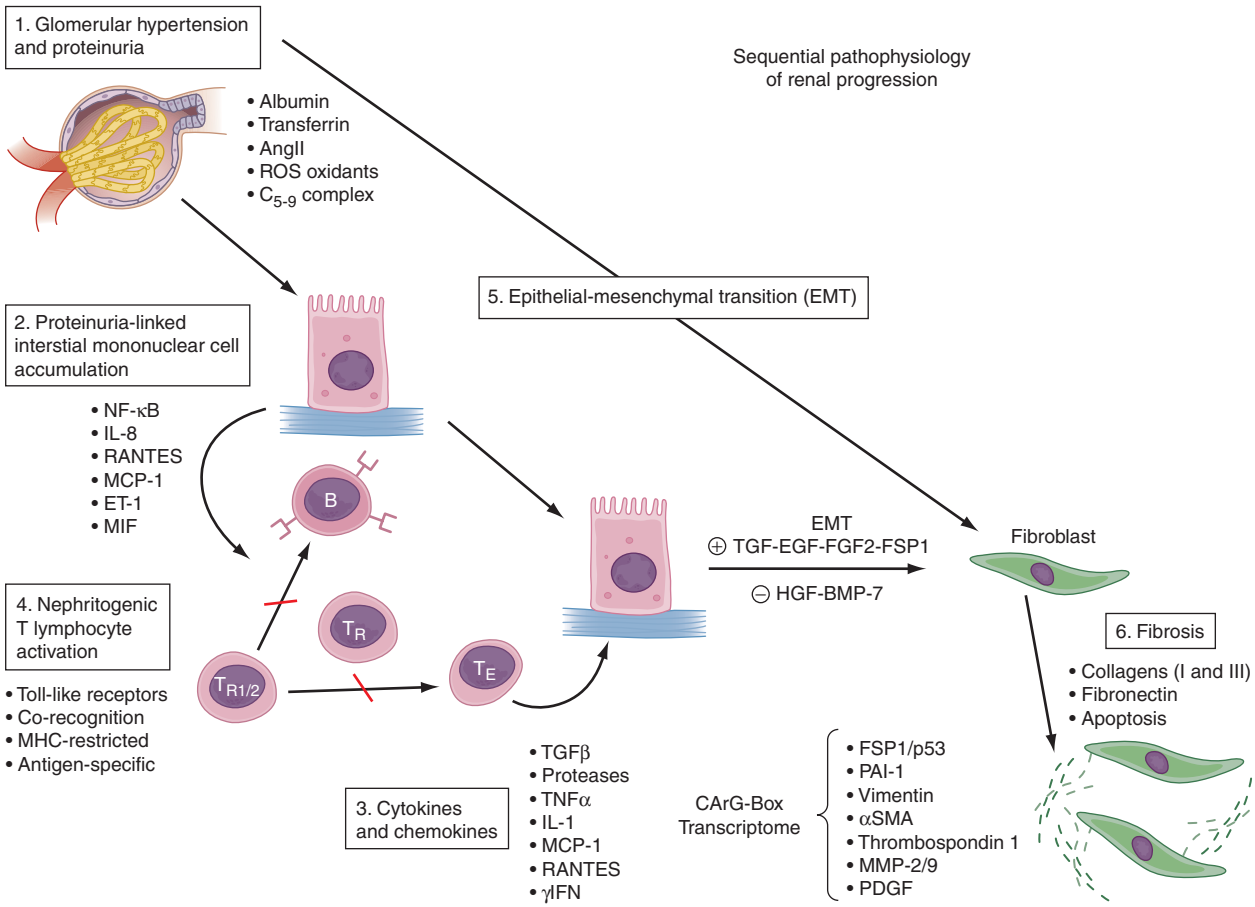

FIGURE 272-2 Mechanisms of renal progression. The general mechanisms of renal progression advance sequentially through six stages that include hyperfiltration, proteinuria, cytokine bath, mononuclear cell infiltration, epithelial-mesenchymal transition, and fibrosis. *(Modified from Harris and Neilson, 2006.)*

tent cytokine activity during renal inflammation and disruption of underlying basement membrane by local proteases initiates the process of transition. Rather than collapsing into the tubular lumens and dying, some epithelia become fibroblasts while translocating back into the interstitial space behind deteriorating tubules through holes in the ruptured basement membrane. Wnt proteins, integrin-linked kinases, insulin-like growth factors, EGF, FGF-2, and TGF-β are among the classic modulators of epithelial-mesenchymal transition. Fibroblasts that deposit collagen during fibrogenesis also replicate locally at sites of persistent inflammation. Estimates indicate that half of the total fibroblasts found in fibrotic renal tissues are products of the proliferation of newly transitioned or preexisting fibroblasts. Fibroblasts are stimulated to multiply by activation of cognate cell-surface receptors for PDGF and TGF-β.

Tubulointerstitial scars are composed principally of fibronectin, collagen types I and III, and tenascin, but other glycoproteins such as thrombospondin, SPARC, osteopontin, and proteoglycan may be also important. Although tubular epithelia can synthesize collagens I and III and are modulated by a variety of growth factors, these epithelia disappear through transition and tubular atrophy, leaving fibroblasts as the major contributor to matrix production. After fibroblasts acquire a synthetic phenotype, expand their population, and locally migrate around areas of inflammation, they begin to deposit fibronectin, which provides a scaffold for interstitial collagens. When fibroblasts outdistance their survival factors, they die from apoptosis, leaving an acellular scar.

RESPONSE TO REDUCTION IN NUMBERS OF FUNCTIONING NEPHRONS

The response to the loss of many functioning nephrons produces an increase in renal blood flow with glomerular hyperfiltration. Hyperfiltration is the result of increased vasoconstriction in postglomerular efferent arterioles relative to preglomerular afferent arterioles, increasing the intraglomerular capillary pressure and filtration fraction. The discovery of this intraglomerular hypertension and the demonstration in experimental animals that maneuvers to decrease its effect will abrogate the further expression of glomerular and tubulointerstitial injury led to the formulation of the hyperfiltration hypothesis. The hypothesis explains why residual nephrons in the setting of persistent disease will first stabilize or increase the rate of glomerular filtration, only to succumb later to inexorable deterioration and progression to renal failure. Persistent intraglomerular hypertension is critical to this transition.

Although the hormonal and metabolic factors mediating hyperfiltration are not fully understood, a number of vasoconstrictive and vasodilatory substances have been implicated, chief among them being angiotensin II. Angiotensin II incrementally vasoconstricts the efferent arteriole, and studies in animals and humans demonstrate that interruption of the renin-angiotensin system with either angiotensin-converting inhibitors or angiotensin II receptor blockers will decrease intraglomerular capillary pressure, decrease proteinuria, and slow the rate of nephron destruction. The vasoconstrictive agent, endothelin, has also been implicated in hyperfiltration, and increases in afferent vasodilatation have been attributed, at least in part, to local prostaglandins and release of endothelium-derived nitric oxide. Finally, hyperfiltration may be mediated in part by a resetting of the kidney's intrinsic autoregulatory mechanism of glomerular filtration by a *tubuloglomerular feedback system*. This feedback originates from the macula densa and modulates renal blood flow and glomerular filtration (Chap. 271).

Even with the loss of functioning nephrons, there is some continued maintenance of *glomerulotubular balance,* by which the residual tubules adapt to increases in single-nephron glomerular filtration with appropriate alterations in reabsorption or excretion of filtered water

and solutes in order to maintain homeostasis. Glomerulotubular balance results both from tubular hypertrophy and from regulatory adjustments in tubular oncotic pressure or solute transport along the proximal tubule. Some studies have indicated that these alterations in tubule size and function may themselves be maladaptive and, as a trade-off, predispose to further tubule injury.

TUBULAR FUNCTION IN CHRONIC RENAL FAILURE

SODIUM

Na^+ ions are reclaimed along most of the nephron by various transport mechanisms (Chap. 271). This transport function and its contribution to extracellular blood volume is usually maintained near normal until limitations from advanced renal disease can no longer keep up with dietary Na^+ intake. Prior to this point in the spectrum of renal progression, increasing the fractional excretion of Na^+ in final urine at reduced rates of glomerular filtration provides a mechanism of early adaptation. Na^+ excretion increases predominantly by decreasing Na^+ reabsorption in the loop of Henle and distal nephron. Increases in the osmotic obligation of residual nephrons lower the concentration of Na^+ in tubular fluid, and increased excretion of inorganic and organic anions obligates more Na^+ excretion. In addition, hormonal influences, notably increased expression of atrial natriuretic peptides that increase distal Na^+ excretion, as well as levels of GFR, play an important role in maintaining adequate Na^+ excretion. Although many details of these adjustments are only understood conceptually, it is an example of a trade-off by which initial adjustments following the loss of functioning nephrons lead to compensatory responses that maintain homeostasis. Eventually, with advancing nephron loss, the atrial natriuretic peptides lose their effectiveness, and Na^+ retention results in intravascular volume expansion, edema, and worsening hypertension.

URINARY DILUTION AND CONCENTRATION

Patients with progressive renal injury gradually lose the capacity either to dilute or concentrate their urine, and urine osmolality becomes relatively fixed around 350 mosmol/L (specific gravity approximating 1.010). Although the ability of a single nephron to excrete water free of solute may not be impaired, the reduced number of functioning nephrons obligates increased fractional solute excretion by residual nephrons, and this greater obligation impairs the ability to dilute tubular fluid maximally. Similarly, urinary concentrating ability falls due to the need for more water to hydrate the increased solute load. Tubulointerstitial damage also creates insensitivity to the antidiuretic effects of vasopressin along the collecting duct or loss of the medullary gradient, which eventually disturbs control of variation in urine osmolality. Patients with moderate degrees of chronic renal failure often complain of *nocturia* as a manifestation of this fixed urine osmolality and are prone to extracellular volume depletion if they do not keep up with the persistent loss of Na^+, or hypotonicity if they drink too much water.

POTASSIUM

Renal excretion is a major pathway for reducing excess total-body K^+. Normally, the kidney excretes 90% of dietary K^+, while 10% is excreted in the stool, with a trivial amount lost to sweat. Although the colon possesses some capacity to increase K^+ excretion—up to 30% of ingested K^+ may be excreted in the stool of patients with worsening renal failure—the majority of the K^+ load continues to be excreted by the kidneys due to elevation in levels of serum K^+ that increase this filtered load. Aldosterone also regulates collecting duct Na^+ reabsorption and K^+ secretion. Aldosterone is released from the adrenal cortex not only in response to the renin-angiotensin system but also in direct response to elevated levels of serum K^+, and for a while a compensatory increase in the capacity of the collecting duct to secrete K^+ keeps up with renal progression. As serum K^+ levels rise with renal failure, circulating levels of aldosterone also increase over what is required to maintain normal levels of blood volume.

ACID-BASE REGULATION

The kidneys excrete one meq/kg per day of noncarbonic H^+ ion on a normal diet. To do this, all of the filtered HCO_3^{2-} needs to be reabsorbed proximally so that H^+ pumps in the intercalated cells of the collecting duct can secrete H^+ ions that are subsequently trapped by urinary buffers, particularly phosphates and ammonia (Chap. 271). While remaining nephrons increase their solute load with loss of renal mass, the ability to maintain total-body H^+ excretion is often impaired by the gradual loss of H^+ pumps or with reductions in ammoniagenesis leading to development of a non-delta acidosis. Although hypertrophy of the proximal tubules initially increases their ability to reabsorb filtered HCO_3^{2-} and increase ammoniagenesis, with progressive loss of nephrons this compensation is eventually overwhelmed. In addition, with advancing renal failure, ammoniagenesis is further inhibited by elevation in levels of serum K^+, producing type IV renal tubular acidosis. Once the GFR falls below 25 mL/min, organic acids accumulate, producing a delta metabolic acidosis. Hyperkalemia can also inhibit tubular HCO_3^{2-} reabsorption, as can extracellular volume expansion and elevated levels of parathyroid hormone (PTH). Eventually, as the kidneys fail, the level of serum HCO_3^{2-} falls severely, reflecting the exhaustion of all body buffer systems, including bone.

CALCIUM AND PHOSPHATE

The kidney and gut play an important role in the regulation of serum levels of Ca^{2+} and PO_4^{2-}. With decreasing renal function and the appearance of tubulointerstitial nephritis, the expression of α_1-hydroxylase by the proximal tubule is reduced, lowering levels of calcitriol and Ca^{2+} absorption by the gut. Loss of nephron mass with progressive renal failure also gradually reduces the excretion of PO_4^{2-} and Ca^{2+}, and elevations in serum PO_4^{2-} further lower serum levels of Ca^{2+}, causing sustained secretion of PTH. Unregulated increases in levels of PTH cause Ca^{2+} mobilization from bone, Ca^{2+}/PO_4^{2-} precipitation in tissues, abnormal bone remodeling, decreases in tubular bicarbonate reabsorption, and increases in renal PO_4^{2-} excretion. While elevated serum levels of PTH initially maintain serum PO_4^{2-} near normal, with progressive nephron destruction the capacity for renal PO_4^{2-} excretion is overwhelmed, the serum PO_4^{2-} elevates, and bone is progressively demineralized from secondary hyperparathyroidism. These adaptations evoke another classic functional trade-off (Fig. 272-3).

MODIFIERS INFLUENCING THE PROGRESSION OF RENAL DISEASE

Well-described risk factors for the progressive loss of renal function include systemic hypertension, diabetes, and activation of the renin-angiotensin-aldosterone system (Table 272-1). Poor glucose control will aggravate renal progression in both diabetic and nondiabetic renal disease. Angiotensin II produces intraglomerular hypertension and stimulates fibrogenesis. Aldosterone also serves as an independent fibrogenic mediator of progressive nephron loss apart from its role in modulating Na^+ and K^+ homeostasis.

Lifestyle choices also have an impact on the progression of renal disease. Cigarette smoking has been shown to either predispose or accelerate the progression of nephron loss. Whether the effect of cigarettes is related to systemic hemodynamic alterations or specific damage to the renal microvasculature and/or tubules is unclear. Lipid oxidation associated with obesity or central adiposity can also accelerate cardiovascular disease and progressive renal damage. Recent epidemiologic studies confirm an association between high-protein diets and progression of renal disease. Progressive nephron loss in experimental animals, and possibly in humans, can be slowed by adherence to a low-protein diet. Although a large multicenter trial, the Modification of Diet in Renal Disease, did not provide conclusive evidence that dietary protein restriction could retard progression to renal failure, secondary analyses and a number of meta-analyses suggest a renoprotective effect from supervised low-protein diets in the range of 0.6–0.75 g/kg per day. Abnormal Ca^{2+} and PO_4^{2-} metabolism in chronic kidney disease also plays a role in renal progression, and administration of calcitriol or its analogues can attenuate progression in a variety of models of chronic kidney disease.

An intrinsic paucity in the number of functioning nephrons predisposes to the development of renal disease. A reduced number of nephrons can lead to permanent hypertension, either through direct renal

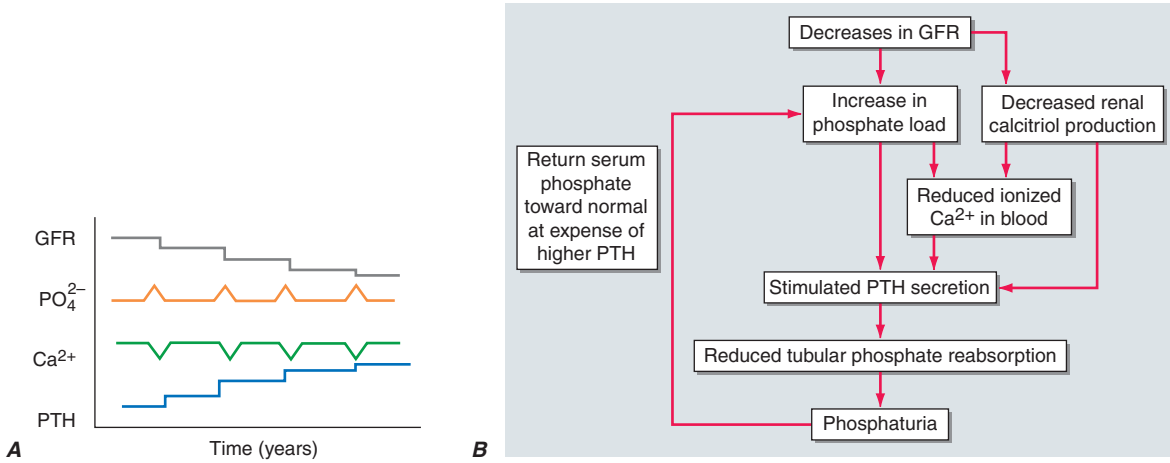

FIGURE 272-3 The "trade-off hypothesis" for Ca^{2+}/PO_4^{2-} homeostasis with progressively declining renal function. *A.* How adaptation to maintain Ca^{2+}/PO_4^{2-} homeostasis leads to increasing levels of parathyroid hormone ("classic" presentation from Slatopolsky E, Bricker NS: The role of phosphorous restriction in the prevention of secondary hyperparathyroidism in chronic renal disease. Kidney Int 4:141, 1973). ***B.*** Current understanding of the underlying mechanisms for this Ca^{2+}/PO_4^{2-} trade-off. GFR, glomerular filtration rate; PTH, parathyroid hormone.

damage or hyperfiltration producing glomerulosclerosis, or by primary induction of systemic hypertension that further exacerbates glomerular barotrauma. Younger individuals with hypertension who died suddenly as a result of trauma have 47% fewer glomeruli per kidney than age-matched controls.

A consequence of low birth weight is a relative deficit in the number of total nephrons; low birth weight is associated in adulthood with more hypertension and renal failure, among other abnormalities. In this regard, in addition to or instead of a genetic predisposition to development of a specific disease or condition such as low birth weight, different epigenetic phenomena may produce varying clinical phenotypes from a single genotype, depending on maternal exposure to different environmental stimuli during gestation, a phenomenon known as *developmental plasticity*. A specific clinical phenotype can also be selected in response to an adverse environmental exposure during critical periods of intrauterine development, also known as *fetal programming*. In the United States there is at least a twofold increased incidence of low birth weight among African Americans compared with Caucasians, much but not all of which can be attributed to maternal age, health, or socioeconomic status.

TABLE 272-1 POTENTIAL MODIFIERS OF RENAL DISEASE PROGRESSION

Hypertension	Hyperlipidemia
RAS activation	Abnormal calcium/phosphorus homeostasis
Angiotensin II	Cigarette smoking
Aldosterone	Intrinsic paucity in nephron number
Diabetes	Prematurity/low birth weight
Obesity	Genetic predisposition
Excessive dietary protein	Undefined genetic factors

As in other conditions producing nephron loss, the glomeruli of low-birth-weight individuals are enlarged and associated with early hyperfiltration to maintain normal levels of renal function. With time, the resulting intraglomerular hypertension may initiate a progressive decline in residual hyperfunctioning nephrons, ultimately accelerating renal failure. In African Americans, as well as other populations at increased risk for kidney failure, such as Pima Indians and Australian aborigines, large glomeruli are seen at early stages of kidney disease. An association between low birth weight and the development of albuminuria and nephropathy has been reported for both diabetic and nondiabetic renal disease.

273 Acute Renal Failure

Kathleen D. Liu, Glenn M. Chertow

Acute renal failure (ARF) is characterized by a rapid decline in glomerular filtration rate (GFR) over hours to days. Depending on the exact definition used, ARF complicates approximately 5–7% of hospital admissions and up to 30% of admissions to intensive care units. Retention of nitrogenous waste products, oliguria (urine output <400 mL/d contributing to extracellular fluid overload), and electrolyte and acid-base abnormalities are frequent clinical features. ARF is usually asymptomatic and diagnosed when biochemical monitoring of hospitalized patients reveals a new increase in blood urea and serum creatinine concentrations. For purposes of diagnosis and management, causes of ARF are generally divided into three major categories: (1) diseases that cause renal hypoperfusion, resulting in decreased function without frank parenchymal damage (*prerenal ARF*, or azotemia) (~55%); (2) diseases that directly involve the renal parenchyma (*intrinsic ARF*) (~40%); and (3) diseases associated with urinary tract obstruction (*postrenal ARF*) (~5%). ARF is often considered to be reversible, although a return to baseline serum creatinine concentrations postinjury might not be sufficiently sensitive to detect clinically significant irreversible damage that may ultimately contribute to chronic kidney disease. ARF is associated

with significant in-hospital morbidity and mortality, the latter in the range of 30–60%, depending on the clinical setting and presence or absence of nonrenal organ system failure.

ETIOLOGY AND PATHOPHYSIOLOGY

PRERENAL ARF (PRERENAL AZOTEMIA)

The most common form of ARF is prerenal ARF, which occurs in the setting of renal hypoperfusion. Prerenal ARF is generally reversible when renal perfusion pressure is restored. By definition, renal parenchymal tissue is not damaged. More severe or prolonged hypoperfusion may lead to ischemic injury, often termed *acute tubular necrosis*, or ATN. Thus, prerenal ARF and ischemic ATN fall along a spectrum of manifestations of renal hypoperfusion. As shown in Table 273-1, prerenal ARF can complicate any disease that induces hypovolemia, low cardiac output, systemic vasodilatation, or selective intrarenal vasoconstriction.

Hypovolemia leads to a fall in mean systemic arterial pressure, which is detected as reduced stretch by arterial (e.g., carotid sinus) and cardiac baroreceptors. In turn, this triggers a coordinated series of neurohormonal responses that aim to restore blood volume and arterial pressure. These include activation of the sympathetic nervous system and renin-angiotensin-aldosterone system, as well as release of arginine vasopressin. Relatively "nonessential" vascular beds (such as the musculocutaneous and splanchnic circulations) undergo vasoconstriction in an attempt to preserve cardiac and cerebral perfusion pressure. In addition, salt loss through sweat glands is inhibited, and thirst and salt appetite are stimulated. Renal salt and water retention also occur.

In states of mild hypoperfusion, glomerular perfusion and the filtration fraction are preserved through several compensatory mechanisms. In response to the reduction in perfusion pressure, stretch receptors in afferent arterioles trigger afferent arteriolar vasodilatation through a local myogenic reflex (autoregulation). Angiotensin II increases biosynthesis of vasodilator prostaglandins (e.g., prostaglandin E_2 and prostacyclin), also resulting in afferent arteriolar vasodilation. In addition, angiotensin II induces preferential constriction of efferent arterioles. As a result, the fraction of plasma flowing through glomerular capillaries that is filtered is increased (filtration fraction), intraglomerular pressure is maintained, and GFR is preserved. With more severe hypoperfusion, these compensatory responses are overwhelmed and GFR falls, leading to prerenal ARF.

Autoregulatory dilatation of afferent arterioles allows for maintenance of GFR despite systemic hypotension; however, when hypotension is severe or prolonged, these autoregulatory mechanisms fail, resulting in a precipitous decline in GFR. Lesser degrees of hypotension may provoke prerenal ARF in those at risk: the elderly and patients with diseases that affect the integrity of afferent arterioles (e.g., hypertensive nephrosclerosis, diabetic vasculopathy and other forms of occlusive (including atherosclerotic) renovascular disease). In addition, drugs that interfere with adaptive responses to hypoperfusion may convert compensated renal hypoperfusion into overt prerenal ARF or ATN. Pharmacologic inhibitors of renal prostaglandin biosynthesis [nonsteroidal anti-inflammatory drugs (NSAIDs)] or angiotensin-converting enzyme (ACE) activity (ACE inhibitors) and angiotensin II receptor blockers (ARBs) are major culprits. While NSAIDs do not compromise GFR in healthy individuals, these medications may precipitate prerenal ARF in patients with volume depletion or in those with chronic kidney disease (in whom GFR is maintained, in part, through prostaglandin-mediated hyperfiltration by the remaining functional nephrons). ACE inhibitors should be used with special care in patients with bilateral renal artery stenosis or unilateral stenosis in a solitary functioning kidney. In these settings, glomerular perfusion and filtration may be exquisitely dependent on the actions of angiotensin II. Angiotensin II preserves GFR in these circumstances by raising systemic arterial pressure and by triggering selective constriction of efferent arterioles. ACE inhibitors and ARBs blunt these responses and can precipitate ARF.

Hepatorenal Syndrome Hepatorenal syndrome (HRS) is a unique form of prerenal ARF that frequently complicates advanced cirrhosis as well as acute liver failure. In HRS the kidneys are structurally normal but fail due to splanchnic vasodilation and arteriovenous shunting, resulting in profound renal vasoconstriction. Correction of the underlying liver disease (e.g., by liver transplantation) results in resolution of the acute renal failure. There are two forms of HRS, type I and type II, that differ in their clinical course. In type I HRS, the more aggressive form of the disease, ARF progresses even after optimization of systemic hemodynamics and carries a mortality rate of >90%. **The diagnosis and management of this condition are discussed in Chap. 302.**

TABLE 273-1 CLASSIFICATION AND MAJOR CAUSES OF ACUTE RENAL FAILURE

Prerenal ARF

I. Hypovolemia
- A. Increased extracellular fluid losses: hemorrhage
- B. Gastrointestinal fluid loss: vomiting, diarrhea, enterocutaneous fistula
- C. Renal fluid loss: diuretics, osmotic diuresis, hypoadrenalism, nephrogenic diabetes insipidus
- D. Extravascular sequestration: burns, pancreatitis, severe hypoalbuminemia (hypoproteinemia)
- E. Decreased intake: dehydration, altered mental status

II. Altered renal hemodynamics resulting in hypoperfusion
- A. Low cardiac output state: diseases of the myocardium, valves, and pericardium (including tamponade); pulmonary hypertension or massive pulmonary embolism leading to right and left heart failure; impaired venous return (e.g., abdominal compartment syndrome or positive pressure ventilation)
- B. Systemic vasodilation: sepsis, antihypertensives, afterload reducers, anaphylaxis
- C. Renal vasoconstriction: hypercalcemia, catecholamines, calcineurin inhibitors, amphotericin B
- D. Impairment of renal autoregulatory responses: cyclooxygenase inhibitors (e.g., nonsteroidal anti-inflammatory drugs), angiotensin-converting enzyme inhibitors, or angiotensin II receptor blockers
- E. Hepatorenal syndrome

Intrinsic ARF

I. Renovascular obstruction (bilateral, or unilateral in the setting of one kidney)
- A. Renal artery obstruction: atherosclerotic plaque, thrombosis, embolism, dissection aneurysm, large vessel vasculitis
- B. Renal vein obstruction: thrombosis or compression

II. Diseases of the glomeruli or vasculature
- A. Glomerulonephritis or vasculitis
- B. Other: thrombotic microangiopathy, malignant hypertension, collagen vascular diseases (systemic lupus erythematosus, scleroderma), disseminated intravascular coagulation, preeclampsia

III. Acute tubular necrosis
- A. Ischemia: causes are the same as for prerenal ARF, but generally the insult is more severe and/or more prolonged
- B. Infection, with or without sepsis syndrome
- C. Toxins:
  1. Exogenous: radiocontrast, calcineurin inhibitors, antibiotics (e.g., aminoglycosides), chemotherapy (e.g., cisplatin), antifungals (e.g., amphotericin B), ethylene glycol
  2. Endogenous: rhabdomyolysis, hemolysis

IV. Interstitial nephritis
- A. Allergic: antibiotics (β-lactams, sulfonamides, quinolones, rifampin), nonsteroidal anti-inflammatory drugs, diuretics, other drugs
- B. Infection: pyelonephritis (if bilateral)
- C. Infiltration: lymphoma, leukemia, sarcoidosis
- D. Inflammatory, nonvascular: Sjögren's syndrome, tubulointerstitial nephritis with uveitis

V. Intratubular obstruction
- A. Endogenous: myeloma proteins, uric acid (tumor lysis syndrome), systemic oxalalosis
- B. Exogenous: acyclovir, gancyclovir, methotrexate, indinavir

Postrenal ARF (Obstruction)

I. Ureteric (bilateral, or unilateral in the case of one kidney): calculi, blood clots, sloughed papillae, cancer, external compression (e.g., retroperitoneal fibrosis)

II. Bladder neck: neurogenic bladder, prostatic hypertrophy, calculi, blood clots, cancer

III. Urethra: stricture or congenital valves

INTRINSIC ARF

Intrinsic causes of ARF can be conceptually divided based on the predominant compartment of the kidney that is affected: (1) ischemic or nephrotoxic tubular injury, (2) tubulointerstitial diseases, (3) diseases of the renal microcirculation and glomeruli, and (4) diseases of larger renal vessels (Table 273-1). Ischemia and nephrotoxins classically induce acute tubular injury. Although many patients with ischemic or nephrotoxic ARF do not have morphologic evidence of cellular necrosis, this disease is often referred to as *acute tubular necrosis*, or ATN. More recently, because of the important role of sublethal injury to tubular epithelial and other renal cells (e.g., endothelial cells) in the pathogenesis of this syndrome, the term *acute kidney injury* (AKI) has been proposed.

Etiology and Pathophysiology of Ischemic ATN Prerenal ARF and ischemic ATN are part of a spectrum of manifestations of renal hypoperfusion. In its most extreme form, ischemia leads to bilateral renal cortical necrosis and irreversible renal failure. ATN differs from prerenal ARF in that the renal tubular epithelial cells are injured in the latter. ATN occurs most frequently in patients undergoing major cardiovascular surgery or suffering severe trauma, hemorrhage, sepsis, and/or volume depletion (Table 273-1). Patients with other risk factors for ARF (e.g., exposure to nephrotoxins or preexisting chronic kidney disease) are at increased risk for ATN. Recovery typically takes 1–2 weeks after normalization of renal perfusion, as it requires repair and regeneration of renal cells.

The course of ischemic ATN is typically characterized by four phases: initiation, extension, maintenance, and recovery (Fig. 273-1). These phases are often preceded by a period of prerenal azotemia. During the *initiation phase* (lasting hours to days), GFR declines because (1) glomerular ultrafiltration pressure is reduced as renal blood flow falls, (2) the flow of filtrate within tubules is obstructed by casts comprised of shed epithelial cells and necrotic debris, and (3) there is backleak of glomerular filtrate through injured tubular epithelium. Ischemic injury is most prominent in the S_3 segment of the proximal tubule and the medullary portion of the thick ascending limb of the loop of Henle. These segments of the tubule are particularly sensitive to ischemia because of high rates of active (ATP-dependent) solute transport and location in the outer medulla, where the partial pressure of oxygen is low, even under basal conditions. Cellular ischemia results in ATP depletion, inhibition of active sodium transport, cytoskeletal disruption, loss of cell polarity, cell-cell and cell-matrix attachment, and oxygen free-radical formation. Renal injury may be limited by restoration of renal blood flow during this period. If severe, cell injury results in apoptosis or necrosis.

The *extension phase* follows the initiation phase and is characterized by continued ischemic injury and inflammation. It has been proposed that endothelial damage (resulting in vascular congestion) contributes to both of these processes. During the *maintenance phase* (typically 1–2 weeks), GFR stabilizes at its nadir (typically 5–10 mL/min), urine output is lowest, and uremic complications may arise (see below). It is not clear why the GFR remains low during this phase, despite correction of systemic hemodynamics. Proposed mechanisms include persistent intrarenal vasoconstriction and medullary ischemia triggered by dysregulated release of vasoactive mediators from injured endothelial cells, congestion of medullary blood vessels, and reperfusion injury induced by reactive oxygen species and inflammatory mediators released by leukocytes or renal parenchymal cells. In addition, epithelial cell injury may contribute to persistent intrarenal vasoconstriction through *tubuloglomerular feedback*. Specialized epithelial cells in the macula densa region of distal tubules detect increases in distal salt delivery that occur as a consequence of impaired reabsorption by more proximal nephron segments. Macula densa cells, in turn, stimulate constriction of adjacent afferent arterioles by a poorly defined mechanism and further compromise glomerular perfusion and filtration, thereby contributing to a vicious circle.

The *recovery phase* is characterized by tubular epithelial cell repair and regeneration as well as a gradual return of GFR toward premorbid levels. The recovery phase may be complicated by a marked diuretic phase due to delayed recovery of epithelial cell function (solute and water reabsorption) relative to glomerular filtration (see below).

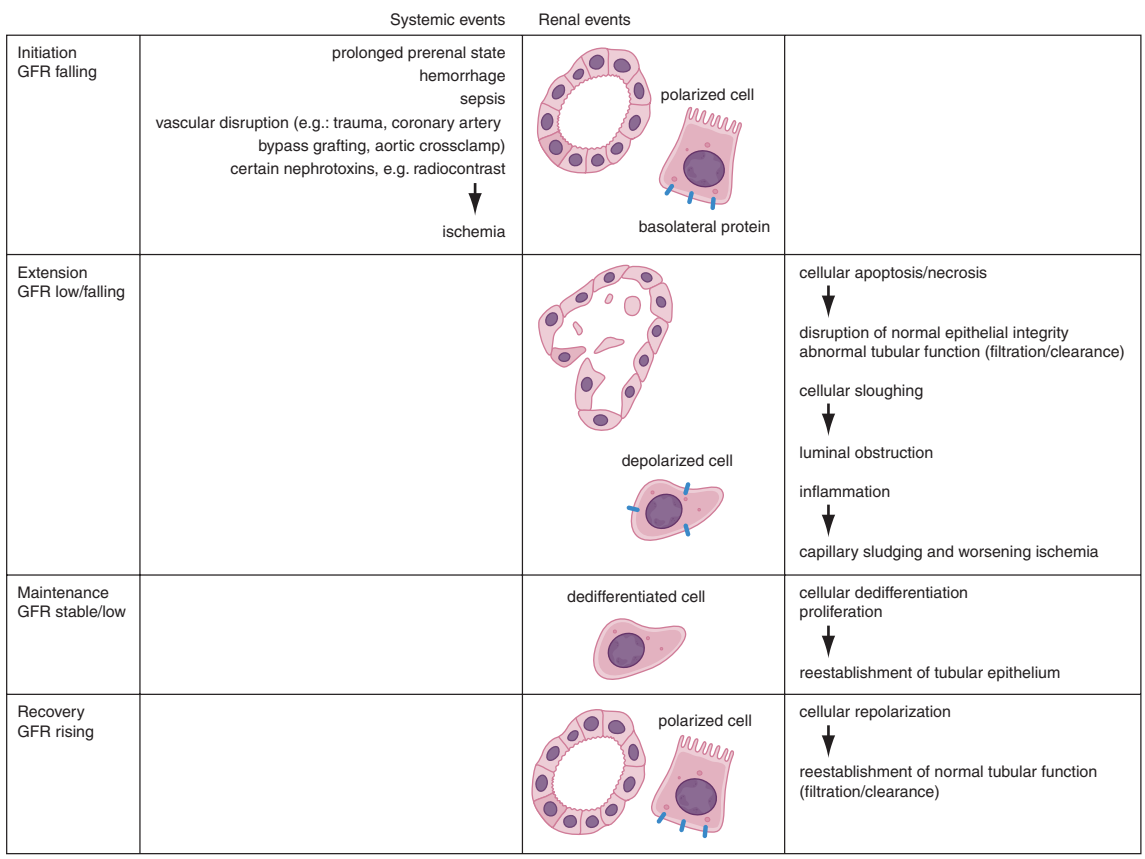

FIGURE 273-1 Four phases of acute tubular necrosis.

Etiology and Pathophysiology of Nephrotoxic ARF Nephrotoxic ATN may complicate exposure to many structurally diverse pharmacologic agents (Table 273-1). With most nephrotoxins, the incidence of ARF is increased in the elderly and in patients with preexisting chronic kidney disease, true or "effective" hypovolemia, or concomitant exposure to other toxins.

Radiocontrast agents, cyclosporine, and tacrolimus (FK506) cause kidney injury through intrarenal vasoconstriction. Consequently, ATN in association with these medications is characterized by an acute fall in renal blood flow and GFR, a relatively benign urine sediment, and a low fractional excretion of sodium (see below). Severe cases may show clinical or pathologic evidence of tubular cell necrosis. Contrast nephropathy is also thought to result from the generation of reactive oxygen species that are directly toxic to renal tubular epithelial cells. Contrast nephropathy classically presents as an acute (onset within 24–48 h) but reversible (peak 3–5 days, resolution within 1 week) rise in blood urea nitrogen and serum creatinine. Contrast nephropathy is most common in individuals with preexisting chronic kidney disease, diabetes mellitus, congestive heart failure, hypovolemia, or multiple myeloma. The type (low vs. isoosmolar contrast) and dose of contrast also influence the likelihood of injury associated with its administration.

Antibiotics and anticancer drugs typically cause ATN through direct toxicity to the tubular epithelial cells and/or intratubular obstruction. ARF complicates 10–30% of courses of *aminoglycoside antibiotics*. Aminoglycosides accumulate in renal tubular epithelial cells, where they cause oxidative stress and cell injury; thus, ARF usually occurs after several days of aminoglycoside therapy. Damage may occur in both the proximal and distal tubule; defects in the distal tubule may result in decreased concentrating ability. *Amphotericin B* causes dose-related ARF through intrarenal vasoconstriction and direct toxicity to proximal tubule epithelium. Newer (liposomal) formulations of amphotericin B may be associated with less nephrotoxicity. Acyclovir may precipitate in the renal tubules and cause acute renal failure. Foscarnet and pentamidine are less commonly prescribed antimicrobials also frequently associated with acute renal failure. Cisplatin and carboplatin, like the aminoglycosides, are accumulated by proximal tubule cells and typically provoke ARF after 7–10 days of exposure, typically in association with potassium and magnesium wasting. Ifosphamide administration may lead to hemorrhagic cystitis, manifested by hematuria, as well as acute and chronic renal failure. Type II renal tubular acidosis (Fanconi syndrome) often accompanies ifosphamide-associated ARF.

Endogenous nephrotoxins include calcium, myoglobin, hemoglobin, urate, oxalate, and myeloma light chains. Hypercalcemia can compromise GFR, predominantly by inducing intrarenal vasoconstriction as well as volume depletion from obligate water loss. Both *rhabdomyolysis* and *hemolysis* can induce ARF. Common causes of rhabdomyolysis include traumatic crush injury, acute muscle ischemia, prolonged seizure activity, excessive exercise, heat stroke or malignant hyperthermia, and infectious or metabolic disorders (e.g., hypophosphatemia, severe hypothyroidism). ARF due to hemolysis is relatively rare and is observed following blood transfusion reactions. It has been postulated that myoglobin and hemoglobin promote intrarenal oxidative stress, resulting in injury to tubular epithelial cells and inducing intratubular cast formation. In addition, cell-free hemoglobin and myoglobin are potent inhibitors of nitric oxide bioactivity and may trigger intrarenal vasoconstriction and ischemia. Hypovolemia or acidosis may further promote intratubular cast formation. Intratubular casts containing filtered immunoglobulin light chains and other proteins (including Tamm-Horsfall protein produced by thick ascending limb cells) cause ARF in patients with *multiple myeloma* (myeloma cast nephropathy). Light chains are also directly toxic to tubule epithelial cells. Intratubular obstruction is an important cause of ARF in patients with severe *hyperuricosuria* or *hyperoxaluria*. Acute uric acid nephropathy can complicate the treatment of selected lymphoproliferative or myeloproliferative disorders (e.g., Burkitt's lymphoma, acute myelogenous leukemia), especially after the administration of chemotherapy, resulting in increased cell lysis ("tumor lysis syndrome").

Pathology of Ischemic and Nephrotoxic ATN The classic pathologic features of ischemic ATN are patchy and focal necrosis of the tubular epithelium, with detachment of cells from the basement membrane, and occlusion of tubule lumens with casts composed of intact or degenerating epithelial cells, Tamm-Horsfall protein, and pigments. Leukocyte accumulation is frequently observed in vasa recta; however, the morphology of the glomeruli and renal vasculature is characteristically normal. Necrosis is most severe in the S3 segment of proximal tubules but may also affect the medullary thick ascending limb of the loop of Henle.

With exposure to nephrotoxins, morphologic changes tend to be most prominent in both the convoluted and straight portions of proximal tubules. Cellular necrosis is less pronounced than in ischemic ATN.

Other Causes of Intrinsic ARF Virtually any pharmacologic agent may trigger allergic interstitial nephritis, which is characterized by infiltration of the tubulointerstitium by granulocytes (typically but not invariably eosinophils), macrophages, and/or lymphocytes and by interstitial edema. The most common offenders are antibiotics (e.g., penicillins, cephalosporins, quinolones, sulfonamides, rifampin) and NSAIDs (Table 273-1).

Patients with advanced atherosclerosis can develop ARF after manipulation of the aorta or renal arteries during surgery or angiography, following trauma, or, rarely, spontaneously (atheroembolic ARF). Cholesterol crystals embolize to the renal vasculature, lodge in small- and medium-sized arteries, and incite a giant cell and fibrotic reaction in the vessel wall with narrowing or obstruction of the vessel lumen. Atheroembolic ARF is often associated with hypocomplementemia and eosinophiluria, and it is frequently irreversible. The acute glomerulonephritides are immune-mediated diseases characterized by proliferative or crescentic glomerular inflammation (glomerulonephritis). **These diseases are discussed in detail in Chap. 277.**

POSTRENAL ARF

(See also Chap. 283) Urinary tract obstruction accounts for fewer than 5% of cases of hospital-acquired ARF. Because one kidney has sufficient reserve to handle generated nitrogenous waste products, ARF from obstruction requires obstruction to urine flow between the external urethral meatus and bladder neck, bilateral ureteric obstruction, or unilateral ureteric obstruction in a patient with one functioning kidney or with significant preexisting chronic kidney disease. Bladder neck obstruction is the most common cause of postrenal ARF and is usually due to prostatic disease (e.g., hypertrophy, neoplasia, or infection), neurogenic bladder, or therapy with anticholinergic drugs. Less common causes of acute lower urinary tract obstruction include blood clots, calculi, and urethritis with spasm. Ureteric obstruction may result from intraluminal obstruction (e.g., calculi, blood clots, sloughed renal papillae), infiltration of the ureteric wall (e.g., neoplasia), or external compression (e.g., retroperitoneal fibrosis, neoplasia or abscess, inadvertent surgical ligature). During the early stages of obstruction (hours to days), continued glomerular filtration leads to increased intraluminal pressure upstream to the site of obstruction. As a result, there is gradual distention of the proximal ureter, renal pelvis, and calyces and a fall in GFR.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

The first step in evaluating a patient with renal failure is to determine if the disease is acute or chronic. If review of laboratory records demonstrates that the rise in blood urea nitrogen and creatinine is recent, this suggests that the process is acute. However, previous measurements are not always available. Findings that suggest chronic kidney disease (Chap. 274) include anemia, evidence of renal osteodystrophy (radiologic or laboratory), and small scarred kidneys. However, anemia may also complicate ARF (see below), and renal size may be normal or increased in several chronic renal diseases (e.g., diabetic nephropathy, amyloidosis, polycystic kidney disease, HIV associated nephropathy). Once a diagnosis of ARF has been established, the etiol-

ogy of ARF needs to be determined. Depending on the cause, specific therapies may need to be instituted. If the etiology is felt to be an exogenous nephrotoxin (often a medication), the nephrotoxin should be eliminated or discontinued. Lastly, the prevention and management of complications should be instituted.

CLINICAL ASSESSMENT

Symptoms of *prerenal* ARF include thirst and orthostatic dizziness. Physical signs of orthostatic hypotension, tachycardia, reduced jugular venous pressure, decreased skin turgor and dry mucous membranes suggest prerenal ARF. Careful clinical examination may reveal stigmata of chronic liver disease and portal hypertension, advanced cardiac failure, sepsis, or other causes of reduced "effective" arterial blood volume (Table 273-1). Case records should be reviewed for documentation of a progressive fall in urine output and body weight and recent initiation of treatment with diuretics, NSAIDs, ACE inhibitors, or ARBs.

Hypovolemia, septic shock, and major surgery are important risk factors for ischemic ATN. The risk of ischemic ATN is increased further if ARF persists despite normalization of systemic hemodynamics. Diagnosis of nephrotoxic ATN requires careful review of the clinical data and records for evidence of recent exposure to nephrotoxic medications, radiocontrast agents, or endogenous toxins.

Although ischemic and nephrotoxic ATN account for >90% of cases of intrinsic ARF, other renal parenchymal diseases must be considered (Table 273-2). Fever, arthralgias, and a pruritic erythematous rash following exposure to a new drug suggest allergic interstitial nephritis, although systemic features of hypersensitivity are frequently absent. Flank pain may be a prominent symptom following occlusion of a renal artery or vein and with other parenchymal diseases distending the renal capsule (e.g., severe glomerulonephritis or pyelonephritis). Subcutaneous nodules, livedo reticularis, bright orange retinal arteriolar plaques, and digital ischemia ("purple toes"), despite palpable pedal pulses, suggest atheroembolization. ARF in association with oliguria, edema, and hypertension, with an "active" urine sediment (nephritic syndrome), suggests acute glomerulonephritis or vasculitis. Malignant hypertension may result in ARF, often in association with hypertensive injury to other organs (e.g., papilledema, neurologic dysfunction, left ventricular hypertrophy) and may mimic glomerulonephritis in its other clinical manifestations.

Postrenal ARF may present with suprapubic and flank pain due to distention of the bladder and of the renal collecting system and capsule, respectively. Colicky flank pain radiating to the groin suggests acute ureteric obstruction. Prostatic disease is likely if there is a history of nocturia, frequency, and hesitancy and enlargement of the prostate on rectal examination. Neurogenic bladder should be suspected in patients receiving anticholinergic medications or with physical evidence of autonomic dysfunction. Definitive diagnosis of postrenal ARF hinges on judicious use of radiologic investigations and rapid improvement in renal function following relief of obstruction.

URINALYSIS

(See also **Chap. e9**) Anuria suggests complete urinary tract obstruction but may complicate severe cases of prerenal or intrinsic renal ARF. Wide fluctuations in urine output raise the possibility of intermittent obstruction, whereas patients with partial urinary tract obstruction may present with polyuria due to impairment of urine concentrating mechanisms.

TABLE 273-2 EPIDEMIOLOGY, CLINICAL FEATURES, AND DIAGNOSTIC STUDIES FOR MAJOR CAUSES OF ACUTE RENAL FAILURE

Etiology	Epidemiology	Clinical Features	Serum Studies	Urine Studies	Other Testing
Prerenal ARF	Most common cause of community-acquired ARF; history of poor fluid intake, treatment with NSAIDs/ACE inhibitors/ARBs, worsening heart failure	Volume depletion (absolute/postural hypotension, low jugular venous pressure, dry mucus membranes) or decreased effective circulatory volume (e.g., heart failure or liver disease)	High BUN/CR ratio (≥20) is suggestive but not diagnostic	Hyaline casts FE_{Na} <1% U_{Na} <10 mmol/L SG >1.018	
Intrinsic ARF					
Diseases of large renal vessels					
Renal artery thrombosis	More common in those with atrial fibrillation or arterial thrombosis	Flank or abdominal pain	Elevated LDH	Mild proteinuria Occasional hematuria	Renal angiogram or MR angiogram are diagnostic
Atheroembolic disease	Vascular disease; classically occurs within days–weeks of manipulation of the aorta or other large vessels, often in the setting of anticoagulation	Retinal plaques, palpable purpura, livedo reticularis	Eosinophilia Hypocomplementemia	Eosinophiluria	Skin or renal biopsy
Renal vein thrombosis	History of nephrotic syndrome or pulmonary embolism	Flank pain		Mild proteinuria Occasional hematuria	Renal venogram or MR venogram are diagnostic
Diseases of small vessels and glomeruli					
Glomerulonephritis/vasculitis	Associated with recent infection (postinfectious or endocarditis), systemic lupus erythematosus, liver disease (hepatitis B or C) Anti-GBM disease: Typically men in their 20s–40s ANCA disease: Two peaks: 20s–30s and 50s–60s	New cardiac murmur (postinfectious) Skin rash/ulcers, arthralgias (lupus) Sinusitis (anti-GBM disease) Lung hemorrhage (anti-GBM, ANCA, lupus)	ANA, ANCA, anti-GBM antibody, hepatitis serologies, cryoglobulins, blood cultures, ASO, complements (positive tests depend on etiology)	Hematuria with red cell casts/dysmorphic red blood cells Granular casts Proteinuria (usually <1 g/d)	Renal biopsy

(continued)

TABLE 273-2 EPIDEMIOLOGY, CLINICAL FEATURES, AND DIAGNOSTIC STUDIES FOR MAJOR CAUSES OF ACUTE RENAL FAILURE (CONTINUED)

Etiology	Epidemiology	Clinical Features	Serum Studies	Urine Studies	Other Testing
Hemolytic-uremic syndrome/ thrombotic thrombocytopenic	Recent GI infection (*E. coli*) or use of calcineurin inhibitors (FK506 and cyclosporine)	Fever, neurologic abnormalities	Schistocytes on peripheral blood smear, elevated LDH, anemia, thrombocytopenia	Hematuria Mild proteinuria Red cell casts (rare)	Renal biopsy
Malignant hypertension	Severe/uncontrolled hypertension	Evidence of damage to other organs: headache, papilledema, heart failure with LVH by echocardiography/ECG Typically resolves with blood pressure control		Hematuria with red cell casts/ proteinuria	
Acute tubular necrosis					
Ischemia	Recent hemorrhage or severe hypotension			Muddy brown granular or tubular epithelial cell casts FE_{Na} >1% U_{Na} >20 mmol/L SG <1.015	
Exogenous toxins	Recent exposure to nephrotoxic antibiotics or chemotherapy, often in association with sepsis, or volume depletion			Muddy brown granular or tubular epithelial cell casts FE_{Na} >1% U_{Na} >20 mmol/L SG <1.015	
	Recent exposure to radiocontrast, often in association with volume depletion, diabetes or CKD			Muddy brown granular or tubular epithelial cell casts Urinalysis may be normal FE_{Na} often <1% U_{Na} often <20 mmol/L	
Endogenous toxins	Rhabdomyolysis	Post ictal state (seizures), evidence of trauma or prolonged immobilization	Increased myoglobin, creatine kinase	U/A positive for heme but no hematuria	
	Hemolysis: recent blood transfusion	Fever, other evidence of transfusion reaction	Pink plasma, increased LDH	Pink, heme-positive urine without hematuria	Transfusion reaction workup
	Tumor lysis: recent chemotherapy		Hyperuricemia, increased LDH	Urate crystals	
	Multiple myeloma	Individuals >60 years of age, ongoing constitutional symptoms (fatigue, malaise)	Circulating monoclonal spike, anemia	Dipstick-negative proteinuria, monoclonal spike on electrophoresis	Bone marrow or renal biopsy
	Ethylene glycol ingestion	History of alcohol abuse, altered mental status	Metabolic gap acidosis with osmolal gap, positive toxicology	Oxalate crystals	
Diseases of the tubulointerstitium					
Allergic interstitial nephritis	Recent medication exposure	Fever, rash, arthralgias	Eosinophilia	White cell casts, eosinophiluria	Renal biopsy
Acute bilateral pyelonephritis		Fever, flank pain and tenderness	Positive blood cultures	Leukocytes, proteinuria, positive urine culture	
Postrenal ARF	History of renal stones or prostatic disease	Palpable bladder, flank or abdominal pain		Usually normal; hematuria if due to stones	Imaging to assess obstruction: CT scan and/or ultrasound

Note: ACE, angiotensin-converting enzyme; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; ARBs, angiotensin II receptor blockers; ARF, acute renal failure; ASO, antistreptolysin O; BUN, blood urea nitrogen; CKD, chronic kidney disease; CR, creatinine; CT, computed tomography; ECG, electrocardiogram; FE_{Na}, fractional excretion of sodium; GBM, glomerular basement membrane; GI, gastrointestinal; LDH, lactate dehydrogenase; LVH, left ventricular hypertrophy; MR, magnetic resonance; NSAIDs, nonsteroidal anti-inflammatory drugs; SG, specific gravity; U/A, urinalysis; U_{Na}, urine sodium concentration.

In prerenal ARF, the sediment is characteristically acellular and contains transparent hyaline casts ("bland," "benign," "inactive" urine sediment). Hyaline casts are formed in concentrated urine from normal constituents of urine—principally Tamm-Horsfall protein, which is secreted by epithelial cells of the loop of Henle. Postrenal ARF may also present with an inactive sediment, although hematuria and pyuria are common in patients with intraluminal obstruction or prostatic disease. Pigmented "muddy brown" granular casts and casts containing tubule epithelial cells are characteristic of ATN and suggest an ischemic or nephrotoxic etiology. These casts are usually found in association with mild "tubular" proteinuria (<1 g/d), reflecting impaired reabsorption and processing of filtered proteins by injured proximal tubules. Casts may be absent in 20–30% of patients with ATN and are not required for diagnosis. In general, red blood cell casts indicate glomerular injury or, less often, acute tubulointerstitial nephritis. White cell casts and nonpigmented granular casts suggest interstitial nephritis, whereas broad granular casts are characteristic of chronic kidney disease and probably reflect interstitial fibrosis and dilatation of tubules. Eosinophiluria (>5% of urine leukocytes) is a common finding (~90%) in antibiotic-induced allergic interstitial nephritis and can be detected with Hansel's stain; however, lymphocytes may predominate in allergic interstitial nephritis induced by NSAIDs and some other drugs (i.e., ampicillin, rifampicin, and interferon α). Occasional uric acid crystals (pleomorphic in shape) are common in the concentrated urine of prerenal ARF but suggest acute urate nephropathy if seen in abundance. Oxalate (envelope-shaped) and hippurate (needle-shaped) crystals raise the possibility of ethylene glycol ingestion and toxicity.

Proteinuria of >1 g/d suggests injury to the glomerular ultrafiltration barrier ("glomerular proteinuria") or excretion of myeloma light chains. The latter may not be detected by conventional dipstick analysis, and other tests may be needed (e.g., sulfosalicylic acid precipitation, immunoelectrophoresis). Hemoglobinuria or myoglobinuria should be suspected if urine is strongly positive for heme by dipstick but contains few red cells, and if the supernatant of centrifuged urine is positive for free heme. Bilirubinuria may provide a clue to the presence of HRS.

RENAL FAILURE INDICES

Analysis of urine and blood biochemistry may be useful for distinguishing prerenal ARF from ischemic or nephrotoxic intrinsic renal ARF. The fractional excretion of sodium (FE_{Na}) is most useful in this regard. The FE_{Na} relates sodium clearance to creatinine clearance. Sodium is reabsorbed avidly from glomerular filtrate in patients with prerenal ARF, in an attempt to restore intravascular volume. The FE_{Na} tends to be high in ischemic ATN but is often low in patients with sepsis-induced, pigment-induced, and some forms of nephrotoxic ATN (e.g., contrast-associated). In contrast, creatinine is not reabsorbed in either setting. Consequently, patients with prerenal ARF typically have a FE_{Na} of <1.0% (frequently <0.1%). In patients with metabolic alkalosis, where there may be obligate losses of sodium in the urine to maintain electroneutrality, the fractional excretion of chloride (FE_{Cl}) may be more sensitive than the FE_{Na} in detecting prerenal azotemia. The *urine sodium concentration* is a less-sensitive index for distinguishing prerenal ARF from ischemic and nephrotoxic ARF as values overlap between groups. Similarly, indices of urinary concentrating ability such as urine specific gravity, urine osmolality, urine-to-plasma urea ratio, and blood urea-to-creatinine ratio are of limited value in differential diagnosis.

Many caveats apply when interpreting biochemical renal failure indices. The FE_{Na} may be >1.0% in prerenal ARF if patients are receiving diuretics or with preexisting chronic kidney disease, certain salt-wasting syndromes, or adrenal insufficiency.

LABORATORY FINDINGS

Serial serum creatinine measurements can provide useful insights to the cause of ARF. Prerenal ARF is typified by fluctuating serum creatinine levels that parallel changes in hemodynamic status. Creatinine rises rapidly (within 24–48 h) in patients with ARF following renal ischemia, atheroembolization, and radiocontrast exposure. Peak serum creatinine concentrations are observed after 3–5 days with contrast nephropathy and return to baseline after 5–7 days. In contrast, serum creatinine concentrations typically peak later (7–10 days) in ATN and atheroembolic disease. The initial rise in serum creatinine is characteristically delayed until the second week of therapy with many tubular epithelial cell toxins (e.g., aminoglycosides, cisplatin) and is thought to reflect the need for accumulation of these agents within tubular epithelial cells to cause injury.

Hyperkalemia, hyperphosphatemia, hypocalcemia, and elevations in serum uric acid and creatine kinase (MM isoenzyme) levels at presentation suggest a diagnosis of rhabdomyolysis. Hyperuricemia [>890 μmol/L (>15 mg/dL)] in association with hyperkalemia, hyperphosphatemia, and increased circulating levels of intracellular enzymes such as lactate dehydrogenase may indicate acute urate nephropathy and tumor lysis syndrome following cancer chemotherapy. A wide anion and osmolal gap [the latter calculated as the difference between the observed (measured) serum osmolality minus the expected osmolality calculated from serum sodium, glucose, and urea concentrations] indicate the presence of an unusual anion or osmole in the circulation (e.g., ingestion of ethylene glycol or methanol). Severe anemia in the absence of hemorrhage raises the possibility of hemolysis, multiple myeloma, or thrombotic microangiopathy. Systemic eosinophilia suggests allergic interstitial nephritis but is also a feature of atheroembolic disease and polyarteritis nodosa.

RADIOLOGIC FINDINGS

Imaging of the urinary tract by ultrasonography is useful to exclude postrenal ARF. CT and MRI are alternative imaging modalities. Whereas pelvicalyceal dilatation is usual with urinary tract obstruction (98% sensitivity), dilatation may be absent immediately following obstruction or in patients with ureteric encasement (e.g., retroperitoneal fibrosis, neoplasia). Retrograde or anterograde pyelography are more definitive investigations in complex cases and provide precise localization of the site of obstruction. A plain film of the abdomen or unenhanced helical CT scan is a valuable initial screening technique in patients with suspected nephrolithiasis. Magnetic resonance angiography (MRA) is often used to assess patency of renal arteries and veins in patients with suspected vascular obstruction. Alternative methods include Doppler ultrasound (which is much more operator-dependent than MRA) and CT-based angiography. Catheter-based angiography may be required for definitive diagnosis and treatment.

RENAL BIOPSY

Biopsy is reserved for patients in whom prerenal and postrenal ARF have been excluded and the cause of intrinsic ARF is unclear. Renal biopsy is particularly useful when clinical assessment and laboratory investigations suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy. Examples include glomerulonephritis, vasculitis, and allergic interstitial nephritis.

COMPLICATIONS

ARF impairs renal excretion of sodium, potassium, and water and perturbs divalent cation homeostasis and urinary acidification mechanisms. As a result, ARF is frequently complicated by intravascular volume overload, hyponatremia, hyperkalemia, hyperphosphatemia, hypocalcemia, hypermagnesemia, and metabolic acidosis. In addition, patients are unable to excrete nitrogenous waste products and are prone to develop the uremic syndrome (Chap. 45). The speed of development and the severity of these complications reflect the degree of renal impairment and catabolic state of the patient.

Expansion of extracellular fluid volume is an inevitable consequence of diminished salt and water excretion in oliguric or anuric individuals. Whereas milder forms are characterized by weight gain, bibasilar lung rales, raised jugular venous pressure, and dependent edema, continued volume expansion may precipitate life-threatening pulmonary edema. Excessive administration of free water, either through ingestion and na-

sogastric administration or as hypotonic saline or isotonic dextrose solutions, can induce *hypoosmolality* and *hyponatremia*, which, if severe, lead to neurologic abnormalities, including seizures.

Hyperkalemia is a frequent complication of ARF. Coexistent metabolic acidosis may exacerbate hyperkalemia by promoting potassium efflux from cells. Hyperkalemia may be particularly severe, even at the time of diagnosis, in patients with rhabdomyolysis, hemolysis, and tumor lysis syndrome. Mild hyperkalemia (<6.0 mmol/L) is usually asymptomatic. Higher levels may trigger electrocardiographic abnormalities and/or arrhythmias.

ARF is typically complicated by *metabolic acidosis*, often with an increased anion gap (Chap. 48). Acidosis can be particularly severe when endogenous production of hydrogen ions is increased by other mechanisms (e.g., diabetic or fasting ketoacidosis; lactic acidosis complicating generalized tissue hypoperfusion, liver disease, or sepsis; metabolism of ethylene glycol or methanol).

Hyperphosphatemia is an almost invariable complication of ARF. Severe hyperphosphatemia may develop in highly catabolic patients or following rhabdomyolysis, hemolysis, or tissue ischemia. Metastatic deposition of calcium phosphate can lead to *hypocalcemia*, particularly with elevation of serum calcium (mg/dL) and phosphate (mg/dL) concentrations. Other factors that contribute to hypocalcemia include tissue resistance to the actions of parathyroid hormone and reduced levels of 1,25-dihydroxyvitamin D. Hypocalcemia is often asymptomatic but can cause perioral paresthesia, muscle cramps, seizures, altered mental status, prolongation of the QT interval and other nonspecific T-wave changes on electrocardiography.

Anemia develops rapidly in ARF and is usually multifactorial in origin. Contributing factors include impaired erythropoiesis, hemolysis, bleeding, hemodilution, and reduced red cell survival time. Prolongation of the *bleeding time* is also common. Common contributors to the bleeding diathesis include mild thrombocytopenia, platelet dysfunction, and/or clotting factor abnormalities (e.g., factor VIII dysfunction). *Infection* is a common and serious complication of ARF. It is unclear whether patients with ARF have a clinically significant defect in host immune responses or whether the high incidence of infection reflects repeated breaches of mucocutaneous barriers (e.g., intravenous cannulae, mechanical ventilation, bladder catheterization). *Cardiopulmonary complications* of ARF include arrhythmias, pericarditis and pericardial effusion, and pulmonary edema.

Protracted periods of severe ARF are invariably associated with the development of the *uremic syndrome* (Chap. 45).

A *vigorous diuresis* can occur during the recovery phase of ARF (see above), which may be inappropriate on occasion and lead to intravascular volume depletion. *Hypernatremia* can also complicate recovery if water losses via hypotonic urine are not replaced or if losses are inappropriately replaced by relatively hypertonic saline solutions. *Hypokalemia*, *hypomagnesemia*, *hypophosphatemia*, and *hypocalcemia* are less common metabolic complications during this period but may develop in response to injury associated with selected drugs (e.g., ifosphamide may lead to Fanconi syndrome or type II renal tubular acidosis associated with hypokalemia, acidosis, hypophosphatemia, and glycosuria).

℞ ACUTE RENAL FAILURE

PREVENTION Because there are no specific therapies for ischemic or nephrotoxic ARF, prevention is of paramount importance. Many cases of ischemic ARF can be avoided by close attention to cardiovascular function and intravascular volume in high-risk patients, such as the elderly and those with preexisting chronic kidney disease. Indeed, aggressive restoration of intravascular volume has been shown to dramatically reduce the incidence of ischemic ARF after major surgery or trauma, burns, or cholera. The incidence of nephrotoxic ARF can be reduced by tailoring the administration (dose and frequency) of nephrotoxic drugs to body size and GFR. In this regard, it should be noted that serum creatinine is a relatively insensitive index of GFR and may overestimate GFR considerably in small or elderly patients. For purposes of drug dosing, it is advisable to estimate the GFR using the Cockcroft-Gault formula (which factors in age, sex, and weight) or the simplified Modification of Diet in Renal Disease (MDRD) equation (which factors in age, sex, weight, and race) (Chap. 277). Of note, these equations cannot be used to estimate GFR when creatinine is not at steady state (e.g., during evolving ARF). Adjusting drug dosage according to circulating drug levels also appears to limit renal injury in patients receiving aminoglycoside antibiotics, cyclosporine, or tacrolimus. Diuretics, NSAIDs, ACE inhibitors, ARBs, and vasodilators should be used with caution in patients with suspected true or "effective" hypovolemia or renovascular disease as they may precipitate prerenal ARF or convert the latter to ischemic ARF. Allopurinol and forced alkaline diuresis are useful prophylactic measures in patients at high risk for acute urate nephropathy (e.g., cancer chemotherapy in hematologic malignancies) to limit uric acid generation and prevent precipitation of urate crystals in renal tubules. Rasburicase, a recombinant urate-oxidase enzyme, catalyzes enzymatic oxidation of uric acid into a soluble metabolite, allantoin. Forced alkaline diuresis may also prevent or attenuate ARF in patients receiving high-dose methotrexate or suffering from rhabdomyolysis. *N*-acetylcysteine limits acetaminophen-induced renal injury if given within 24 h of ingestion.

A number of preventive measures have been proposed for contrast nephropathy. It is clear that hydration is an effective preventive measure. Other measures that have been proposed include loop diuretics and mannitol, dopamine, fenoldopam, *N*-acetylcysteine, theophylline, and sodium bicarbonate. Despite favorable experimental data, there is insufficient evidence to support the use of loop diuretics or mannitol to prevent radiocontrast nephropathy or any other cause of ARF. Likewise, despite its widespread use, dopamine has proved ineffective as a prophylactic agent. Fenoldopam, a dopamine a-1 specific agonist approved for use as a parenteral antihypertensive agent, has been tested in several clinical trials and does not appear to reduce the incidence of contrast nephropathy. Moreover, fenoldopam is associated with significant side effects, including systemic hypotension, and its use as an agent to prevent radiocontrast nephropathy should be discouraged. In contrast, several (relatively small) randomized clinical trials (RCTs) have suggested a clinical benefit to the use of *N*-acetylcysteine, although meta-analyses have been inconclusive. However, aside from the potential hazards associated with a delay in radiographic imaging, *N*-acetylcysteine appears to be safe, and its use in patients at high risk for radiocontrast nephropathy is reasonable, based on its low side effect profile. Larger RCTs will be required to show definitive benefit. Theophylline and aminophylline (adenosine antagonists) offer the potential advantage of use immediately preceding radiocontrast administration, although the benefit, if present, appears marginal in most studies. Lastly, volume expansion with bicarbonate-containing intravenous fluids has been suggested to be superior to sodium chloride (saline) administration and showed a significant benefit in a single center RCT. Unlike *N*-acetylcysteine, the use of sodium bicarbonate does not obligate a delay in imaging (the published protocol began IV fluids 1 h before the imaging study was begun). Whether a combination of strategies (e.g., *N*-acetylcysteine + sodium bicarbonate) offers additive benefit and that patients require treatment remain unclear and warrant further study.

SPECIFIC THERAPIES By definition, prerenal ARF is rapidly reversible upon correction of the primary hemodynamic abnormality, and postrenal ARF resolves upon relief of obstruction. To date there are no specific therapies for established AKI. Management of these disorders should focus on elimination of the causative hemodynamic abnormality or toxin, avoidance of additional insults, and prevention and treatment of complications. Specific treatment of other causes of intrinsic renal ARF depends on the underlying pathology.

Prerenal ARF The composition of replacement fluids for treatment of prerenal ARF due to hypovolemia should be tailored according to the composition of the lost fluid. Severe hypovolemia due to hemorrhage should be corrected with packed red cells, whereas isotonic saline is usually appropriate replacement for mild to moderate hemorrhage or plasma loss (e.g., burns, pancreatitis). Urinary and gastrointestinal fluids can vary greatly in composition but are usually hypotonic. Hypotonic solutions (e.g., 0.45% saline) are usually recommended as initial replacement in patients with prerenal ARF due to increased urinary or gastrointestinal fluid losses, although isotonic saline may be more appropriate in severe cases. Subsequent therapy should be based on measurements of the volume and ionic content of excreted or drained fluids. Serum potassium and acid-base status should be monitored carefully, and potassium and bicarbonate supplemented as appropriate. Cardiac failure may require aggressive management with inotro-

pic agents, preload and afterload reducing agents, antiarrhythmic drugs, and mechanical aids such as intraaortic balloon pumps. Invasive hemodynamic monitoring may be required in selected cases to guide therapy for complications in patients in whom clinical assessment of cardiovascular function and intravascular volume is difficult.

Fluid management may be particularly challenging in patients with cirrhosis complicated by ascites. In this setting, it is important to distinguish between full-blown HRS (Chap. 302), which carries a grave prognosis, and reversible ARF due to true or "effective" hypovolemia induced by overzealous use of diuretics or sepsis (e.g., spontaneous bacterial peritonitis). The contribution of hypovolemia to ARF can be definitively assessed only by administration of a fluid challenge. Fluids should be administered slowly and titrated to jugular venous pressure and, if necessary, central venous and pulmonary capillary wedge pressure. Patients with a reversible prerenal component typically have an increase in urine output and fall in serum creatinine with fluid challenge, whereas patients with HRS do not. Patients with HRS may suffer increased ascites formation and pulmonary compromise if not monitored closely during fluid challenge. Large volumes of ascitic fluid can usually be drained by paracentesis without deterioration in renal function if intravenous albumin is administered simultaneously. Indeed, "large-volume paracentesis" may afford an increase in GFR, likely by lowering intraabdominal pressure and improving flow in renal veins. Alternatively, for patients with refractory ascites, transjugular intrahepatic portosystemic shunting is an alternative. Older peritoneal-venous shunts (LaVeen or Denver shunt) have largely fallen out of favor. Transjugular intrahepatic portosystemic shunts may improve renal function through increased central blood volume and suppression of aldosterone and norepinephrine secretion.

Intrinsic ARF Many different approaches to attenuate injury or hasten recovery have been tested in ischemic and nephrotoxic AKI. These include atrial natriuretic peptide, low-dose dopamine, endothelin antagonists, loop-blocking diuretics, calcium channel blockers, α-adrenoreceptor blockers, prostaglandin analogues, antioxidants, antibodies against leukocyte adhesion molecules, and insulin-like growth factor type I. Whereas many of these are beneficial in experimental models of ischemic or nephrotoxic ATN, they have either failed to confer consistent benefit or proved ineffective in humans.

ARF due to other intrinsic renal diseases such as acute glomerulonephritis or vasculitis may respond to immunosuppressive agents (glucocorticoids, alkylating agents, and/or plasmapheresis, depending on the primary pathology). Glucocorticoids also may hasten remission in allergic interstitial nephritis, although data are limited to small-case series. Aggressive control of systemic arterial pressure is of paramount importance in limiting renal injury in malignant hypertensive nephrosclerosis. Hypertension and ARF due to scleroderma may be exquisitely sensitive to treatment with ACE inhibitors.

Postrenal ARF Management of postrenal ARF requires close collaboration between nephrologist, urologist, and radiologist. Obstruction of the urethra or bladder neck is usually managed initially by transurethral or suprapubic placement of a bladder catheter, which provides temporary relief while the obstructing lesion is identified and treated definitively. Similarly, ureteric obstruction may be treated initially by percutaneous catheterization of the dilated renal pelvis or ureter. Indeed, obstructing lesions can often be removed percutaneously (e.g., calculus, sloughed papilla) or bypassed by insertion of a ureteric stent (e.g., carcinoma). Most patients experience an appropriate diuresis for several days following relief of obstruction. Approximately 5% of patients develop a transient salt-wasting syndrome that may require administration of intravenous saline to maintain blood pressure.

SUPPORTIVE MEASURES **(Table 273-3)** Following correction of hypovolemia, salt and water intake are tailored to match losses. Hypervolemia can usually be managed by restriction of salt and water intake and diuretics. Indeed, there is, as yet, no proven rationale for administration of diuretics in ARF except to treat this complication. Despite the fact that subpressor doses of dopamine may transiently promote salt and water excretion by increasing renal blood flow and GFR and by inhibiting tubule sodium reabsorption, subpressor ("low-dose," "renal-dose") dopamine has proved ineffective in clinical trials, may trigger arrhythmias, and should not be used as a renoprotective agent in this setting. Ultrafiltration or dialysis is used to treat severe hypervolemia when conservative measures fail. Hypo-

TABLE 273-3 MANAGEMENT OF ISCHEMIC AND NEPHROTOXIC ACUTE RENAL FAILURE[a]

Management Issue	Therapy
Reversal of Renal Insult	
Ischemic ATN	Restore systemic hemodynamics and renal perfusion through volume resuscitation and use of vasopressors
Nephrotoxic ATN	Eliminate nephrotoxic agents Consider toxin-specific measures: e.g., forced alkaline diuresis for rhabdomyolysis, allopurinol/rasburicase for tumor lysis syndrome
Prevention and Treatment of Complications	
Intravascular volume overload	Salt and water restriction Diuretics Ultrafiltration
Hyponatremia	Restriction of enteral free water intake Avoidance of hypotonic intravenous solutions, including dextrose-containing solutions
Hyperkalemia	Restriction of dietary K^+ intake Eliminate K^+ supplements and K^+-sparing diuretics Loop diuretics to promote K^+ excretion Potassium binding ion-exchange resins (e.g., sodium polystyrene sulfonate or Kayexelate) Insulin (10 units regular) and glucose (50 mL of 50% dextrose) to promote intracellular mobilization Inhaled β-agonist therapy to promote intracellular mobilization Calcium gluconate or calcium chloride (1 g) to stabilize the myocardium Dialysis
Metabolic acidosis	Sodium bicarbonate (maintain serum bicarbonate >15 mmol/L or arterial pH >7.2) Administration of other bases, e.g., THAM Dialysis
Hyperphosphatemia	Restriction of dietary phosphate intake Phosphate binding agents (calcium carbonate, calcium acetate, sevelamer hydrochloride, aluminum hydroxide)
Hypocalcemia	Calcium carbonate or gluconate (if symptomatic)
Hypermagnesemia	Discontinue Mg^{++} containing antacids
Hyperuricemia	Treatment usually not necessary if <890 μmol/L or <15mg/dL Allopurinol, forced alkaline diuresis, rasburicase
Nutrition	Protein and calorie intake to avoid net negative nitrogen balance
Dialysis	To prevent complications of acute renal failure
Choice of agents	Avoid other nephrotoxins: ACE inhibitors/ARBs, aminoglycosides, NSAIDs, radiocontrast unless absolutely necessary and no alternative
Drug dosing	Adjust doses and frequency of administration for degree of renal impairment

[a]Note that these are general recommendations and need to be tailored to the individual patient.

Abbreviations: ATN, acute tubular necrosis; THAM, tris(hydroxymethyl)aminomethane; ACE, angiotensin-converting enzyme; ARBs, angiotensin II receptor blockers; NSAIDs, nonsteroidal anti-inflammatory drugs.

free water intake. Conversely, hypernatremia is treated by administration of water or intravenous hypotonic saline or isotonic dextrose-containing solutions. **The management of hyperkalemia is described in Chap. 46.**

Metabolic acidosis is not usually treated unless serum bicarbonate concentration falls below 15 mmol/L or arterial pH falls below 7.2. More severe acidosis is corrected by oral or intravenous sodium bicarbonate. Initial rates of replacement are guided by estimates of bicarbonate deficit and adjusted thereafter according to serum levels (Chap. 48). Patients should be monitored for complications of sodium bicarbonate administration such as hypervolemia, metabolic alkalosis, hypocalcemia, and hypokalemia. From a practical point of view, most patients who require supplemental sodium bicarbonate administration will need emergency dialysis within days. Hyperphosphatemia is usually controlled by restriction of dietary phosphate and by oral phosphate binders (calcium carbonate, calcium acetate, sevelamer, and aluminum hydroxide) to reduce gastrointestinal ab-

sorption of phosphate. Hypocalcemia does not usually require treatment unless severe, as may occur with rhabdomyolysis or pancreatitis or following administration of bicarbonate. Hyperuricemia is typically mild [<890 μmol/L (<15 mg/dL)] and does not require intervention.

The objective of *nutritional management* during the maintenance phase of ARF is to provide sufficient calories and protein to minimize catabolism. Nutritional requirements will vary based on the underlying disease process; for example, those with sepsis-associated AKI are likely to be hypercatabolic. The presence of oliguria complicates nutritional management, and if the patient is not on dialysis, minimizing production of nitrogenous waste is a consideration. Often, the institution of dialysis facilitates the provision of adequate nutritional support. There is no clear benefit of parenteral nutrition compared with enteral nutrition; indeed, those supported with parenteral nutrition are at increased risk of complications, including infection.

Anemia may necessitate blood transfusion if severe. Recombinant human erythropoietin is rarely used in ARF because bone marrow resistance to erythropoietin is common, and more immediate treatment of anemia (if any) is required. Uremic bleeding may respond to administration of desmopressin or estrogens. Often dialysis is instituted to control bleeding that appears to be related to uremia. Gastrointestinal prophylaxis with histamine receptor (H2) antagonists or proton pump inhibitors should be prescribed, especially in the setting of critical illness. Meticulous care of intravenous and bladder catheters, and other invasive devices is mandatory to avoid infections.

Indications and Modalities of Dialysis (See also Chap. 275) During ARF, dialysis is often used to support renal function until renal repair/recovery occur. Absolute indications for dialysis include symptoms or signs of the uremic syndrome and management of refractory hypervolemia, hyperkalemia, or acidosis. Many nephrologists also initiate dialysis empirically for blood urea levels of >100 mg/dL; however, this approach has yet to be validated in controlled clinical trials. Although direct clinical comparisons are limited, hemodialysis appears to be somewhat more effective than peritoneal dialysis for management of ARF. Peritoneal dialysis may be useful when hemodialysis is unavailable or if it is impossible to obtain vascular access. However, peritoneal dialysis is associated with increased protein losses and is contraindicated in those patients who have undergone recent abdominal surgery or those with ongoing infection. Peritoneal dialysis access requires insertion of a cuffed catheter into the peritoneal cavity.

Vascular access for hemodialysis requires insertion of a temporary double-lumen hemodialysis catheter into the internal jugular or femoral vein. Insertion into the subclavian vein is generally avoided owing to the risk of subclavian stenosis. Hemodialysis may be provided in the form of intermittent hemodialysis (typically performed for 3–4 hours per day, 3–4 times per week), slow low-efficiency dialysis (performed for 6–12 hours per day, 3–6 times per week), or continuous renal replacement therapy (CRRT). CCRTs are particular valuable techniques in patients in whom intermittent therapy fails to control hypervolemia, uremia, or acidosis or in those who do not tolerate intermittent hemodialysis due to hemodynamic instability. In those patients where hemodynamic instability is a primary consideration, slow low-efficiency hemodialysis (SLED), a relatively new hybrid mode of dialysis, is an excellent alternative to CRRT.

Continuous arteriovenous modalities [continuous arteriovenous hemofiltration, hemodialysis, and hemodiafiltration (CAVH, CAVHD, and CAVHDF, respectively)] require both arterial and venous access. The patient's own blood pressure generates an ultrafiltrate of plasma across a porous biocompatible dialysis membrane. With the advent of peristaltic pumps, the arteriovenous modalities have fallen out of favor, in part because of the complications associated with cannulation of a large artery with a large bore catheter. In continuous venovenous hemodialysis (CVVHD), a blood pump generates ultrafiltration pressure across the dialysis membrane. In continuous venovenous hemofiltration (CVVH), the hemodialysis (diffusive clearance) component is eliminated, and an ultrafiltrate of plasma is removed across the dialysis membrane and replaced by a physiologic crystalloid solution (convective clearance). In continuous venovenous hemodiafiltration (CVVHDF), these two methods of clearance are combined. The bulk of evidence to date suggests that intermittent and continuous dialytic therapies are equally effective for the treatment of ARF. The choice of technique is currently tailored to the specific needs of the patient, the resources of the institution, and the expertise of the physician. Potential disadvantages of continuous techniques include the need for prolonged immobilization, systemic anticoagulation, and prolonged exposure of blood to synthetic (albeit biocompatible) dialysis membranes.

The optimal dose of dialysis for ARF remains unclear at present. Recent evidence (from a single center, nonrandomized trial) suggests that more intensive hemodialysis (e.g., daily rather than alternate-day intermittent dialysis) may be clinically superior and confers improved survival in ARF once dialysis is required. This conclusion may not be as intuitive as it first appears since dialysis itself has been postulated to prolong ARF by inducing hypotension and other adverse effects related to the blood-dialyzer contact (e.g., complement activation and inflammation). Similarly, data suggest that increased doses of continuous renal replacement therapy may be of benefit for ARF, although these results need to be confirmed in a larger, multicenter study.

OUTCOME AND LONG-TERM PROGNOSIS

The in-hospital mortality rate among patients with ARF ranges from 20 to 50% or more, depending on underlying conditions, and has declined only marginally over the past 15 years. Most patients who survive an episode of ARF recover sufficient renal function to remain dialysis-independent, although a fraction (roughly 10–20%) go on to require maintenance dialysis.

Common etiologies for acute renal failure will vary, depending on the availability of health care in a given country. In general, the most common cause of community-acquired ARF is prerenal azotemia. However, in countries with less well-developed health care systems, infective etiologies for ARF predominate. In developed countries, postoperative and ischemic/nephrotoxic causes of ARF are more common.

ACKNOWLEDGMENT

We are grateful to Dr. Hugh Brady and Dr. Barry Brenner, authors of this chapter in the 16th edition, for contributions to this edition.

274 Chronic Kidney Disease

Joanne M. Bargman, Karl Skorecki

Chronic kidney disease (CKD) encompasses a spectrum of different pathophysiologic processes associated with abnormal kidney function, and a progressive decline in glomerular filtration rate (GFR). Table 274-1 provides a widely accepted classification, based on recent guidelines of the National Kidney Foundation [Kidney Dialysis Outcomes Quality Initiative (KDOQI)], in which stages of CKD are defined according to the estimated GFR.

The term *chronic renal failure* applies to the process of continuing significant irreversible reduction in nephron number, and typically corresponds to CKD stages 3–5. The pathophysiologic processes and adaptations associated with chronic renal failure will be the focus of

this chapter. The dispiriting term *end-stage renal disease* represents a stage of CKD where the accumulation of toxins, fluid, and electrolytes normally excreted by the kidneys results in the *uremic syndrome*. This syndrome leads to death unless the toxins are removed by renal replacement therapy, using dialysis or kidney transplantation. These latter interventions are discussed in Chaps. 275 and 276. *End-stage renal disease* will be supplanted in this chapter by the term *stage 5 CKD*.

PATHOPHYSIOLOGY OF CHRONIC KIDNEY DISEASE

The pathophysiology of CKD involves two broad sets of mechanisms of damage: (1) initiating mechanisms specific to the underlying etiology (e.g., immune complexes and mediators of inflammation in certain types of glomerulonephritis, or toxin exposure in certain diseases of the renal tubules and interstitium); and (2) a set of progressive mechanisms, involving hyperfiltration and hypertrophy of the remaining viable nephrons, that are a common consequence following long-term reduction of renal mass, irrespective of underlying etiology (Chap. 272). The responses to reduction in nephron number are mediated by vasoactive hormones, cytokines, and growth factors. Eventually, these short-term adaptations of hypertrophy and hyperfiltration become maladaptive as the increased pressure and flow predisposes to sclerosis and dropout of the remaining nephrons. Increased intrarenal activity of the renin-angiotensin axis appears to contribute both to the initial adaptive hyperfiltration and to the subsequent maladaptive hypertrophy and sclerosis, the latter, in part, owing to the stimulation of transforming growth factor β (TGF-β). This process explains why a reduction in renal mass from an isolated insult may lead to a progressive decline in renal function over many years.

THE STAGES OF CKD AND IDENTIFICATION OF AT-RISK POPULATIONS

It is important to identify factors that increase the risk for CKD, even in individuals with normal GFR. Risk factors include hypertension, diabetes mellitus, autoimmune disease, older age, African ancestry, a family history of renal disease, a previous episode of acute renal failure, and the presence of proteinuria, abnormal urinary sediment, or structural abnormalities of the urinary tract.

In order to stage CKD, it is necessary to estimate the GFR. Two equations commonly used to estimate GFR are shown in Table 274-2, and incorporate the measured plasma creatinine concentration, age, sex, and ethnic origin. Many laboratories now report an estimated GFR, or "e-GFR," using one of these equations.

The normal annual mean decline in GFR with age from the peak GFR (~120 mL/min per 1.73 m^2) attained during the third decade of life is ~1 mL/min per year per 1.73 m^2, reaching a mean value of 70 mL/min per 1.73 m^2 at age 70. The mean GFR is lower in women than in men. For example, a woman in her 80s with a normal serum creatinine may have a GFR of just 50 mL/min per 1.73 m^2. Thus, even a mild elevation in serum creatinine concentration [e.g., 130 μmol/L (1.5 mg/dL)], often signifies a substantial reduction in GFR in most individuals.

Measurement of albuminuria is also helpful for monitoring nephron injury and the response to therapy in many forms of CKD, especially chronic glomerular diseases. While an accurate 24-h urine collection is the "gold standard" for measurement of albuminuria, the measurement of albumin-to-creatinine ratio in a spot first-morning urine sample is often more practical to obtain and correlates well, but not perfectly, with 24-h urine collections. Persistence in the urine of >17 mg of albumin per gram of creatinine in adult males and 25 mg albumin per gram of creatinine in adult females usually signifies chronic renal damage. *Microalbuminuria* refers to the excretion of amounts of albumin too small to detect by urinary dipstick or conventional measures of urine protein. It is a good screening test for early detection of renal disease, in particular, and may be a marker for the presence of microvascular disease in general. If a patient has a large amount of excreted albumin, there is no reason to perform an assay for microalbuminuria.

Stages 1 and 2 CKD are usually not associated with any symptoms arising from the decrement in GFR. However, there may be symptoms from the underlying renal disease itself, such as edema in patients with nephrotic syndrome or signs of hypertension secondary to the renal parenchymal disease in patients with polycystic kidney disease, some forms of glomerulonephritis, and many other parenchymal and vascular renal diseases, even with well-preserved GFR. If the decline in GFR progresses to stages 3 and 4, clinical and laboratory complications of CKD become more prominent. Virtually all organ systems are affected, but the most evident complications include anemia and associated easy fatigability; decreasing appetite with progressive malnutrition, abnormalities in calcium, phosphorus, and mineral-regulating hormones, such as $1,25(OH)_2D_3$ (calcitriol) and parathyroid hormone (PTH); and abnormalities in sodium, potassium, water, and acid-base homeostasis. If the patient progresses to stage 5 CKD, toxins accumulate such that patients usually experience a marked disturbance in their activities of daily living, well-being, nutritional status, and water and electrolyte homeostasis, eventuating in the *uremic syndrome*. As discussed above, this state will culminate in death unless renal replacement therapy (dialysis or transplantation) is instituted.

ETIOLOGY AND EPIDEMIOLOGY

It has been estimated from population survey data that at least 6% of the adult population in the United States has chronic kidney disease at stages 1 and 2. An unknown subset of this group will progress to more advanced stages of CKD. An additional 4.5% of the U.S. population is estimated to have stages 3 and 4 CKD. The most frequent cause of CKD is diabetic nephropathy, most often secondary to type 2 diabetes mellitus. Hypertensive nephropathy is a common cause of CKD in the elderly, in whom chronic renal ischemia as a result of small and large vessel renovascular disease may be underrecognized. Progressive nephrosclerosis from vascular disease is the renal correlate of the same processes that lead to coronary heart disease and cerebrovascular disease. The increasing incidence of CKD in the elderly has been ascribed, in part, to decreased mortality from the cardiac and cerebral complications of atherosclerotic vascular disease in these individuals, enabling a greater segment of the population to manifest the renal component of general-

ized vascular disease. Nevertheless, it should be appreciated that overwhelmingly the vast majority of those with early stages of renal disease, especially of vascular origin, will succumb to the cardiovascular and cerebrovascular consequences of the vascular disease before they can progress to the most advanced stages of CKD. The early stage of CKD, manifesting as albuminuria and even a minor decrement in GFR, is now recognized as a major risk factor for cardiovascular disease.

The striking interindividual variability in the rate of progression to CKD has an important heritable component, and a number of genetic loci that contribute to the progression of CKD have been identified. Similarly, it has been noted that women of reproductive age are relatively protected against progression of many renal diseases, and sex-specific responses to angiotensin II and its blockade have been identified.

TABLE 274-3 CLINICAL ABNORMALITIES IN UREMIA[a]

Fluid and electrolyte disturbances
Volume expansion (I)
Hyponatremia (I)
Hyperkalemia (I)
Hyperphosphatemia (I)

Endocrine-metabolic disturbances
Secondary hyperparathyroidism (I or P)
Adynamic bone (D)
Vitamin D–deficient osteomalacia (I)
Carbohydrate resistance (I)
Hyperuricemia (I or P)
Hypertriglyceridemia (I or P)
Increased Lp(a) level (P)
Decreased high-density lipoprotein level (P)
Protein-energy malnutrition (I or P)
Impaired growth and development (P)
Infertility and sexual dysfunction (P)
Amenorrhea (I/P)
β_2-Microglobulin associated amyloidosis (P or D)

Neuromuscular disturbances
Fatigue (I)[b]
Sleep disorders (P)
Headache (P)
Impaired mentation (I)[b]
Lethargy (I)[b]
Asterixis (I)
Muscular irritability
Peripheral neuropathy (I or P)
Restless legs syndrome (I or P)
Myoclonus (I)
Seizures (I or P)
Coma (I)
Muscle cramps (P or D)
Dialysis disequilibrium syndrome (D)
Myopathy (P or D)

Cardiovascular and pulmonary disturbances
Arterial hypertension (I or P)
Congestive heart failure or pulmonary edema (I)
Pericarditis (I)
Hypertrophic or dilated cardiomyopathy (I, P, or D)
Uremic lung (I)
Accelerated atherosclerosis (P or D)

Hyperpigmentation (I, P, or D)
Pruritus (P)
Ecchymoses (I)
Nephrogenic fibrosing dermopathy (D)
Uremic frost (I)

Gastrointestinal disturbances
Anorexia (I)
Nausea and vomiting (I)
Gastroenteritis (I)
Peptic ulcer (I or P)
Gastrointestinal bleeding (I, P, or D)
Idiopathic ascites (D)
Peritonitis (D)

Hematologic and immunologic disturbances
Anemia (I)[b]
Lymphocytopenia (P)
Bleeding diathesis (I or D)[b]
Increased susceptibility to infection (I or P)
Leukopenia (D)
Thrombocytopenia (D)

[a]Virtually all abnormalities in this table are completely reversed in time by successful renal transplantation. The response of these abnormalities to hemodialysis or peritoneal dialysis therapy is more variable. (I) denotes an abnormality that usually improves with an optimal program of dialysis and related therapy; (P) denotes an abnormality that tends to persist or even progress, despite an optimal program; (D) denotes an abnormality that develops only after initiation of dialysis therapy.
[b]Improves with dialysis and erythropoietin therapy.
Note: Lp(a), lipoprotein A.

PATHOPHYSIOLOGY AND BIOCHEMISTRY OF UREMIA

Although serum urea and creatinine concentrations are used to measure the excretory capacity of the kidneys, accumulation of these two molecules themselves do not account for the many symptoms and signs that characterize the uremic syndrome in advanced renal failure. Hundreds of toxins that accumulate in renal failure have been implicated in the uremic syndrome. These include water-soluble, hydrophobic, protein-bound, charged, and uncharged compounds. Additional categories of nitrogenous excretory products include guanido compounds, urates and hippurates, products of nucleic acid metabolism, polyamines, myoinositol, phenols, benzoates, and indoles. Compounds with a molecular mass between 500 and 1500 Da, the so-called middle molecules, are also retained and contribute to morbidity and mortality. It is thus evident that the plasma concentrations of urea and creatinine should be viewed as being readily measured, but incomplete, surrogate markers for these compounds, and monitoring the levels of urea and creatinine in the patient with impaired kidney function represents a vast oversimplification of the uremic state.

The uremic syndrome and the disease state associated with advanced renal impairment involve more than renal excretory failure. A host of metabolic and endocrine functions normally undertaken by the kidneys are also impaired, and this results in anemia, malnutrition, and abnormal metabolism of carbohydrates, fats, and proteins. Furthermore, plasma levels of many hormones, including PTH, insulin, glucagon, sex hormones, and prolactin, change with renal failure as a result of urinary retention, decreased degradation, or abnormal regulation. Finally, progressive renal impairment is associated with worsening systemic inflammation. Elevated levels of C-reactive protein are detected along with other acute-phase reactants, while levels of so-called negative acute-phase reactants, such as albumin and fetuin, decline with progressive renal impairment. Thus, renal impairment is important in the malnutrition-inflammation-atherosclerosis/calcification syndrome, which contributes in turn to the acceleration of vascular disease and comorbidity associated with advanced renal disease.

In summary, the pathophysiology of the uremic syndrome can be divided into manifestations in three spheres of dysfunction: (1) those consequent to the accumulation of toxins normally undergoing renal excretion, including products of protein metabolism; (2) those consequent to the loss of other renal functions, such as fluid and electrolyte homeostasis and hormone regulation; and (3) progressive systemic inflammation and its vascular and nutritional consequences.

CLINICAL AND LABORATORY MANIFESTATIONS OF CHRONIC KIDNEY DISEASE AND UREMIA

Uremia leads to disturbances in the function of virtually every organ system. Chronic dialysis can reduce the incidence and severity of many of these disturbances, so that the overt and florid manifestations of uremia have largely disappeared in the modern health setting. However, as indicated in Table 274-3, even optimal dialysis therapy is not completely effective as renal replacement therapy, because some disturbances resulting from impaired renal function fail to respond to dialysis.

FLUID, ELECTROLYTE AND ACID-BASE DISORDERS

Sodium and Water Homeostasis In most patients with stable CKD, the total-body content of sodium and water is modestly increased, although this may not be apparent on clinical examination. Normal renal function guarantees that the tubular reabsorption of filtered sodium and water is adjusted so that urinary excretion matches net intake. Many forms of renal disease (e.g., glomerulonephritis) disrupt this glomerulotubular balance such that dietary intake of sodium exceeds its urinary excretion, leading to sodium retention and attendant extracellular fluid volume (ECFV) expansion. This expansion may contribute to hypertension, which itself can accelerate the nephron injury. As long as water intake does not exceed the capacity for water clearance, the ECFV expansion will be isotonic and the patient will have a normal plasma sodium concentration and effective osmolality (Chap. 272). Hyponatremia is not commonly seen in CKD patients but, when present, can respond to water restriction. If the patient has evidence of ECFV expansion (peripheral edema, sometimes hyperten-

sion poorly responsive to therapy) he or she should be counseled regarding salt restriction. Thiazide diuretics have limited utility in stages 3–5 CKD, such that administration of loop diuretics, including furosemide, bumetanide, or torsemide, may also be needed. Resistance to loop diuretics in renal failure often mandates use of higher doses than those used in patients with near-normal kidney function. The combination of loop diuretics with metolazone, which inhibits the sodium-chloride co-transporter of the distal convoluted tubule, can help effect renal salt excretion. Ongoing diuretic resistance with intractable edema and hypertension in advanced CKD may serve as an indication to initiate dialysis.

In addition to problems with salt and water excretion, some patients with CKD may also have impaired renal conservation of sodium and water. When an extrarenal cause for fluid loss, such as gastrointestinal (GI) loss, is present, these patients may be prone to ECFV depletion because of the inability of the failing kidney to reclaim filtered sodium adequately. Furthermore, depletion of ECFV, whether due to GI losses or over-zealous diuretic therapy, can further compromise kidney function on a "pre-renal" basis, lead to acute-on-chronic kidney failure and result in overt uremia. In this setting, cautious volume repletion with normal saline may return the ECFV to normal and restore renal function to baseline without having to intervene with dialysis.

Potassium Homeostasis In CKD, the decline in GFR is not necessarily accompanied by a parallel decline in urinary potassium excretion, which is predominantly mediated by aldosterone-dependent secretory events in the distal nephron segments. Another defense against potassium retention in these patients is augmented potassium excretion in the GI tract. Notwithstanding these two homeostatic responses, hyperkalemia may be precipitated in certain settings. These include increased dietary potassium intake, protein catabolism, hemolysis, hemorrhage, transfusion of stored red blood cells, and metabolic acidosis. In addition, a host of medications can inhibit potassium entry into cells and renal potassium excretion. The most important medications in this respect include the angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and spironolactone and other potassium-sparing diuretics such as amiloride, eplerenone, and triamterene.

Certain causes of CKD can be associated with earlier and more severe disruption of potassium-secretory mechanisms in the distal nephron, out of proportion to the decline in GFR. These include conditions associated with hyporeninemic hypoaldosteronism, such as diabetes, and renal diseases that preferentially affect the distal nephron, such as obstructive uropathy and sickle cell nephropathy.

Hypokalemia is not common in CKD and usually reflects markedly reduced dietary potassium intake, especially in association with excessive diuretic therapy or concurrent GI losses. Hypokalemia can also occur as a result of primary renal potassium wasting in association with other solute transport abnormalities, such as Fanconi's syndrome, renal tubular acidosis, or other forms of hereditary or acquired tubulointerstitial disease. However, even with these conditions, as the GFR declines, the tendency to hypokalemia diminishes and hyperkalemia may supervene. Therefore, the use of potassium supplements and potassium-sparing diuretics should be constantly reevaluated as GFR declines.

Metabolic Acidosis Metabolic acidosis is a common disturbance in advanced CKD. The majority of patients can still acidify the urine, but they produce less ammonia and, therefore, cannot excrete the normal quantity of protons in combination with this urinary buffer. Hyperkalemia, if present, further depresses ammonia production. The combination of hyperkalemia and hyperchloremic metabolic acidosis (known as type IV renal tubular acidosis, or hyporeninemic hypoaldosteronism) is often seen in patients with diabetic nephropathy or in those with predominant tubulointerstitial disease or obstructive uropathy; this is a non-anion-gap metabolic acidosis. Treatment of hyperkalemia may increase renal ammonia production, improve renal generation of bicarbonate, and improve the metabolic acidosis.

With worsening renal function, the total urinary net daily acid excretion is usually limited to 30–40 mmol, and the anions of retained organic acids can then lead to an anion-gap metabolic acidosis. Thus, the non-anion-gap metabolic acidosis that can be seen in earlier stages of CKD may be complicated by the addition of an anion-gap metabolic acidosis as CKD progresses. In most patients, the metabolic acidosis is mild; the pH is rarely <7.35 and can usually be corrected with oral sodium bicarbonate supplementation. Animal and human studies have suggested that even modest degrees of metabolic acidosis may be associated with the development of net protein catabolism, and it has been suggested that alkali supplementation be considered when the serum bicarbonate concentration falls below 20–23 mmol/L. The concomitant sodium load mandates careful attention to volume status and the potential need for diuretic agents.

Rx FLUID, ELECTROLYTE, AND ACID-BASE DISORDERS

Adjustments in the dietary intake of salt and use of loop diuretics, occasionally in combination with metolazone, may be needed to maintain euvolemia. In contrast, overzealous salt restriction or diuretic use can lead to ECFV depletion and precipitate a further decline in GFR. The rare patient with salt-losing nephropathy may require a sodium-rich diet or salt supplementation. Water restriction is indicated only if there is a problem with hyponatremia. Otherwise, patients with CKD and an intact thirst mechanism may be instructed to drink fluids in a quantity that keeps them just ahead of their thirst. Intractable ECFV expansion, despite dietary salt restriction and diuretic therapy, may be an indication to start renal replacement therapy. Hyperkalemia often responds to dietary restriction of potassium, avoidance of potassium supplements (including occult sources, such as dietary salt substitutes) or potassium-retaining medications (especially ACE inhibitors or ARBs), or the use of kaliuretic diuretics. Potassium-binding resins, such as calcium resonium or sodium polystyrene, can promote potassium loss through the GI tract and may reduce the incidence of hyperkalemia in CKD patients. Intractable hyperkalemia is an indication (although uncommon) to consider institution of dialysis in a CKD patient. The renal tubular acidosis and subsequent anion-gap metabolic acidosis in progressive CKD will respond to alkali supplementation, typically with sodium bicarbonate. Recent studies suggest that this replacement should be considered when the serum bicarbonate concentration falls to 20 mmol/L to avoid the protein catabolic state seen with even mild degrees of metabolic acidosis.

DISORDERS OF CALCIUM AND PHOSPHATE METABOLISM

The principal complications of abnormalities of calcium and phosphate metabolism in CKD occur in the skeleton and the vascular bed, with occasional severe involvement of extraosseous soft tissues. It is likely that disorders of bone turnover and disorders of vascular and soft tissue calcification are related to each other (Fig. 274-1).

Bone Manifestations of CKD The major disorders of bone disease can be classified into those associated with high bone turnover with increased PTH levels (including osteitis fibrosa cystica, the classic lesion of secondary hyperparathyroidism) and low bone turnover with low or normal PTH levels (adynamic bone disease and osteomalacia).

The pathophysiology of secondary hyperparathyroidism and the consequent high-turnover bone disease is related to abnormal mineral metabolism through the following events: (1) declining GFR leads to reduced excretion of phosphate, and, thus phosphate retention; (2) the retained phosphate stimulates increased synthesis of PTH and growth of parathyroid gland mass; and (3) decreased levels of ionized calcium, resulting from diminished calcitriol production by the failing kidney as well as phosphate retention, also stimulate PTH production. Low calcitriol levels contribute to hyperparathyroidism, both by leading to hypocalcemia and also by a direct effect on PTH gene transcription.

In addition to increased production of PTH from the parathyroid cells, the mass of the parathyroid glands increases progressively with CKD. The cell mass may assume one of the following growth patterns: (1) diffuse hyperplasia (polyclonal), (2) nodular growth (monoclonal) within diffuse hyperplasia, or (3) diffuse monoclonal hyperplasia ("ade-

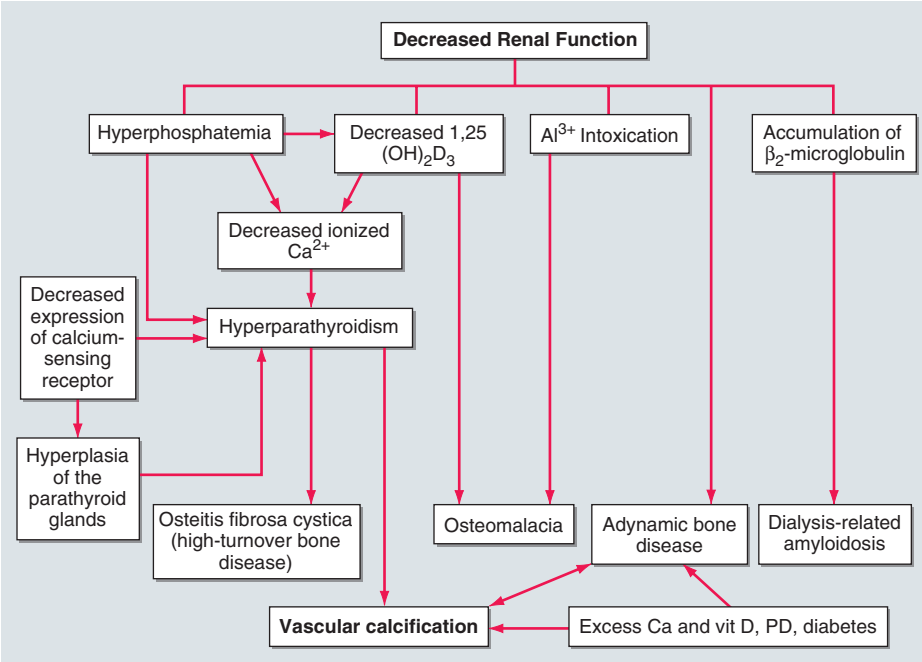

FIGURE 274-1 Flowchart for the development of bone, phosphate, and calcium abnormalities in chronic renal disease. PD, peritoneal dialysis.

noma" or tertiary autonomous hyperparathyroidism). Patients with the monoclonal ("autonomous") hyperplasia are especially prone to develop resistant hypercalcemia and may require surgical parathyroidectomy.

The hyperparathyroidism stimulates bone turnover and leads to osteitis fibrosa cystica. Bone histology shows abnormal osteoid, bone and bone marrow fibrosis, and formation of bone cysts, sometimes with hemorrhagic elements so that they appear brown in color, hence the term *brown tumor*. Clinical manifestations of severe hyperparathyroidism include bone pain and fragility, the brown tumors, rare compression syndromes caused by brown tumors, and erythropoietin resistance in part related to the bone marrow fibrosis. Furthermore, PTH is a uremic toxin, and high levels are associated with muscle weakness, fibrosis of cardiac muscle, and nonspecific constitutional symptoms.

Low-turnover bone disease can be grouped into two categories—adynamic bone disease and osteomalacia. In the latter condition, there is accumulation of unmineralized bone matrix that may be caused by vitamin D deficiency, excess aluminum deposition, or even metabolic acidosis. Adynamic bone disease is increasing in prevalence, especially among diabetics and the elderly. It is characterized by reduced bone volume and mineralization and may result from excessive suppression of PTH production. The latter can result from the use of vitamin D preparations or from excessive calcium exposure in the form of calcium-containing phosphate binders or high-calcium dialysis solutions. Complications of adynamic bone disease include an increased incidence of fracture and an association with increased vascular and cardiac calcification.

Calcium, Phosphorus, and the Cardiovascular System Recent epidemiologic evidence has shown a strong association between hyperphosphatemia and increased cardiovascular mortality in patients with stage 5 CKD and even in patients with earlier stages of CKD. Hyperphosphatemia and hypercalcemia are associated with increased vascular calcification, but it is unclear whether the excessive mortality is mediated by this mechanism. Studies using CT and electron-beam CT scanning show that CKD patients have calcification of coronary arteries and even heart valves that appear to be orders of magnitude greater than that in patients without renal disease. The magnitude of the calcification is proportional to age and hyperphosphatemia and is also associated with low PTH levels and low bone turnover. It is possible that in patients with advanced kidney disease, ingested calcium intake cannot be deposited in bones with low turnover and, therefore is deposited at extraosseous sites, such as the vascular bed and soft tissues. It is interesting in this regard that there is also an association between osteoporosis and vascular calcification in the general population. Finally, there is recent evidence indicating that hyperphosphatemia can induce a change in gene expression in vascular cells to an osteoblast-like profile.

Other Complications of Abnormal Mineral Metabolism Calciphylaxis is a devastating condition seen almost exclusively in patients with advanced CKD. It is heralded by livedo reticularis and advances to patches of ischemic necrosis, especially on the legs, thighs, abdomen, and breasts (Fig. 274-2). Pathologically, there is evidence of vascular occlusion in association with extensive vascular calcification. It appears that this condition is increasing in incidence. Originally it was ascribed to severe abnormalities in calcium and phosphorus control in dialysis patients, usually associated with advanced hyperparathyroidism. However, more recently, calciphylaxis has been seen with increasing frequency in the absence of severe hyperparathyroidism. Other etiologies have been suggested, including the increased use of oral calcium as a phosphate binder. Warfarin is commonly used in hemodialysis patients, and one of the effects of warfarin therapy is to decrease the vitamin K–dependent regeneration of matrix GLA protein. This latter protein is important in preventing vascular calcification. Thus, warfarin treatment is considered a risk factor for calciphylaxis, and if a patient develops this syndrome, this medication should be discontinued and replaced with alternative forms of anticoagulation.

DISORDERS OF CALCIUM AND PHOSPHATE METABOLISM

The optimal management of secondary hyperparathyroidism and osteitis fibrosa is prevention. Once the parathyroid gland mass is very large, it is difficult to control the disease. Careful attention should be paid to the plasma phosphate concentration in CKD patients, who should be counseled on a

FIGURE 274-2 Calciphylaxis. This peritoneal dialysis patient was on chronic warfarin therapy for prophylactic anticoagulation for a mechanical heart valve. She slept with the dialysis catheter pressed between her legs. A small abrasion was followed by progressive skin necrosis along the catheter tract on her inner thighs. Despite treatment with hyperbaric oxygen, intravenous thiosulfate, and discontinuation of warfarin, she succumbed to systemic complications of the necrotic process.

low-phosphate diet as well as the appropriate use of phosphate-binding agents. These are agents that are taken with meals and complex the dietary phosphate to limit its GI absorption. Examples of phosphate binders are calcium acetate and calcium carbonate. A major side effect of calcium-based phosphate binders is total-body calcium accumulation and hypercalcemia, especially in patients with low-turnover bone disease. Sevelamer, a non-calcium-containing polymer, also functions as a phosphate binder; it does not predispose CKD patients to hypercalcemia, and may attenuate calcium deposition in the vascular bed.

Calcitriol exerts a direct suppressive effect on PTH secretion and also indirectly suppresses PTH secretion by raising the concentration of ionized calcium. However, calcitriol therapy may result in hypercalcemia and/or hyperphosphatemia through increased GI absorption of these minerals. Certain analogues of calcitriol are available (e.g., paricalcitol) that suppress PTH secretion with less attendant hypercalcemia.

Recognition of the role of the extracellular calcium-sensing receptor has led to the development of calcimimetic agents that enhance the sensitivity of the parathyroid cell to the suppressive effect of calcium. This class of drug produces a dose-dependent reduction in PTH and plasma calcium concentration in some patients.

Current KDOQI recommendations call for a target PTH level between 150 and 300 pg/mL, recognizing that very low PTH levels are associated with adynamic bone disease and possible consequences of fracture and ectopic calcification.

CARDIOVASCULAR ABNORMALITIES

Cardiovascular disease is the leading cause of morbidity and mortality in patients at every stage of CKD. The incremental risk of cardiovascular disease in those with CKD compared to the age- and sex-matched general population ranges from 10- to 200-fold, depending on the stage of CKD (Fig. 274-3). Between 30 and 45% of patients reaching stage 5 CKD already have advanced cardiovascular complications. As a result, most patients with CKD succumb to cardiovascular disease (Fig. 274-4) before ever reaching stage 5 CKD. Thus, the focus of patient care in earlier CKD stages should be directed to prevention of cardiovascular complications.

Ischemic Vascular Disease The presence of any stage of CKD is a major risk factor for ischemic cardiovascular disease, including occlusive coronary, cerebrovascular, and peripheral vascular disease. The increased prevalence of vascular disease in CKD patients derives from both traditional ("classic") and nontraditional (CKD-related) risk factors. Traditional risk factors include hypertension, hypervolemia, dyslipidemia, sympathetic overactivity, and hyperhomocysteinemia. The CKD-related risk factors comprise anemia, hyperphosphatemia, hyperparathyroidism, sleep apnea, and generalized inflammation. The inflammatory state associated with a reduction in kidney function is reflected in increased circulating acute-phase reactants, such as inflammatory cytokines and C-reactive protein, with a corresponding fall in the "negative acute-phase reactants," such as serum albumin and fetuin. The inflammatory state appears to accelerate vascular occlusive disease, and low levels of fetuin may permit more rapid vascular calcification, especially in the face of hyperphosphatemia. Other abnormalities seen in CKD may augment myocardial ischemia, including left ventricular hypertrophy and microvascular disease. Coronary reserve, defined as the increase in coronary blood flow in response to greater demand, is also attenuated. There is diminished availability of nitric oxide because of increased concentration of asymmetric dimethyl-1-arginine and increased scavenging by reactive oxygen species. In addition, hemodialysis, with its attendant episodes of hypotension and hypovolemia, may further aggravate coronary ischemia.

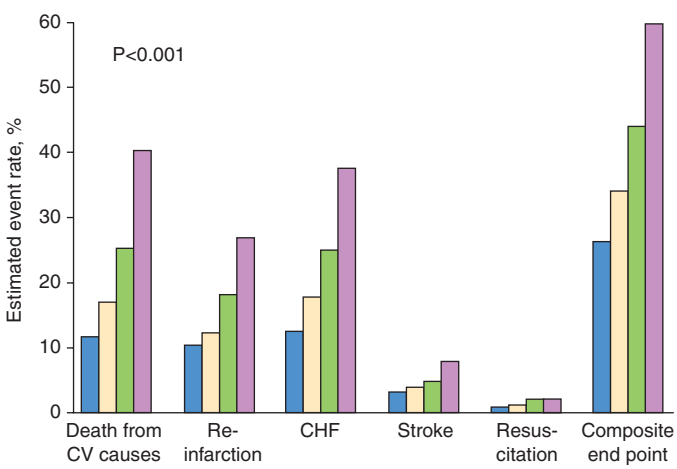

FIGURE 274-3 An analysis of the correlation between the decline in kidney function, as estimated by glomerular filtration rate (GFR), and the increasing incidence of cardiovascular (CV) complications and death from CV disease. Studies such as these suggest that a GFR that is less than normal should be considered a risk factor for CV events and mortality. CHF, congestive heart failure. Volume of GFR in mL/min per 1.73 m^2: [1], ≥75.0; [2], 60.0–74.9; [3], 45.0–59.9; [4], < 45. *(From NS Anavekar et al: N Engl J Med 351:1285, 2004.)*

DM; diabetes mellitus. (*Adapted from Collins, Adv Studies in Med (3c)2003, Medicare Cohort, 1998–1999.*)

Heart Failure Abnormal cardiac function secondary to myocardial ischemia, left ventricular hypertrophy, and frank cardiomyopathy, in combination with the salt and water retention that can be seen with CKD, often results in heart failure or even episodes of pulmonary edema. Heart failure can be a consequence of diastolic or systolic dysfunction, or both. A form of "low-pressure" pulmonary edema can also occur in advanced CKD, manifesting as shortness of breath and a "bat wing" distribution of alveolar edema fluid on the chest x-ray. This finding can occur even in the absence of ECFV overload and is associated with normal or mildly elevated pulmonary capillary wedge pressure. This process has been ascribed to increased permeability of alveolar capillary membranes as a manifestation of the uremic state, and it responds to dialysis. Other CKD-related risk factors, including anemia and sleep apnea, may contribute to the risk of heart failure.

Hypertension and Left Ventricular Hypertrophy Hypertension is one of the most common complications of CKD. It usually develops early during the course of CKD and is associated with adverse outcomes, including the development of ventricular hypertrophy and a more rapid loss of renal function. Many studies have shown a relationship between the level of blood pressure and the rate of progression of diabetic and non-diabetic kidney disease. Left ventricular hypertrophy and dilated cardiomyopathy are among the strongest risk factors for cardiovascular morbidity and mortality in patients with CKD and are thought to be related primarily, but not exclusively, to prolonged hypertension and ECFV overload. In addition, anemia and the placement of an arteriovenous fistula for hemodialysis can generate a high cardiac output state and consequent heart failure.

The absence of hypertension may signify the presence of a salt-wasting form of renal disease, the effect of antihypertensive therapy, or volume depletion or may signify poor left ventricular function. Indeed, in epidemiologic studies of dialysis patients, low blood pressure actually carries a worse prognosis than does high blood pressure. This mechanism, in part, accounts for the "reverse causation" seen in dialysis patients, wherein the presence of traditional risk factors, such as hypertension, hyperlipidemia, and obesity, appear to portend a better prognosis. Importantly, these observations derive from cross-sectional studies of late-stage CKD patients and should not be interpreted to discourage appropriate management of these risk factors in CKD patients, especially at early stages. In contrast to the general population, it is possible that in late-stage CKD, low blood pressure, reduced body mass index, and hypolipidemia indicate the presence of a malnutrition-inflammation state, with poor prognosis.

The use of exogenous erythropoietic products can increase blood pressure and the requirement for antihypertensive drugs. Chronic ECFV overload is also a contributor to hypertension, and improvement in blood pressure can often be seen with the use of oral sodium restriction, diuretics, and fluid removal with dialysis. Nevertheless, because of activation of the renin-angiotensin-aldosterone axis and other disturbances in the balance of vasoconstrictors and vasodilators, some patients remain hypertensive despite careful attention to ECFV status.

Rx CARDIOVASCULAR ABNORMALITIES

MANAGEMENT OF HYPERTENSION There are two overall goals of therapy for hypertension in these patients: to slow the progression of the kidney disease itself, and to prevent the extrarenal complications of high blood pressure, such as cardiovascular disease and stroke. In all patients with CKD, blood pressure should be controlled to levels recommended by national guideline panels. In CKD patients with diabetes or proteinuria > 1 g per 24 h, blood pressure should be reduced to 125/75, if achievable without prohibitive adverse effects. Salt restriction and diuretics should be the first line of therapy. When volume management alone is not sufficient, the choice of antihypertensive agent is similar to that in the general population. The ACE inhibitors and ARBs slow the rate of decline of kidney function, even in dialysis patients, but their use may be complicated by the development of hyperkalemia. Often the concomitant use of a kaliuretic diuretic, such as metolazone, can improve potassium excretion in addition to improving blood pressure control. Potassium-sparing diuretics should be used with caution or avoided altogether in most patients.

MANAGEMENT OF CARDIOVASCULAR DISEASE There are many strategies available to treat the traditional and nontraditional risk factors in CKD patients. While these have been proven effective in the general population, there is little evidence for their benefit in patients with advanced CKD, especially those on dialysis. Certainly hypertension, elevated serum levels of homocysteine, and dyslipidemia promote atherosclerotic disease and are treatable complications of CKD. Renal disease complicated by nephrotic syndrome is associated with a very atherogenic lipid profile and hypercoagulability, which increases the risk of occlusive vascular disease. Since diabetes mellitus and hypertension are the two most frequent causes of advanced CKD, it is not surprising that cardiovascular disease is the most frequent cause of death in dialysis patients. The role of "inflammation" may be quantitatively more important in patients with kidney disease, and the treatment of more traditional risk factors may result in only modest success. However, modulation of traditional risk factors may be the only weapon in the therapeutic armamentarium for these patients until the nature of inflammation in CKD and its treatment are better understood.

Lifestyle changes, including regular exercise, should be advocated but are not often implemented. Hyperhomocysteinemia may respond to vitamin therapy, including oral folate supplementation, but this therapy is of unproven benefit. Hyperlipidemia in patients with CKD should be managed according to national guidelines. If dietary measures are not sufficient, preferred lipid-lowering medications, such as statins, should be used. Again, the use of these agents has not been of proven benefit for patients with advanced CKD.

Pericardial Disease Pericardial pain with respiratory accentuation, accompanied by a friction rub, is diagnostic of uremic pericarditis. Classic electrocardiographic abnormalities include PR-interval depression and diffuse ST-segment elevation. Pericarditis can be accompanied by pericardial effusion that is seen on echocardiography and can rarely lead to tamponade. However, the pericardial effusion can be asymptomatic, and pericarditis can be seen without significant effusion.

Pericarditis is observed in advanced uremia, and with the advent of timely initiation of dialysis, is not as common as it once was. It is now more often observed in underdialyzed, nonadherent patients than in those starting dialysis.

Rx PERICARDIAL DISEASE

Uremic pericarditis is an absolute indication for the urgent initiation of dialysis or for intensification of the dialysis prescription in those already receiving dialysis. Because of the propensity to hemorrhage in pericardial fluid, hemodialysis should be performed without heparin. A pericardial drainage procedure should be considered in patients with recurrent pericardial effusion. Nonuremic causes of pericarditis and effusion include viral, malignant, tuberculous, and autoimmune etiologies. It may also be seen after myocardial infarction and as a complication of treatment with minoxidil.

HEMATOLOGIC ABNORMALITIES

Anemia A normocytic, normochromic anemia is observed as early as stage 3 CKD and is almost universal by stage 4. The primary cause in patients with CKD is insufficient production of erythropoietin (EPO) by the diseased kidneys. Additional factors include iron deficiency, acute and chronic inflammation with impaired iron utilization ("anemia of chronic disease"), severe hyperparathyroidism with consequent bone marrow fibrosis, and shortened red cell survival in the uremic environment. Less common causes include folate and vitamin B_{12} deficiency and aluminum toxicity. In addition, comorbid conditions such as hemoglobinopathy can worsen the anemia (Table 274-4).

The anemia of CKD is associated with a number of adverse pathophysiologic consequences, including decreased tissue xygen delivery and utilization, increased cardiac output, ventricular dilatation, and ventricular hypertrophy. Clinical manifestations include angina, heart failure, decreased cognition and mental acuity, and impaired host defense against infection. In addition, anemia may play a role in growth retardation in children with CKD. While many studies in CKD patients have found that anemia and resistance to exogenous EPO are associated with a poor prognosis, it is unclear as to how much the low hematocrit itself versus inflammation leads to a poor outcome.

Rx ANEMIA

The availability of recombinant human EPO and modified EPO products, such as darbopoetin-alpha, has been one of the most significant advances in the care of renal patients since the introduction of dialysis and renal transplantation. The routine use of these products has obviated the need for regular blood transfusions in severely anemic CKD patients, thus dramatically reducing the incidence of transfusion-associated infections and iron overload. Frequent blood transfusions in dialysis patients also led to the development of alloantibodies that could sensitize the patient to donor kidney antigens and make renal transplantation more problematic.

Adequate bone marrow iron stores should be available before treatment with EPO is initiated. Iron supplementation is ousually essential to

TABLE 274-4 CAUSES OF ANEMIA IN CKD

ensure an adequate response to EPO in patients with CKD because the demand for iron by the marrow frequently exceeds the amount of iron that is immediately available for erythropoiesis (measured by percent transferrin saturation), as well as the amount in iron stores (measured by serum ferritin). For the CKD patient not yet on dialysis or the patient treated with peritoneal dialysis, oral iron supplementation should be attempted. If there is GI intolerance, the patient may have to undergo IV iron infusion, often during the dialysis session. In addition to iron, an adequate supply of other major substrates and cofactors for red cell production must be assured, including vitamin B_{12} and folate. Anemia resistant to recommended doses of EPO in the face of adequate iron stores may be due to some combination of the following: acute or chronic inflammation, inadequate dialysis, severe hyperparathyroidism, chronic blood loss or hemolysis, chronic infection, or malignancy. Patients with a hemoglobinopathy, such as sickle cell disease or thalassemia, will usually not respond normally to exogenous EPO; however, an increase in hemoglobin concentration is still seen in many of these patients. Blood transfusions may contribute to suppression of erythropoiesis in CKD; because they increase the risk of hepatitis, iron overload, and transplant sensitization, they should be avoided unless the anemia fails to respond to EPO and the patient is symptomatic.

Normalization of the hemoglobin concentration has not been demonstrated to be of incremental benefit to dialysis patients. Current practice is to target a hemoglobin concentration of 110 to 120 g/L.

Abnormal Hemostasis Patients with later stages of CKD may have a prolonged bleeding time, decreased activity of platelet factor III, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption. Clinical manifestations include an increased tendency to bleeding and bruising, prolonged bleeding from surgical incisions, menorrhagia, and spontaneous GI bleeding. Interestingly, CKD patients also have a greater susceptibility to thromboembolism, especially if they have renal disease that includes nephrotic-range proteinuria. The latter condition results in hypoalbuminemia and renal loss of anticoagulant factors, which can lead to a thrombophilic state.

℞ ABNORMAL HEMOSTASIS

Abnormal bleeding time and coagulopathy in patients with renal failure may be reversed temporarily with desmopressin (DDAVP), cryoprecipitate, IV conjugated estrogens, blood transfusions, and EPO therapy. Optimal dialysis will often correct a prolonged bleeding time.

Given the coexistence of bleeding disorders and a propensity to thrombosis that is unique in the CKD patient, decisions about anticoagulation that have a favorable risk-benefit profile in the general population may not be applicable to the patient with advanced CKD. One example is warfarin anticoagulation for atrial fibrillation: the decision to anticoagulate should be made on an individual basis in the CKD patient.

Certain anticoagulants, such as fractionated low-molecular-weight heparin, may need to be avoided or dose-adjusted in these patients, with monitoring of factor Xa activity where available. It is often more prudent to use conventional high-molecular-weight heparin, titrated to the measured partial thromboplastin time, in hospitalized patients requiring an alternative to warfarin anticoagulation.

NEUROMUSCULAR ABNORMALITIES

Central nervous system (CNS), peripheral, and autonomic neuropathy as well as abnormalities in muscle structure and function are all well-recognized complications of CKD. Retained nitrogenous metabolites and middle molecules, including PTH, contribute to the pathophysiology of neuromuscular abnormalities. Subtle clinical manifestations of uremic neuromuscular disease usually become evident at stage 3 CKD. Early manifestations of CNS complications include mild disturbances in memory and concentration and sleep disturbance. Neuromuscular irritability, including hiccups, cramps, and fasciculations or twitching of muscles, becomes evident at later stages. In advanced untreated kidney failure, asterixis, myoclonus, seizures, and coma can be seen.

Peripheral neuropathy usually becomes clinically evident after the patient reaches stage 4 CKD, although electrophysiologic and histologic evidence occurs earlier. Initially, sensory nerves are involved more than motor, lower extremities more than upper, and distal parts of the extremities more than proximal. The "restless leg syndrome" is characterized by ill-defined sensations of sometimes debilitating discomfort in the legs and feet relieved by frequent leg movement. If dialysis is not instituted soon after onset of sensory abnormalities, motor involvement follows, including muscle weakness. Evidence of peripheral neuropathy without another cause (e.g., diabetes mellitus) is a firm indication for starting renal replacement therapy. Many of the complications described above will resolve with dialysis, although subtle nonspecific abnormalities may persist. Successful renal transplantation may reverse residual neurologic changes.

GASTROINTESTINAL AND NUTRITIONAL ABNORMALITIES

Uremic fetor, a urine-like odor on the breath, derives from the breakdown of urea to ammonia in saliva and is often associated with an unpleasant metallic taste (dysgeusia). Gastritis, peptic disease, and mucosal ulcerations at any level of the GI tract occur in uremic patients and can lead to abdominal pain, nausea, vomiting, and GI bleeding. These patients are also prone to constipation, which can be worsened by the administration of calcium and iron supplements. The retention of uremic toxins also leads to anorexia, nausea, and vomiting.

Protein restriction may be useful to decrease nausea and vomiting; however, it may put the patient at risk for malnutrition and should be carried out, if possible, in consultation with a registered dietitian. Protein-energy malnutrition, a consequence of low protein and caloric intake, is common in advanced CKD and is often an indication for initiation of renal replacement therapy. In addition to diminished intake, these patients are resistant to the anabolic actions of insulin and other hormones and growth factors. Metabolic acidosis and the activation of inflammatory cytokines can promote protein catabolism. Assessment for protein-energy malnutrition should begin at stage 3 CKD. A number of indices are useful in this assessment and include dietary history, including diary and subjective global assessment; edema-free body weight; serum albumin concentration; and measurement of urinary protein nitrogen appearance. Dual-energy x-ray absorptiometry is now widely used to estimate lean body mass versus ECFV. Adjunctive tools include clinical signs, such as skinfold thickness, mid-arm muscle circumference, and additional laboratory tests such as serum pre-albumin and cholesterol levels. Nutritional guidelines for patients with CKD are summarized in the section below on "Principles of Treatment of CKD."

ENDOCRINE-METABOLIC DISTURBANCES

Glucose metabolism is impaired in CKD, as evidenced by a slowing of the rate at which blood glucose levels decline after a glucose load. However, fasting blood glucose is usually normal or only slightly elevated, and the mild glucose intolerance does not require specific therapy. Because the kidney contributes to insulin removal from the circulation, plasma levels of insulin are slightly to moderately elevated in most uremic patients, both in the fasting and postprandial states. Because of this diminished renal degradation of insulin, patients on insulin therapy may need progressive reduction in dose as their renal function worsens. Many hypoglycemic agents require dose reduction in renal failure, and some, such as metformin, are contraindicated when the GFR is less than half of normal.

In women with CKD, estrogen levels are low, and menstrual abnormalities and inability to carry pregnancies to term are common. When the GFR has declined to ~40 mL/min, pregnancy is associated with a high rate of spontaneous abortion, with only ~20% of pregnancies leading to live births, and pregnancy may hasten the progression of the kidney disease itself. Men with CKD have reduced plasma testosterone levels, and sexual dysfunction and oligospermia may supervene. Sexual maturation may be delayed or impaired in adolescent children with CKD, even among those treated with dialysis. Many of these abnormalities improve or reverse with intensive dialysis or successful renal transplantation.

DERMATOLOGIC ABNORMALITIES

Abnormalities of the skin are prevalent in progressive CKD. Anemic patients may be pale, and those with defective hemostasis may show multiple ecchymoses. Pruritus is quite common. In advanced CKD, even on dialysis, patients may become more pigmented, and this is felt to reflect the deposition of retained pigmented metabolites, or *urochromes*. Although many of the cutaneous abnormalities improve with dialysis, pruritus is often tenacious. The first lines of management are to rule out unrelated skin disorders, such as scabies, and to control phosphate concentration. EPO therapy was initially reported to improve uremic pruritus, although that is not always the case. Local moisturizers, mild topical glucocorticoids, oral antihistamines, and ultraviolet radiation have been reported to be helpful.

A skin condition called *nephrogenic fibrosing dermopathy* has recently been reported in which progressive subcutaneous induration, especially on the arms and legs, is described. The condition is similar to scleromyxedema and is seen in patients with CKD, most commonly on dialysis. Recent reports suggest that exposure to the magnetic resonance contrast agent, gadolinium, may precipitate this syndrome.

EVALUATION AND MANAGEMENT OF PATIENTS WITH CKD

INITIAL APPROACH

History and Physical Examination Symptoms and overt signs of kidney disease are often absent until renal failure supervenes. Thus, the diagnosis of kidney disease often surprises patients and may be a cause of skepticism and denial. Particular aspects of the history that are germane to renal disease include a history of hypertension (which can cause CKD or be a reflection of CKD), diabetes mellitus, abnormal urinalyses, and problems with pregnancy such as preeclampsia or early pregnancy loss. A careful drug history should be elicited: patients may not volunteer use of analgesics, for example. Other drugs to consider include nonsteroidal anti-inflammatory agents, gold, penicillamine, antimicrobials, antiretroviral agents, proton pump inhibitors, and lithium. In evaluating the uremic syndrome, questions about appetite, weight loss, nausea, hiccups, peripheral edema, muscle cramps, pruritus, and restless legs are especially helpful.

The physical examination should focus on blood pressure and target organ damage from hypertension. Thus, funduscopy and precordial examination (left ventricular heave, a fourth heart sound) should be carried out. Funduscopy is important in the diabetic patient, seeking evidence of diabetic retinopathy, which is associated with nephropathy. Other physical examination manifestations of CKD include edema and sensory polyneuropathy. The finding of asterixis or a pericardial friction rub not attributable to other causes usually signifies the presence of the uremic syndrome.

Laboratory Investigation Laboratory studies should focus on a search for clues to an underlying causative or aggravating disease process and on the degree of renal damage and its consequences. If appropriate, tests for systemic lupus erythematosus and vasculitis should be performed. Serum and urine protein electrophoresis should be obtained in all patients >35 years with unexplained CKD, especially if there is associated anemia and elevated, or even inappropriately normal, serum calcium concentration in the face of renal insufficiency. In the presence of glomerulonephritis, underlying infectious etiologies such as hepatitis B and C and HIV should be assessed. Serial measurements of renal function should be obtained to determine the pace of renal deterioration and ensure that the disease is truly chronic rather than subacute and hence potentially reversible. Serum concentrations of calcium, phosphorus, and PTH should be measured to evaluate metabolic bone disease. Hemoglobin concentration, iron, B_{12}, and folate should also be evaluated. A 24-h urine collection may be helpful, as protein excretion > 300 mg may be an indication for therapy with ACE inhibitors or ARBs.

Imaging Studies The most useful imaging study is a renal ultrasound, which can verify the presence of two kidneys, determine if they are symmetric, provide an estimate of kidney size, and rule out renal masses and evidence of obstruction. Since it takes time for kidneys to shrink as a result of chronic disease, the finding of bilaterally small kidneys supports the diagnosis of CKD of long-standing duration, with an irreversible component of scarring. If the kidney size is normal, it is possible that the renal disease is acute or subacute. The exceptions are diabetic nephropathy (where kidney size is increased at the outset of diabetic nephropathy before CKD with loss of GFR supervenes), amyloidosis, and HIV nephropathy, where kidney size may be normal in the face of CKD. Polycystic kidney disease that has reached some degree of renal failure will almost always present with enlarged kidneys with multiple cysts (Chap. 278). A discrepancy >1 cm in kidney length suggests either a unilateral developmental abnormality or disease process or renovascular disease with arterial insufficiency affecting one kidney more than the other. The diagnosis of renovascular disease can be undertaken with different techniques, including Doppler sonography, nuclear medicine studies, or CT or MRI studies. If there is a suspicion of reflux nephropathy (recurrent childhood urinary tract infection, asymmetric renal size with scars on the renal poles), a voiding cystogram may be indicated. However, in most cases by the time the patient has CKD, the reflux has resolved, and even if still present, repair does not improve renal function. Radiographic contrast imaging studies are not particularly helpful in the investigation of CKD. Intravenous or intraarterial dye should be avoided where possible in the CKD patient, especially with diabetic nephropathy, because of the risk of radiographic contrast dye–induced renal failure. When unavoidable, appropriate precautionary measures include avoidance of hypovolemia at the time of contrast exposure, minimization of the dye load, and choice of radiographic contrast preparations with the least nephrotoxic potential.

Renal Biopsy In the patient with bilaterally small kidneys, renal biopsy is not advised because (1) it is technically difficult and has a greater likelihood of causing bleeding and other adverse consequences, (2) there is usually so much scarring that the underlying disease may not be apparent, and (3) the window of opportunity to render disease-specific therapy has passed. Other contraindications to renal biopsy include uncontrolled hypertension, active urinary tract infection, bleeding diathesis, and morbid obesity. Ultrasound-guided percutaneous biopsy is the favored approach, but a surgical or laparoscopic approach can be considered, especially in the patient with a single kidney where direct visualization and control of bleeding are crucial. In the CKD patient in whom a kidney biopsy is indicated (e.g., suspicion of a concomitant or superimposed active process, such as interstitial nephritis or accelerated loss of GFR), the bleeding time should be measured, and, if increased, desmopressin should be administered immediately prior to the procedure. A brief run of hemodialysis (without heparin) may also be considered prior to renal biopsy to normalize the bleeding time.

ESTABLISHING THE DIAGNOSIS AND ETIOLOGY OF CKD

The most important initial diagnostic step in the evaluation of a patient presenting with elevated serum creatinine is to distinguish newly diagnosed CKD from acute or subacute renal failure because the latter two conditions may respond to therapy specific to the disease. Previous measurements of plasma creatinine concentration are particularly helpful in this regard. Normal values from recent months or even years suggest that the current extent of renal dysfunction could be more acute, and hence reversible, than might otherwise be appreciated. In contrast, elevated plasma creatinine concentration in the past suggests that the renal disease represents the progression of a chronic process. Even if there is evidence of chronicity, there is the possibility of a superimposed acute process, such as ECFV depletion, supervening on the chronic condition. If the history suggests multiple systemic manifestations of recent onset (e.g., fever, polyarthritis, and rash) it should be assumed that renal insufficiency is part of the acute process.

Some of the laboratory tests and imaging studies outlined above can be helpful. Evidence of metabolic bone disease with hyperphos-

phatemia, hypocalcemia, and elevated PTH and bone alkaline phosphatase levels suggests chronicity. Normochromic, normocytic anemia suggests that the process has been ongoing for some time. The finding of bilaterally reduced kidney size (<8.5 cm in all but the smallest adults) favors CKD.

While renal biopsy can usually be performed in early CKD (stages 1–3), it is not always indicated. For example, in a patient with a history of type 1 diabetes mellitus for 15–20 years with retinopathy, nephrotic-range proteinuria, and absence of hematuria, the diagnosis of diabetic nephropathy is very likely and biopsy is not necessary. However, if there were some other finding not typical of diabetic nephropathy, such as hematuria or white blood cell casts, some other disease may be present and a biopsy may be indicated. Hypertensive nephrosclerosis and progressive ischemic nephropathy are usually diagnosed clinically by the presence of long-standing hypertension, evidence of ischemic disease elsewhere (e.g., cardiac or peripheral vascular disease), and the finding of only mild (< 3g/d) proteinuria in the absence of urinary blood or red cell casts. It is important to consider progressive ischemic nephropathy because a small subset of these patients may respond to revascularization procedures, although this remains controversial.

In the absence of a clinical diagnosis, renal biopsy may be the only recourse to establish an etiology in early-stage CKD. However, as noted above, once the CKD is advanced and the kidneys are small and scarred, there is little utility and significant risk in attempting to arrive at a specific diagnosis.

℞ CHRONIC KIDNEY DISEASE

Treatments aimed at specific causes of CKD are discussed elsewhere. The optimal timing of therapy is usually well before there has been a measurable decline in GFR and certainly before CKD is established **(Table 274-5)**. It is helpful to sequentially measure and plot the rate of decline of GFR in all patients. Any acceleration in the rate of decline should prompt a search for superimposed acute or subacute processes that may be reversible. These include ECFV depletion, uncontrolled hypertension, urinary tract infection, new obstructive uropathy, exposure to nephrotoxic agents [such as nonsteroidal anti-inflammatory drugs (NSAIDs) or radiographic dye], and reactivation or flare of the original disease, such as lupus or vasculitis.

SLOWING THE PROGRESSION OF CKD There is variation in the rate of decline of GFR among patients with CKD. However, the following interventions should be considered in an effort to stabilize or slow the decline of renal function.

Protein Restriction While protein restriction has been advocated to reduce symptoms associated with uremia, it may also slow the rate of renal decline at earlier stages of renal disease. This concept is based on clinical and experimental evidence that protein-mediated hyperfiltration contributes to ongoing decline in renal function in many different forms of renal disease. A number of studies have shown that protein restriction may be effective in slowing the progression of CKD, especially proteinuric and diabetic renal diseases. However, the Modification of Diet in Renal Disease study was unable to demonstrate a robust benefit in delaying progression to advanced stages of CKD with dietary restriction of protein intake. Nonetheless, restriction of dietary protein intake has been recommended for CKD patients. KDOQI clinical practice guidelines include a daily protein intake of between 0.60 and 0.75 g/kg per day, depending upon patient adherence, comorbid disease, presence of proteinuria, and nutritional status. It is further advised that at least 50% of the protein intake be of high biologic value. As patients approach stage 5 CKD, spontaneous protein intake tends to decrease, and patients may enter a state of protein-energy malnutrition. In these circumstances, a protein intake of up to 0.90 g/kg per day might be recommended, again, with an emphasis on proteins of high biologic value.

Sufficient energy intake is important to prevent protein-calorie malnutrition, and 35 kcal/kg is recommended. Monitoring of parameters of nutritional status must accompany the dietary intervention, using the parameters outlined above in the section on GI and nutritional abnormalities.

TABLE 274-5 CLINICAL ACTION PLAN

Stage	Description	GFR, mL/min per 1.73 m^2	Action[a]
1	Kidney damage with normal or ↑ GFR	≥90	Diagnosis and treatment, treatment of comorbid conditions, slowing progression, CVD risk reduction
2	Kidney damage with mild ↓ GFR	60–89	Estimating progression
3	Moderate ↓ GFR	30–59	Evaluating and treating complications
4	Severe ↓ GFR	15–29	Preparation for kidney replacement therapy
5	Kidney failure	<15 (or dialysis)	Kidney replacement (if uremia present)

[a]Includes actions from preceding stages.
Note: CVD, cardiovascular disease.

Reducing Intraglomerular Hypertension and Proteinuria Increased intraglomerular filtration pressures and glomerular hypertrophy develop as a response to loss of nephron number from different kidney diseases. This response is maladaptive, as it promotes the ongoing decline of kidney function even if the inciting process has been treated or spontaneously resolved. Control of systemic and glomerular hypertension is at least as important as dietary protein restriction in slowing the progression of CKD. Therefore, in addition to reduction of cardiovascular disease risk, antihypertensive therapy in patients with CKD also aims to slow the progression of nephron injury by reducing intraglomerular hypertension. Elevated blood pressure increases proteinuria through its transmission to the glomerulus. Conversely, the renoprotective effect of antihypertensive medications is gauged through the consequent reduction of proteinuria. Thus, the more effective a given treatment is in lowering protein excretion, the greater the subsequent impact on protection from decline in GFR. This observation is the basis for the treatment guideline establishing 125/75 mmHg as the target blood pressure in proteinuric CKD patients.

ACE inhibitors and ARBs inhibit the angiotensin-induced vasoconstriction of the efferent arterioles of the glomerular microcirculation. This inhibition leads to a reduction in both intraglomerular filtration pressure and proteinuria. Several controlled studies have shown that these drugs are effective in slowing the progression of renal failure in patients with both diabetic and nondiabetic renal failure. This slowing in progression of CKD is strongly associated with their proteinuria-lowering effect. In the absence of an anti-proteinuric response with either agent alone, combined treatment with both ACE inhibitors and ARBs can be tried. Adverse effects from these agents include cough and angioedema with ACE inhibitors, anaphylaxis, and hyperkalemia with either class. A progressive increase in plasma creatinine concentration may suggest the presence of renovascular disease within the large or small arteries. Development of these side effects may mandate the use of second-line antihypertensive agents instead of the ACE inhibitors or ARBs. Among the calcium channel blockers, diltiazem and verapamil may exhibit superior antiproteinuric and renoprotective effects compared to the dihydropyridines. At least two different categories of response can be considered: one in which progression is strongly associated with systemic and intraglomerular hypertension and proteinuria (e.g., diabetic nephropathy, glomerular diseases) and in which ACE inhibitors and ARBs are likely to be the first choice; and another in which proteinuria is mild or absent initially (e.g., adult polycystic kidney disease and other tubulointerstitial diseases) and hence the contribution of intraglomerular hypertension less prominent, for which reason other antihypertensive agents can be useful for control of systemic hypertension.

SLOWING PROGRESSION OF DIABETIC RENAL DISEASE (See also Chap. 338) Diabetic nephropathy is now the leading cause of CKD requiring renal replacement therapy in many parts of the world, and its prevalence is increasing disproportionately in the developing world. Furthermore, the prognosis of diabetic patients on dialysis is poor, with survival comparable to many forms of cancer. Accordingly, it is mandatory to develop strategies whose aim is to prevent or slow the progression of diabetic nephropathy in these patients.

Control of Blood Glucose Excellent glycemic control reduces the risk of kidney disease and its progression in both type 1 and type 2 diabetes

mellitus. It is recommended that plasma values for preprandial glucose be kept in the 5.0–7.2 mmol/L (90–130 mg/dL) range and hemoglobin A_{1C} should be < 7%. As the GFR decreases with progressive nephropathy, the use and dose of oral hypoglycemics needs to be reevaluated. For example, chlorpropamide may be associated with prolonged hypoglycemia in patients with decreased renal function; metformin has been reported to cause lactic acidosis in the patient with renal impairment and should be discontinued when the GFR is reduced; and the thiazolidinediones (e.g., rosiglitazone, pioglitazone, and others), may increase renal salt and water absorption and aggravate volume-overloaded states. Finally, as renal function declines, renal degradation of administered insulin will also decline, so that less insulin may be required for glycemic control.

Control of Blood Pressure and Proteinuria Hypertension is found in the majority of type 2 diabetic patients at diagnosis. This finding correlates with the presence of albuminuria and is a strong predictor of cardiovascular events and nephropathy. Microalbuminuria, the finding of albumin in the urine not detectable by the urine dipstick, precedes the decline in GFR and heralds renal and cardiovascular complications. Testing for microalbumin is recommended in all diabetic patients, at least annually. If the patient already has established proteinuria, then testing for microalbumin is not necessary. Antihypertensive treatment reduces albuminuria and diminishes its progression even in normotensive diabetic patients. In addition to treatment of hypertension in general, the use of ACE inhibitors and ARBs in particular is associated with additional renoprotection. These salutary effects are mediated by reducing intraglomerular pressure and inhibition of angiotensin-driven sclerosing pathways, in part through inhibition of TGF-β-mediated pathways.

MANAGING OTHER COMPLICATIONS OF CHRONIC KIDNEY DISEASE **Medication Dose Adjustment** Although the loading dose of most drugs is not affected by CKD because no renal elimination is used in the calculation, the maintenance doses of many drugs will need to be adjusted. For those agents in which > 70% excretion is by a nonrenal route, such as hepatic elimination, dose adjustment may not be needed. Some drugs that should be avoided include metformin, meperidine, and oral hypoglycemics that are eliminated by the kidney. NSAIDs should be avoided because of the risk of further worsening of kidney function. Many antibiotics, antihypertensives, and antiarrhythmics may require a reduction in dosage or change in the dose interval. For a comprehensive, detailed listing of the dose adjustments for most of the commonly used medications, see "Drug Prescribing in Renal Failure" published by the American College of Physicians (see *www.acponline.org*).

Preparation for Renal Replacement Therapy (See also Chap. 276) Temporary relief of symptoms and signs of impending uremia, such as anorexia, nausea, vomiting, lassitude, and pruritus, may sometimes be achieved with protein restriction. However, this carries a significant risk of protein-energy malnutrition, and thus plans for more long-term management should be in place.

The institution of maintenance dialysis and kidney transplantation has extended the lives of hundreds of thousands of patients with CKD worldwide. Clear indications for initiation of renal replacement therapy for patients with CKD include pericarditis, encephalopathy, intractable muscle cramping, anorexia, and nausea not attributable to reversible causes such as peptic ulcer disease, evidence of malnutrition, and fluid and electrolyte abnormalities, principally hyperkalemia, that are refractory to other measures.

Recommendations for the optimal time for initiation of renal replacement therapy have been established by the National Kidney Foundation in their KDOQI Guidelines and are based on recent evidence demonstrating that delaying initiation of renal replacement therapy until patients are malnourished or have severe uremic complications leads to a worse prognosis on dialysis or with transplantation. Because of the interindividual variability in the severity of uremic symptoms and renal function, it is ill-advised to assign an arbitrary urea nitrogen or creatinine level to the need to start dialysis. Moreover, patients may become accustomed to chronic uremia and deny symptoms, only to find that they feel better with dialysis and realize in retrospect how poorly they were feeling before its initiation.

Previous studies suggested that starting dialysis before the onset of severe symptoms and signs of uremia was associated with prolongation of survival. This lead to the concept of "healthy" start and is congruent with the philosophy that it is better to keep patients feeling well all along, rather than allowing them to become ill with uremia before trying to return them to better health with dialysis. Although recent studies have not confirmed a clear association of early-start dialysis with improved patient survival, there is still merit in this approach. On a practical level, advanced preparation may help to avoid problems with the dialysis process itself (e.g., a poorly functioning fistula for hemodialysis or malfunctioning peritoneal dialysis catheter) and thus preempt the morbidity associated with resorting to the insertion of temporary hemodialysis access with its attendant risks of sepsis, bleeding, and thrombosis.

Patient Education Social, psychological, and physical preparation for the transition to renal replacement therapy and the choice of the optimal initial modality are best accomplished with a gradual approach involving a multidisciplinary team. Along with conservative measures discussed in the sections above, it is important to prepare patients with an intensive educational program, explaining the likelihood and timing of initiation of renal replacement therapy and the various forms of therapy available. The more knowledgeable that patients are about hemodialysis (both in-center and home-based), peritoneal dialysis, and kidney transplantation, the easier and more appropriate will be their decisions. Patients who are provided with educational programs are more likely to choose home-based dialysis therapy. This approach is of societal benefit because home-based therapy is less expensive and is associated with improved quality of life. The educational programs should be commenced no later than stage 4 CKD so that the patient has sufficient cognitive function to learn the important concepts.

Exploration of social service support is also important. In those who may perform home dialysis or undergo preemptive renal transplantation, early education of family members for selection and preparation of a home dialysis helper or a related (or unrelated) kidney donor should occur long before the onset of symptomatic renal failure.

Kidney transplantation (Chap. 276) offers the best potential for complete rehabilitation, because dialysis replaces only a small fraction of the kidneys' filtration function and none of the other renal functions, including endocrine and anti-inflammatory effects. Generally, kidney transplantation follows a period of dialysis treatment, although preemptive kidney transplantation (usually from a living donor) can be carried out if it is certain that the renal failure is irreversible.

IMPLICATIONS FOR GLOBAL HEALTH

In distinction to the natural decline and successful eradication of many devastating infectious diseases, there is rapid growth in the prevalence of hypertension and vascular disease in developing countries. Diabetes mellitus is becoming increasingly prevalent in these countries, perhaps due in part to change in dietary habits, diminished physical activity, and weight gain. Therefore, it follows that there will be a proportionate increase in vascular and renal disease. Healthcare agencies must plan for improved screening for early detection, prevention, and treatment plans in these nations and must start considering options for improved availability of renal replacement therapies.

275 Dialysis in the Treatment of Renal Failure

Kathleen D. Liu, Glenn M. Chertow

Dialysis may be required for the treatment of either acute or chronic kidney disease. The use of continuous renal replacement therapies (CRRT) and slow, low-efficiency dialysis (SLED) is specific to the management of acute renal failure and is discussed in Chap. 273. These modalities are performed continuously (CRRT) or over 6–12 hours per session (SLED), in contrast to the 3–4 hours of an intermittent hemodialysis session. **Advantages and disadvantages of CRRT and SLED are discussed in Chap. 273.**

Peritoneal dialysis is rarely used in developed countries for the treatment of acute renal failure because of the increased risk of infection and (as will be discussed in more detail below) less efficient clearance per unit of time. The focus of the majority of this chapter will be on the use of dialysis for end-stage renal disease (ESRD).

With the widespread availability of dialysis, the lives of hundreds of thousands of patients with ESRD have been prolonged. In the United States alone, there are now approximately 450,000 patients with ESRD, the vast majority of whom require dialysis. The incidence rate for ESRD is 330 cases per million population per year. The incidence of ESRD is disproportionately higher in African Americans (approximately 1000 per million population per year) as compared with white Americans (259 per million population per year). In the United States, the leading cause of ESRD is diabetes mellitus, currently accounting for nearly 45% of newly diagnosed cases of ESRD. Over one-quarter (27%) of patients have ESRD that has been attributed to hypertension, although it is unclear whether in these cases hypertension is the cause or a consequence of vascular disease or other unknown causes of kidney failure. Other important causes of ESRD include glomerulonephritis, polycystic kidney disease, and obstructive uropathy.

Globally, mortality rates for patients with ESRD are lowest in Europe and Japan but very high in the developing world because of the limited availability of dialysis. In the United States, the mortality rate of patients on dialysis is approximately 18–20% per year, with a 5-year survival rate of approximately 30–35%. Deaths are due mainly to cardiovascular diseases and infections (approximately 50 and 15% of deaths, respectively). Older age, male sex, nonblack race, diabetes mellitus, malnutrition, and underlying heart disease are important predictors of death.

TREATMENT OPTIONS FOR ESRD PATIENTS

Commonly accepted criteria for initiating patients on maintenance dialysis include the presence of uremic symptoms, the presence of hyperkalemia unresponsive to conservative measures, persistent extracellular volume expansion despite diuretic therapy, acidosis refractory to medical therapy, a bleeding diathesis, and a creatinine clearance or estimated glomerular filtration rate (GFR) below 10 mL/min per 1.73 m^2 (see Chap. 274 for estimating equations). Timely referral to a nephrologist for advanced planning and creation of a dialysis access, education about ESRD treatment options, and management of the complications of advanced chronic kidney disease, including hypertension, anemia, acidosis, and secondary hyperparathyroidism, is advisable.

In ESRD, treatment options include hemodialysis (in center or at home); peritoneal dialysis, as either continuous ambulatory peritoneal dialysis (CAPD) or continuous cyclic peritoneal dialysis (CCPD); or transplantation (Chap. 276). Although there are geographic variations, hemodialysis remains the most common therapeutic modality for ESRD (>90% of patients) in the United States. In contrast to hemodialysis, peritoneal dialysis is continuous, but much less efficient, in terms of solute clearance. While no large-scale clinical trials have been completed comparing outcomes among patients randomized to either hemodialysis or peritoneal dialysis, outcomes associated with both therapies are similar in most reports, and the decision of which modality to select is often based on personal preferences and quality-of-life considerations.

HEMODIALYSIS

Hemodialysis relies on the principles of solute diffusion across a semipermeable membrane. Movement of metabolic waste products takes place down a concentration gradient from the circulation into the dialysate. The rate of diffusive transport increases in response to several factors, including the magnitude of the concentration gradient, the membrane surface area, and the mass transfer coefficient of the membrane. The latter is a function of the porosity and thickness of the membrane, the size of the solute molecule, and the conditions of flow on the two sides of the membrane. According to the laws of diffusion, the larger the molecule, the slower its rate of transfer across the membrane. A small molecule, such as urea (60 Da), undergoes substantial clearance, whereas a larger molecule, such as creatinine (113 Da), is cleared less efficiently. In addition to diffusive clearance, movement of waste products from the circulation into the dialysate may occur as a result of ultrafiltration. Convective clearance occurs because of solvent drag, with solutes being swept along with water across the semipermeable dialysis membrane.

THE DIALYZER

There are three essential components to hemodialysis: the dialyzer, the composition and delivery of the dialysate, and the blood delivery system **(Fig. 275-1)**. The dialyzer consists of a plastic device with the facility to perfuse blood and dialysate compartments at very high flow rates. The surface area of modern dialysis membranes in adult patients is usually in the range of 1.5–2.0 m^2. The hollow-fiber dialyzer is the most common in use in the United States. These dialyzers are composed of bundles of capillary tubes through which blood circulates while dialysate travels on the outside of the fiber bundle.

Recent advances have led to the development of many different types of membrane material. Broadly, there are four categories of dialysis membranes: cellulose, substituted cellulose, cellulosynthetic, and synthetic. Over the past three decades, there has been a gradual switch from cellulose-derived to synthetic membranes, because the latter are more "biocompatible." *Bioincompatibility* is generally defined as the ability of the membrane to activate the complement cascade. Cellulosic membranes are bioincompatible because of the presence of free hydroxyl groups on the membrane surface. In contrast, with the substituted cellulose membranes (e.g., cellulose acetate) or the cellulosynthetic membranes, the hydroxyl groups are chemically bound to either acetate or tertiary amino groups, resulting in limited complement activation. Synthetic membranes, such as polysulfone, polymethylmethacrylate, and polyacrylonitrile membranes, are even more biocompatible because of the absence of these hydroxyl groups. Polysulfone membranes are now used in >60% of the dialysis treatments in the United States.

Reprocessing and reuse of hemodialyzers are often employed for patients on maintenance hemodialysis in the United States. However, as the manufacturing costs for disposable dialyzers have declined, more and more outpatient dialysis facilities are no longer reprocessing dialyzers. In most centers employing reuse, only the dialyzer unit is reprocessed and reused, whereas in the developing world blood lines are also frequently reused. The reprocessing procedure can be either manual or automated. It consists of the sequential rinsing of the blood and dialysate compartments with water, a chemical cleansing step with reverse ultrafiltration from the dialysate to the blood compartment, the testing of the patency of the dialyzer, and, finally, disinfection of the dialyzer. Formaldehyde, peracetic acid–hydrogen peroxide, glutaraldehyde, and bleach have all been used as reprocessing agents.

DIALYSATE

The potassium concentration of dialysate may be varied from 0 to 4 mmol/L depending on the predialysis plasma potassium concentration. The usual dialysate calcium concentration in U.S. hemodialysis centers is

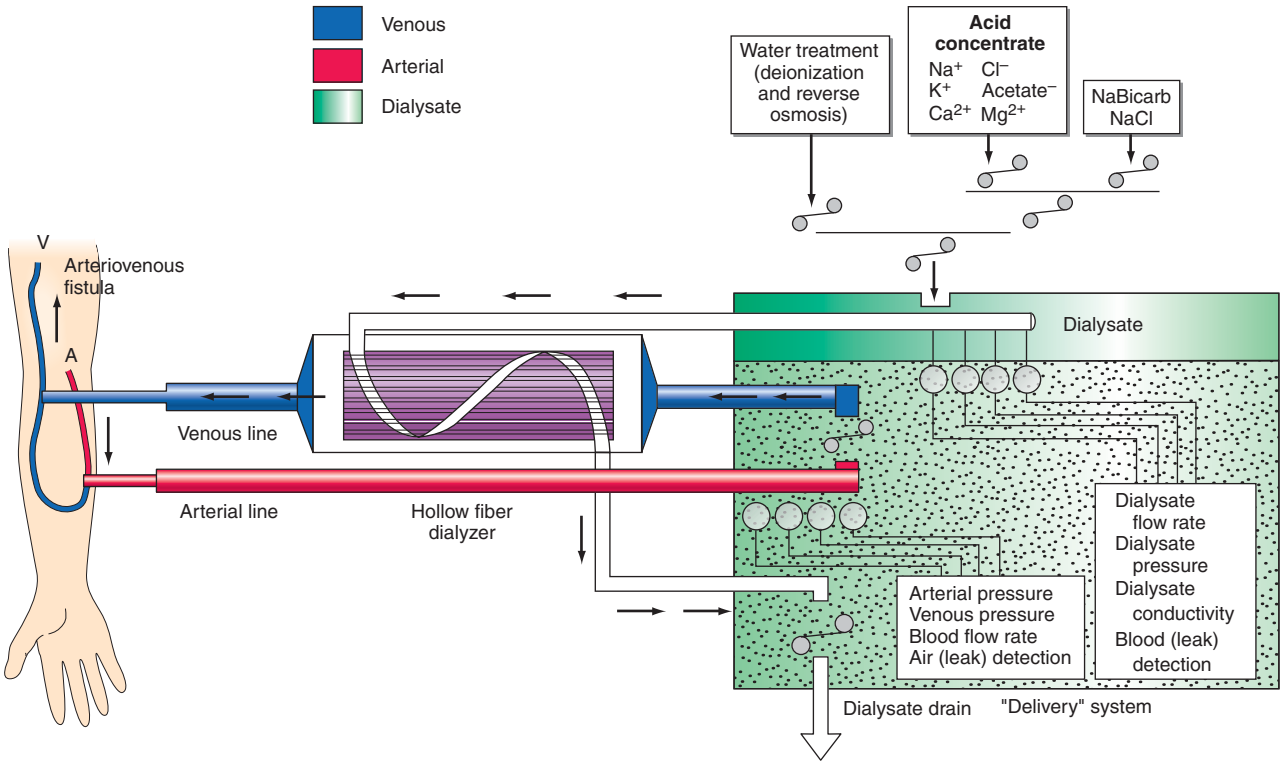

FIGURE 275-1 Schema for hemodialysis.

1.25 mmol/L (2.5 meq/L), although modification may be required in selected settings (e.g., higher dialysate calcium concentrations may be used in patients with hypocalcemia associated with secondary hyperparathyroidism or following parathyroidectomy). The usual dialysate sodium concentration is 140 mmol/L. Lower dialysate sodium concentrations are associated with a higher frequency of hypotension, cramping, nausea, vomiting, fatigue, and dizziness. In patients who frequently develop hypotension during their dialysis run, "sodium modeling" to counterbalance urea-related osmolar gradients is often used. When sodium modeling, the dialysate sodium concentration is gradually lowered from the range of 145–155 meq/L to isotonic concentrations (140 meq/L) near the end of the dialysis treatment, typically declining either in steps or in a linear or exponential fashion. Because patients are exposed to approximately 120 L of water during each dialysis treatment, water used for the dialysate is subjected to filtration, softening, deionization, and, ultimately, reverse osmosis. During the reverse osmosis process, water is forced through a semipermeable membrane at very high pressure to remove microbiologic contaminants and >90% of dissolved ions.

BLOOD DELIVERY SYSTEM

The blood delivery system is composed of the extracorporeal circuit in the dialysis machine and the dialysis access. The dialysis machine consists of a blood pump, dialysis solution delivery system, and various safety monitors. The blood pump moves blood from the access site, through the dialyzer, and back to the patient. The blood flow rate may range from 250–500 mL/min, depending largely on the type and integrity of the vascular access. Negative hydrostatic pressure on the dialysate side can be manipulated to achieve desirable fluid removal or *ultrafiltration*. Dialysis membranes have different ultrafiltration coefficients (i.e., mL removed/min per mmHg) so that along with hydrostatic changes, fluid removal can be varied. The dialysis solution delivery system dilutes the concentrated dialysate with water and monitors the temperature, conductivity, and flow of dialysate.

Dialysis Access The fistula, graft, or catheter through which blood is obtained for hemodialysis is often referred to as a *dialysis access*. A native fistula created by the anastomosis of an artery to a vein (e.g., the Brescia-Cimino fistula, in which the cephalic vein is anastomosed end-to-side to the radial artery) results in arterialization of the vein. This facilitates its subsequent use in the placement of large needles (typically 15 gauge) to access the circulation. Although fistulas have the highest long-term patency rate of all dialysis access options, fistulas are created in a minority of patients in the United States. Many patients undergo placement of an arteriovenous graft (i.e., the interposition of prosthetic material, usually polytetrafluoroethylene, between an artery and a vein) or a tunneled dialysis catheter. In recent years, nephrologists, vascular surgeons, and health care policy makers in the United States have encouraged creation of arteriovenous fistulas in a larger fraction of patients (the "fistula first" initiative). Unfortunately, even when created, arteriovenous fistulas may not mature sufficiently to provide reliable access to the circulation, or they may thrombose early in their development. Novel surgical approaches (e.g., brachiobasilic fistula creation with transposition of the basilic vein fistula to the arm surface) have increased options for "native" vascular access.

Grafts and catheters tend to be used among persons with smaller-caliber veins or persons whose veins have been damaged by repeated venipuncture, or after prolonged hospitalization. The most important complication of arteriovenous grafts is thrombosis of the graft and graft failure, due principally to intimal hyperplasia at the anastomosis between the graft and recipient vein. When grafts (or fistulas) fail, catheter-guided angioplasty can be used to dilate stenoses; monitoring of venous pressures on dialysis and of access flow, though not routinely performed, may assist in the early recognition of impending vascular access failure. In addition to an increased rate of access failure, grafts and (in particular) catheters are associated with much higher rates of infection than fistulas.

Intravenous large-bore catheters are often used in patients with acute and chronic kidney disease. For persons on maintenance hemodialysis, tunneled catheters (either two separate catheters or a single catheter with two lumens) are often used when arteriovenous fistulas and grafts have failed or are not feasible due to anatomical considerations. These catheters are tunneled under the skin; the tunnel reduces bacterial translocation from the skin, resulting in a lower infection rate than with nontunneled temporary catheters. Most tunneled catheters are placed in the internal jugular veins; the external jugular, femoral, and subclavian veins may also be used. Nephrologists, interventional radiologists, and vascular surgeons generally prefer to avoid placement of catheters into the

subclavian veins; while flow rates are usually excellent, subclavian stenosis is a frequent complication and, if present, will likely prohibit permanent vascular access (i.e., a fistula or graft) in the ipsilateral extremity. Infection rates may be higher with femoral catheters. For patients with multiple vascular access complications and no other options for permanent vascular access, tunneled catheters may be the last "lifeline" for hemodialysis. Translumbar or transhepatic approaches into the inferior vena cava may be required if the superior vena cava or other central veins draining the upper extremities are stenosed or thrombosed.

GOALS OF DIALYSIS

The hemodialysis procedure is targeted at removing both low- and high-molecular-weight solutes. The procedure consists of pumping heparinized blood through the dialyzer at a flow rate of 300–500 mL/min, while dialysate flows in an opposite *counter-current* direction at 500–800 mL/min. The efficiency of dialysis is determined by blood and dialysate flow through the dialyzer as well as dialyzer characteristics (i.e., its efficiency in removing solute). The *dose* of dialysis, which is currently defined as a derivation of the fractional urea clearance during a single dialysis treatment, is further governed by patient size, residual kidney function, dietary protein intake, the degree of anabolism or catabolism, and the presence of comorbid conditions.

Since the landmark studies of Sargent and Gotch relating the measurement of the dose of dialysis using urea concentrations with morbidity in the National Cooperative Dialysis Study, the *delivered* dose of dialysis has been measured and considered as a quality assurance and improvement tool. While the fractional removal of urea nitrogen and derivations thereof are considered to be the standard methods by which "adequacy of dialysis" is measured, a large multicenter randomized clinical trial (the HEMO Study) failed to show a difference in mortality associated with a large difference in urea clearance. Still, multiple observational studies and widespread expert opinion have suggested that higher dialysis dose is warranted; current targets include a urea reduction ratio (the fractional reduction in blood urea nitrogen per hemodialysis session) of >65–70% and a body water–indexed clearance × time product (KT/V) above 1.3 or 1.05, depending on whether urea concentrations are "equilibrated."

For the majority of patients with ESRD, between 9 and 12 h of dialysis are required each week, usually divided into three equal sessions. Several studies have suggested that longer hemodialysis session lengths may be beneficial, although these studies are confounded by a variety of patient characteristics, including body size and nutritional status. Hemodialysis "dose" should be individualized, and factors other than the urea nitrogen should be considered, including the adequacy of ultrafiltration or fluid removal. Several authors have highlighted improved intermediate outcomes associated with more frequent hemodialysis (i.e., more than three times a week), although these studies are also confounded by multiple factors. A randomized clinical trial is currently underway to test whether more frequent dialysis results in differences in a variety of physiologic and functional markers.

COMPLICATIONS DURING HEMODIALYSIS

Hypotension is the most common acute complication of hemodialysis, particularly among diabetics. Numerous factors appear to increase the risk of hypotension, including excessive ultrafiltration with inadequate compensatory vascular filling, impaired vasoactive or autonomic responses, osmolar shifts, overzealous use of antihypertensive agents, and reduced cardiac reserve. Patients with arteriovenous fistulas and grafts may develop high output cardiac failure due to shunting of blood through the dialysis access; on rare occasions, this may necessitate ligation of the fistula or graft. Because of the vasodilatory and cardiodepressive effects of acetate, its use as the buffer in dialysate was once a common cause of hypotension. Since the introduction of bicarbonate-containing dialysate, dialysis-associated hypotension has become less common. The management of hypotension during dialysis consists of discontinuing ultrafiltration, the administration of 100–250 mL of isotonic saline or 10 mL of 23% saturated hypertonic saline, and administration of salt-poor albumin. Hypotension during dialysis can frequently be prevented by careful evaluation of the dry weight and by ultrafiltration modeling, such that more fluid is removed at the beginning rather than the end of the dialysis procedure. Additional maneuvers include the performance of sequential ultrafiltration followed by dialysis; the use of midodrine, a selective α_1-adrenergic pressor agent; cooling of the dialysate during dialysis treatment; and avoiding heavy meals during dialysis.

Muscle cramps during dialysis are also a common complication of the procedure. The etiology of dialysis-associated cramps remains obscure. Changes in muscle perfusion because of excessively aggressive volume removal, particularly below the estimated dry weight, and the use of low-sodium–containing dialysate, have been proposed as precipitants of dialysis-associated cramps. Strategies that may be used to prevent cramps include reducing volume removal during dialysis, ultrafiltration profiling, and the use of higher concentrations of sodium in the dialysate or sodium modeling (see above).

Anaphylactoid reactions to the dialyzer, particularly on its first use, have been reported most frequently with the bioincompatible cellulosic-containing membranes. With the gradual phasing out of cuprophane membranes in the United States, dialyzer reactions have become relatively uncommon. Dialyzer reactions can be divided into two types, A and B. Type A reactions are attributed to an IgE-mediated intermediate hypersensitivity reaction to ethylene oxide used in the sterilization of new dialyzers. This reaction typically occurs soon after the initiation of a treatment (within the first few minutes) and can progress to full-blown anaphylaxis if the therapy is not promptly discontinued. Treatment with steroids or epinephrine may be needed if symptoms are severe. The type B reaction consists of a symptom complex of nonspecific chest and back pain, which appears to result from complement activation and cytokine release. These symptoms typically occur several minutes into the dialysis run and typically resolve over time with continued dialysis.

Cardiovascular diseases constitute the major causes of death in patients with ESRD. Cardiovascular mortality and event rates are higher in dialysis patients than in patients posttransplantation, although rates are extraordinarily high in both populations. The underlying cause of cardiovascular disease is unclear but may be related to shared risk factors (e.g., diabetes mellitus), chronic inflammation, massive changes in extracellular volume (especially with high interdialytic weight gains), inadequate treatment of hypertension, dyslipidemia, anemia, dystrophic vascular calcification, hyperhomocysteinemia, and, perhaps, alterations in cardiovascular dynamics during the dialysis treatment. Few studies have targeted cardiovascular risk reduction in ESRD patients; none have demonstrated consistent benefit. Nevertheless, most experts recommend conventional cardioprotective strategies (e.g., lipid-lowering agents, aspirin, β-adrenergic antagonists) in dialysis patients based on the patients' cardiovascular risk profile, which appears to be increased by more than an order of magnitude relative to persons unaffected by kidney disease.

PERITONEAL DIALYSIS

In peritoneal dialysis, 1.5–3 L of a dextrose-containing solution is infused into the peritoneal cavity and allowed to dwell for a set period of time, usually 2–4 h. As with hemodialysis, toxic materials are removed through a combination of convective clearance generated through ultrafiltration and diffusive clearance down a concentration gradient. The clearance of solutes and water during a peritoneal dialysis exchange depends on the balance between the movement of solute and water into the peritoneal cavity versus absorption from the peritoneal cavity. The rate of diffusion diminishes with time and eventually stops when equilibration between plasma and dialysate is reached. Absorption of solutes and water from the peritoneal cavity occurs across the peritoneal membrane into the peritoneal capillary circulation and via peritoneal lymphatics into the lymphatic circulation. The rate of peritoneal solute transport varies from patient to patient and may be altered by the presence of infection (peritonitis), drugs, and physical factors such as position and exercise.

FORMS OF PERITONEAL DIALYSIS

Peritoneal dialysis may be carried out as continuous ambulatory peritoneal dialysis (CAPD), continuous cyclic peritoneal dialysis (CCPD), or a

combination of both. In CAPD, dialysis solution is manually infused into the peritoneal cavity during the day and exchanged three to five times daily. A nighttime dwell is frequently instilled at bedtime and remains in the peritoneal cavity through the night. The drainage of spent dialysate is performed manually with the assistance of gravity to move fluid out of the abdomen. In CCPD, exchanges are performed in an automated fashion, usually at night; the patient is connected to an automated cycler that performs a series of exchange cycles while the patient sleeps. The number of exchange cycles required to optimize peritoneal solute clearance varies by the peritoneal membrane characteristics; as with hemodialysis, experts suggest careful tracking of solute clearances to ensure dialysis "adequacy."

Peritoneal dialysis solutions are available in volumes typically ranging from 1.5 to 3.0 L. Lactate is the preferred buffer in peritoneal dialysis solutions. The most common additives to peritoneal dialysis solutions are heparin to prevent obstruction of the dialysis catheter lumen with fibrin and antibiotics during an episode of acute peritonitis. Insulin may also be added in patients with diabetes mellitus.

ACCESS TO THE PERITONEAL CAVITY

Access to the peritoneal cavity is obtained through a peritoneal catheter. Catheters used for maintenance peritoneal dialysis are flexible, being made of silicon rubber with numerous side holes at the distal end. These catheters usually have two Dacron cuffs to promote fibroblast proliferation, granulation, and invasion of the cuff. The scarring that occurs around the cuffs anchors the catheter and seals it from bacteria tracking from the skin surface into the peritoneal cavity; it also prevents the external leakage of fluid from the peritoneal cavity. The cuffs are placed in the preperitoneal plane and ~2 cm from the skin surface.

The *peritoneal equilibrium test* is a formal evaluation of peritoneal membrane characteristics that measures the transfer rates of creatinine and glucose across the peritoneal membrane. Patients are classified as low, low–average, high–average, and high "transporters." Patients with rapid equilibration (i.e., high transporters) tend to absorb more glucose and lose efficiency of ultrafiltration with long daytime dwells. High transporters also tend to lose larger quantities of albumin and other proteins across the peritoneal membrane. In general, patients with rapid transporting characteristics require more frequent, shorter dwell time exchanges, nearly always obligating use of a cycler for feasibility. Slower (low and low–average) transporters tend to do well with fewer exchanges. The efficiency of solute clearance also depends on the volume of dialysate infused. Larger volumes allow for greater solute clearance, particularly with CAPD in patients with low and low–average transport characteristics. Interestingly, solute clearance also increases with physical activity, presumably related to more efficient flow dynamics within the peritoneal cavity.

As with hemodialysis, the optimal dose of peritoneal dialysis is unknown. Several observational studies have suggested that higher rates of urea and creatinine clearance (the latter generally measured in L/week) are associated with lower mortality rates and fewer uremic complications. However, a randomized clinical trial (ADEMEX) failed to show a significant reduction in mortality or complications with a relatively large increment in urea clearance. In general, patients on peritoneal dialysis do well when they retain residual kidney function. The rates of technique failure increase with years on dialysis and have been correlated with loss of residual function to a greater extent than loss of peritoneal membrane capacity. Recently, a nonabsorbable carbohydrate (icodextrin) has been introduced as an alternative osmotic agent. Studies have demonstrated more efficient ultrafiltration with icodextrin than with dextrose-containing solutions. Icodextrin is typically used as the "last fill" for patients on CCPD or for the longest dwell in patients on CAPD. For some patients in whom CCPD does not provide sufficient solute clearance, a hybrid approach can be adopted where one or more daytime exchanges are added to the CCPD regimen. While this approach can enhance solute clearance and prolong a patient's capacity to remain on peritoneal dialysis, the burden of the hybrid approach can be overwhelming to some.

COMPLICATIONS DURING PERITONEAL DIALYSIS

The major complications of peritoneal dialysis are peritonitis, catheter-associated nonperitonitis infections, weight gain and other metabolic disturbances, and residual uremia (especially among patients with no residual kidney function).

Peritonitis typically develops when there has been a break in sterile technique during one or more of the exchange procedures. Peritonitis is usually defined by an elevated peritoneal fluid leukocyte count (100/mm^3, of which at least 50% are polymorphonuclear neutrophils). The clinical presentation typically consists of pain and cloudy dialysate, often with fever and other constitutional symptoms. The most common culprit organisms are gram-positive cocci, including *Staphylococcus*, reflecting the origin from the skin. Gram-negative rod infections are less common; fungal and mycobacterial infections can be seen in selected patients, particularly after antibacterial therapy. Most cases of peritonitis can be managed either with intraperitoneal or oral antibiotics, depending on the organism; many patients with peritonitis do not require hospitalization. In cases where peritonitis is due to hydrophilic gram negative rods (e.g., *Pseudomonas* sp.) or yeast, antimicrobial therapy is usually not sufficient, and catheter removal is required to ensure complete eradication of infection. Nonperitonitis catheter-associated infections (often termed *tunnel infections*) vary widely in severity. Some cases can be managed with local antibiotic or silver nitrate administration, while others are severe enough to require parenteral antibiotic therapy and catheter removal.

Peritoneal dialysis is associated with a variety of metabolic complications. As noted above, albumin and other proteins can be lost across the peritoneal membrane in concert with the loss of metabolic wastes. The hypoproteinemia induced by peritoneal dialysis obligates a higher dietary protein intake in order to maintain nitrogen balance. Hyperglycemia and weight gain are also common complications of peritoneal dialysis. Several hundred calories in the form of dextrose are absorbed each day, depending on the concentration employed. Peritoneal dialysis patients, particularly those with type II diabetes mellitus, are then prone to other complications of insulin resistance, including hypertriglyceridemia. On the positive side, the continuous nature of peritoneal dialysis usually allows for a more liberal diet, due to continuous removal of potassium and phosphorus—two major dietary components whose accumulation can be hazardous in ESRD.

GLOBAL PERSPECTIVE

The incidence of ESRD is increasing worldwide with longer life expectancies and improved care of infectious and cardiovascular diseases. The management of ESRD varies widely by country and within country by region, and it is influenced by economic and other major factors. In general, peritoneal dialysis is more commonly performed in poorer countries owing to its lower expense and the high cost of establishing in-center hemodialysis units.

ACKNOWLEDGMENT

We are grateful to Dr. Ajay Singh and Dr. Barry Brenner, authors of "Dialysis in the Treatment of Renal Failure" in the 16th edition of Harrison's, for contributions to this chapter.

276 Transplantation in the Treatment of Renal Failure

Charles B. Carpenter, Edgar L. Milford, Mohamed H. Sayegh

Transplantation of the human kidney is the treatment of choice for advanced chronic renal failure. Worldwide, tens of thousands of such procedures have been performed. When azathioprine and prednisone were initially used as immunosuppressive drugs in the 1960s, the results with properly matched familial donors were superior to those with organs from deceased donors—namely, 75–90% compared with 50–60% graft survival rates at 1 year. During the 1970s and 1980s, the success rate at the 1-year mark for deceased-donor transplants rose progressively. By the time cyclosporine was introduced in the early 1980s, deceased-donor grafts had a 70% 1-year survival and reached the 82% level in the mid-1990s. After the first year, graft survival curves show an exponential decline in numbers of functioning grafts from which a half-life ($t_{1/2}$) in years is calculated; this has increased by only 2 years since the 1980s.

Mortality rates after transplantation are highest in the first year and are age-related: 2% for ages 18–34 years, 3% for ages 35–49 years, and 6.8% for ages ≥50–60 years. These rates compare favorably with those in the chronic dialysis population, even after risk adjustments for age, diabetes, and cardiovascular status. Occasionally, acute irreversible rejection may occur after many months of good function, especially if the patient neglects to take the prescribed immunosuppressive drugs. Most grafts, however, succumb at varying rates to a chronic vascular obliterative process termed *chronic allograft nephropathy*, the pathogenesis of which is incompletely understood. Overall, transplantation returns most patients to an improved lifestyle and an improved life expectancy compared with patients on dialysis. There are at least 100,000 patients with functioning kidney transplants in the United States, and when one adds in the numbers of kidney transplants in centers around the world, the total activity is doubled.

RECENT ACTIVITY AND RESULTS

In 1994 there were more than 7000 deceased donor kidney transplants and 3000 living donor transplants in the United States. Table 276-1 shows an increase in numbers of transplants for deceased and living donors over the decade ending in 2003. Whereas deceased donor availability rose by 11%, the living donor rate more than doubled. The backlog of patients with end-stage renal disease (ESRD) has been increasing every year, and it always lags behind the number of available donors. In this decade, the size of the waiting list more than doubled, and the percentage of those on the waiting list receiving deceased donor transplants dropped from 28 to 14%. The increase in the living donor rate is in response to the demand; it continues to rise to exceed the number of deceased donor grafts. As there were 16,534 new registrants added to the waiting list in 1994 and 24,493 in 2003, demand will continue to exceed supply. Waiting lists continue to grow, and the average wait time for a cadaver kidney is now >4 years in many locations.

The overall results of transplantation are presented in Table 276-2 as the survival of grafts and of patients. At the 1-year mark, graft survival is higher for living donor recipients, most likely because those grafts are not subject to as much ischemic injury. The more powerful drugs now in use for immunosuppression have almost equalized the risk of graft rejection in all patients for the first year. At 5 and 10 years, however, there has been a steeper decline in survival of those with deceased-donor kidneys.

RECIPIENT SELECTION

There are few absolute contraindications to renal transplantation. The transplant procedure is relatively noninvasive, as the organ is placed in the inguinal fossa without entering the peritoneal cavity. Recipients without perioperative complications can often be discharged from the hospital in excellent condition within 5 days of the operation.

Virtually all patients with ESRD who receive a transplant have a higher life expectancy than risk-matched patients who remain on dialysis. Even though diabetics and older candidates have a higher mortality rate than other transplant recipients, their survival is improved with transplantation compared with remaining on dialysis. This global benefit of transplantation as a treatment modality poses substantial ethical issues for policy makers, as the number of deceased kidneys available is far from sufficient to meet the current needs of the candidates. The current standard of care is that the candidate should have a life expectancy of >5 years to be put on a deceased organ wait list. Even for living donation, the candidate should have >5 years of life expectancy. This standard has been established because the benefits of kidney transplantation over dialysis are realized only after a perioperative period in which the mortality is higher in transplanted patients than in dialysis patients with comparable risk profiles.

All candidates must have a thorough risk-versus-benefit evaluation prior to being approved for transplantation. In particular, an aggressive approach to diagnosis of correctable coronary artery disease, presence of latent or indolent infection (HIV, hepatitis B or C, tuberculosis), and

neoplasm should be a routine part of the candidate workup. Most transplant centers consider overt AIDS and active hepatitis to be absolute contraindications to transplantation because of the high risk of opportunistic infection. Some centers are now transplanting individuals with hepatitis and even HIV infection under strict protocols to determine whether the risks and benefits favor transplantation over dialysis.

Among the few absolute "immunologic" contraindications to transplantation is the presence of a potentially harmful antibody against the donor kidney at the time of the anticipated transplant. Harmful antibodies that can cause very early graft loss include natural antibodies against the ABO blood group antigens and antibodies against human leukocyte antigen (HLA) class I (A, B, C) or class II (DR) antigens. These antibodies are routinely excluded by proper screening of the candidate's ABO compatibility, HLA typing of donor and recipient, and direct cross-matching of candidate serum with lymphocytes of the donor.

DONOR SELECTION

Donors can be deceased or volunteer living donors. The latter are usually family members selected to have at least partial compatibility for HLA antigens. Living volunteer donors should be normal on physical examination and of the same major ABO blood group, because crossing major blood group barriers prejudices survival of the allograft. It is possible, however, to transplant a kidney of a type O donor into an A, B, or AB recipient. Selective renal arteriography should be performed on donors to rule out the presence of multiple or abnormal renal arteries because the surgical procedure is difficult and the ischemic time of the transplanted kidney long when vascular abnormalities exist. Transplant surgeons are now using a laparoscopic method to isolate and remove the living donor kidney. This operation has the advantage of less evident surgical scars, and, because there is less tissue trauma, the laparoscopic donors have a substantially shorter hospital stay and less discomfort than those who have the traditional surgery. Deceased donors should be free of malignant neoplastic disease, hepatitis, and HIV because of possible transmission to the recipient. Increased risk of graft failure exists when the donor is elderly or has renal failure and when the kidney has a prolonged period of ischemia and storage.

In the United States, there is a coordinated national system of regulations, allocation support, and outcomes analysis for kidney transplantation called the Organ Procurement Transplant Network. It is now possible to remove deceased donor kidneys and to maintain them for up to 48 h on cold pulsatile perfusion or simple flushing and cooling. This approach permits adequate time for typing, cross-matching, transportation, and selection problems to be solved.

TISSUE TYPING AND CLINICAL IMMUNOGENETICS

Matching for antigens of the HLA major histocompatibility gene complex (Chap. 309) is an important criterion for selection of donors for renal allografts. Each mammalian species has a single chromosomal region that encodes the strong, or major, transplantation antigens, and this region on the human sixth chromosome is called *HLA*. HLA antigens have been classically defined by serologic techniques, but methods to define specific nucleotide sequences in genomic DNA are increasingly being used. Other "minor" antigens may play crucial roles, in addition to the ABH(O) blood groups and endothelial antigens that are not shared with lymphocytes. The Rh system is not expressed on graft tissue. Evidence for designation of HLA as the genetic region encoding major transplantation antigens comes from the success rate in living related donor renal and bone marrow transplantation, with superior results in HLA-identical sibling pairs. Nevertheless, 5% of HLA-identical renal allografts are rejected, often within the first weeks after transplantation. These failures represent states of prior sensitization to non-HLA antigens. Non-HLA minor antigens are relatively weak when initially encountered and are, therefore, suppressible by conventional immunosuppressive therapy. Once priming has occurred, however, secondary responses are much more refractory to treatment.

LIVING DONORS

When first-degree relatives are donors, graft survival rates at 1 year are 5–7% greater than those for deceased-donor grafts. The 5-year survival rates still favor the partially matched (3/6 HLA mismatched) family donor over a randomly selected cadaver donor (Table 276-3). In addition, living donors provide the advantage of immediate availability. For both living and deceased donors, the 5-year outcomes are poor if there is a complete (6/6) HLA mismatch.

The survival rate of living unrelated renal allografts is as high as that of perfectly HLA-matched cadaver renal transplants and comparable to that of kidneys from living relatives. This outcome is likely a consequence of both short cold ischemia time and the extra care taken to document that the condition and renal function of the donor are optimal before proceeding with a living unrelated donation. It is illegal in the United States to purchase organs for transplantation.

Concern has been expressed regarding the potential risk to a volunteer kidney donor of premature renal failure after several years of increased blood flow and hyperfiltration per nephron in the remaining kidney. There are a few reports of the development of hypertension, proteinuria, and even lesions of focal segmental sclerosis in donors over long-term follow-up. Difficulties in donors followed for ≥20 years are unusual, however, and it may be that having a single kidney becomes significant only when another condition, such as hypertension, is superimposed. It is also desirable to consider the risk of development of type 1 diabetes mellitus in a family member who is a potential donor to a diabetic renal failure patient. Anti-insulin and anti-islet cell antibodies should be measured, and glucose tolerance tests should be performed in such donors to exclude a prediabetic state.

PRESENSITIZATION

A positive cross-match of recipient serum with donor T lymphocytes representing anti-HLA class I is usually predictive of an acute vasculitic event termed *hyperacute rejection*. Patients with anti-HLA antibodies can be safely transplanted if careful cross-matching of donor blood lymphocytes with recipient serum is performed. The known sources of such sensitization are blood transfusion, prior transplant, and pregnancy. Patients sustained by dialysis often show fluctuating antibody titers and specificity patterns. At the time of assignment of a cadaveric kidney, cross-matches are performed with at least a current serum. Previously analyzed antibody specificities and additional cross-matches are performed accordingly. Techniques for cross-matching are not universally standardized; however, at least two techniques are employed in most laboratories. The minimal purpose for the cross-match is avoidance of hyperacute rejection mediated by recipient antibodies to donor HLA class I antigens. Sensitive tests, such as the use of flow cytometry, can be useful for avoidance of accelerated, and often untreatable, early graft rejection in patients receiving second or third transplants. Donor T lymphocytes, which express only class I antigens, are used as targets for detection of anti–class I (HLA-A and -B) antibodies. Preformed anti–class II (HLA-DR) antibod-

TABLE 276-3 EFFECT OF HLA-A, -B, -DR MISMATCHING ON KIDNEY GRAFT SURVIVAL

Degree of Donor Mismatch	1-Year Survival, %	5-Year Survival, %
Cadaver donor (all)	89.2	61.3
0/6-HLA mismatch	91.3	68.2
3/6-HLA mismatch	90.1	60.8
6/6-HLA mismatch	85.2	55.3
Living related donor (all)	94.7	76.0
0/6-HLA mismatch	96.7	87.0
3/6-HLA mismatch	94.3	73.2
6/6-HLA mismatch	92.7	57.7
Living unrelated donor	95.3	77.4

Note: 0-mismatched related donor transplants are virtually all from HLA-identical siblings, while 3/6-mismatched transplants can be one haplotype mismatched (1-A, 1-B, and 1-DR antigen) from parent, child or sibling; 6/6-HLA-mismatched living related kidneys are derived from siblings or relatives outside of the nuclear family.

ies against the donor carry a higher risk of graft loss as well, particularly in recipients who have suffered early loss of a prior kidney transplant. B lymphocytes expressing both class I and class II antigens are used in these assays. Non-HLA antigens restricted in expression to endothelium and sometimes monocytes have been described, but clinical relevance is not well established. A series of minor histocompatibility antigens do not elicit antibodies, and sensitization to these is detectable only by cytotoxic T cells, an assay too cumbersome for routine use. Desensitization prior to transplantation by reducing the level of antidonor antibodies via plasmapheresis of blood, administration of large doses of immunoglobulin, or both has been useful in reducing the hazard of hyperacute rejection.

IMMUNOLOGY OF REJECTION

Both cellular and humoral (antibody-mediated) effector mechanisms can play roles in kidney transplant rejection. Antibodies can also initiate a form of antibody-dependent but cell-mediated cytotoxicity by recipient cells that bear receptors for the Fc portion of immunoglobulin.

Cellular rejection is mediated by lymphocytes that respond to HLA antigens expressed within the organ. The CD4+ lymphocyte responds to class II (HLA-DR) incompatibility by proliferating and releasing proinflammatory cytokines that augment the proliferative response of both CD4+ and CD8+ cells. CD8+ cytotoxic lymphocyte precursors respond primarily to class I (HLA-A, -B) antigens and mature into cytotoxic effector cells. The cytotoxic effector ("killer") T cells cause organ damage through direct contact and lysis of donor target cells. The natural role of HLA antigen molecules is to present processed peptide fragments of antigen to T lymphocytes, the fragments residing in a "groove" of the HLA molecule distal to the cell surface. T cells can be directly stimulated by intact non-self HLA molecules expressed on donor parenchymal cells and residual donor leukocytes residing in the kidney interstitium. In addition, donor HLA molecules can be processed by a variety of donor or recipient cells capable of antigen presentation of peptides and then presented to T cells in the same manner as most other antigens. The former mode of stimulation is sometimes called *direct presentation* and the latter mode called *indirect presentation* (Fig. 276-1). There is evidence that non-HLA antigens can also play a role in renal transplant rejection episodes. Recipients who receive a kidney from an HLA-identical sibling can have rejection episodes and require maintenance immunosuppression, while identical twin transplants require no immunosuppression. There are documented non-HLA antigens, such as an endothelial-specific antigen system with limited polymorphism and a tubular antigen, that can be targets of humoral or cellular rejection responses, respectively.

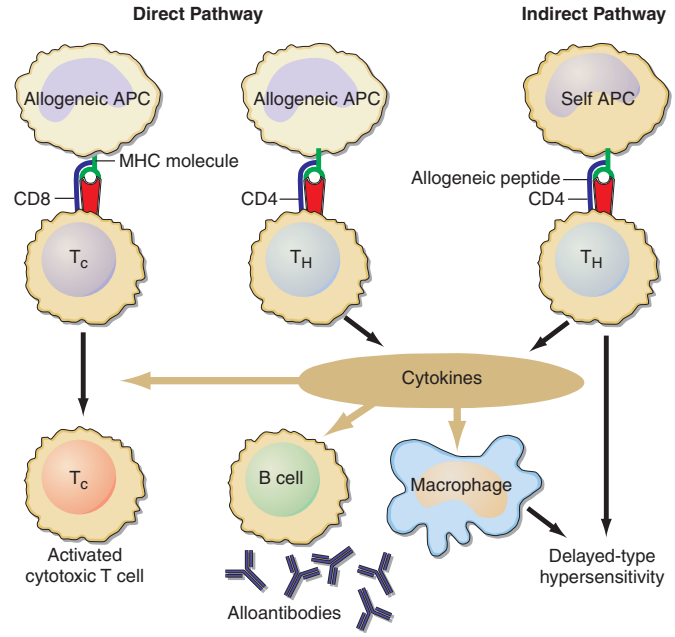

FIGURE 276-1 Recognition pathways for major histocompatibility complex (MHC) antigens. Graft rejection is initiated by CD4 helper T lymphocytes (T_H) having antigen receptors that bind to specific complexes of peptides and MHC class II molecules on antigen-presenting cells (APC). In transplantation, in contrast to other immunologic responses, there are two sets of T cell clones involved in rejection. In the direct pathway the class II MHC of donor allogeneic APCs is recognized by CD4 T_H cells that bind to the intact MHC molecule, and class I MHC allogeneic cells are recognized by CD8 T cells. The latter generally proliferate into cytotoxic cells (T_C). In the indirect pathway, the incompatible MHC molecules are processed into peptides that are presented by the self-APCs of the recipient. The indirect, but not the direct, pathway is the normal physiologic process in T cell recognition of foreign antigens. Once T_H cells are activated, they proliferate, and by secretion of cytokines and direct contact exert strong helper effects on macrophages, T_C, and B cells. *(From Sayegh and Turka, Copyright 1998, Massachusetts Medical Society. IMMUNOSUPPRESSIVE TREATMENT

Immunosuppressive therapy, as presently available, generally suppresses all immune responses, including those to bacteria, fungi, and even malignant tumors. In the 1950s when clinical renal transplantation began, sublethal total-body irradiation was employed. We have now reached the point where sophisticated pharmacologic immunosuppression is available, but it still has the hazard of promoting infection and malignancy. In general, all clinically useful drugs are more selective to primary than to memory immune responses. Agents to suppress the immune response are discussed in the following paragraphs, and those currently in clinical use are listed in Table 276-4.

TABLE 276-4 MAINTENANCE IMMUNOSUPPRESSIVE DRUGS

Agent	Pharmacology	Mechanisms	Side Effects
Glucocorticoids	Increased bioavailability with hypoalbuminemia and liver disease; prednisone/prednisolone generally used	Binds cytosolic receptors and heat shock proteins. Blocks transcription of IL-1,-2,-3,-6, TNF-α, and IFN-γ	Hypertension, glucose intolerance, dyslipidemia, osteoporosis
Cyclosporine (CsA)	Lipid-soluble polypeptide, variable absorption, microemulsion more predictable	Trimolecular complex with cyclophilin and calcineurin → block in cytokine (e.g., IL-2) production; however, stimulates TGF-β production	Nephrotoxicity, hypertension, dyslipidemia, glucose intolerance, hirsutism/hyperplasia of gums
Tacrolimus (FK506)	Macrolide, well absorbed	Trimolecular complex with FKBP-12 and calcineurin → block in cytokine (e.g., IL-2) production; may stimulate TGF-β production	Similar to CsA, but hirsutism/hyperplasia of gums unusual, and diabetes more likely
Azathioprine	Mercaptopurine analogue	Hepatic metabolites inhibit purine synthesis	Marrow suppression (WBC > RBC > platelets)
Mycophenolate mofetil (MMF)	Metabolized to mycophenolic acid	Inhibits purine synthesis via inosine monophosphate dehydrogenase	Diarrhea/cramps; dose-related liver and marrow suppression is uncommon
Sirolimus	Macrolide, poor oral bioavailability	Complexes with FKBP-12 and then blocks p70 S6 kinase in the IL-2 receptor pathway for proliferation	Hyperlipidemia, thrombocytopenia

Note: IL, interleukin; TNF, tumor necrosis factor; IFN, interferon; TGF, transforming growth factor; FKBP-12, FK506 binding protein 12; WBC, white blood cells; RBC, red blood cells.

DRUGS

Azathioprine, an analogue of mercaptopurine, was for two decades the keystone to immunosuppressive therapy in humans but has now given way to more effective agents. This agent can inhibit synthesis of DNA, RNA, or both. Because cell division and proliferation are a necessary part of the immune response to antigenic stimulation, suppression by this agent may be mediated by the inhibition of mitosis of immunologically competent lymphoid cells, interfering with synthesis of DNA. Alternatively, immunosuppression may be brought about by blocking the synthesis of RNA (possibly messenger RNA), inhibiting processing of antigens prior to lymphocyte stimulation. Therapy with azathioprine in doses of 1.5–2.0 mg/kg per d is generally added to cyclosporine as a means of decreasing the requirements for the latter. Because azathioprine is rapidly metabolized by the liver, its dosage need not be varied directly in relation to renal function, even though renal failure results in retention of the metabolites of azathioprine. Reduction in dosage is required because of leukopenia and occasionally thrombocytopenia. Excessive amounts of azathioprine may also cause jaundice, anemia, and alopecia. If it is essential to administer allopurinol concurrently, the azathioprine dose must be reduced. As inhibition of xanthine oxidase delays degradation, this combination is best avoided.

Mycophenolate mofetil (MMF) is now used in place of azathioprine in most centers. It has a similar mode of action and a mild degree of gastrointestinal toxicity but produces minimal bone marrow suppression. Its advantage is its increased potency in preventing or reversing rejection. Patients with hyperuricemia can be given allopurinol without adjustment of the MMF dose. The usual dose is 2–3 g/d in divided doses.

Glucocorticoids are important adjuncts to immunosuppressive therapy. Of all the agents employed, prednisone has effects that are easiest to assess, and in large doses it is usually effective for the reversal of rejection. In general, 200–300 mg prednisone is given immediately prior to or at the time of transplantation, and the dosage is reduced to 30 mg within a week. The side effects of the glucocorticoids, particularly impairment of wound healing and predisposition to infection, make it desirable to taper the dose as rapidly as possible in the immediate postoperative period. Many centers have protocols for early discontinuance or avoidance of steroids because of long-term adverse effects on bone, skin, and glucose metabolism. For treatment of acute rejection, methylprednisolone, 0.5–1.0 g IV, is administered immediately upon diagnosis of beginning rejection and continued once daily for 3 days. When the drug is effective, the results are usually apparent within 96 h. Such "pulse" doses are not effective in chronic rejection. Most patients whose renal function is stable after 6 months or a year do not require large doses of prednisone; maintenance doses of 10–15 mg/d are the rule. Many patients tolerate an alternate-day course of steroids without an increased risk of rejection. A major effect of steroids is on the monocyte-macrophage system, preventing the release of interleukin (IL) 6 and IL-1.

Cyclosporine is a fungal peptide with potent immunosuppressive activity. It acts on the calcineurin pathway to block transcription of mRNA for IL-2 and other proinflammatory cytokines, thereby inhibiting T cell proliferation. Although it works alone, cyclosporine is more effective in conjunction with glucocorticoids and MMF. Clinical results with tens of thousands of renal transplants have been impressive. Of its toxic effects (nephrotoxicity, hepatotoxicity, hirsutism, tremor, gingival hyperplasia, diabetes), only nephrotoxicity presents a serious management problem and is further discussed below.

Tacrolimus (previously called FK506) is a fungal macrolide that has the same mode of action as cyclosporine, as well as a similar side-effect profile; it does not, however, produce hirsutism or gingival hyperplasia. De novo diabetes mellitus is more common with tacrolimus. The drug was first used in liver transplantation and may substitute for cyclosporine entirely or be tried as an alternative in renal patients whose rejections are poorly controlled by cyclosporine.

Sirolimus (previously called rapamycin) is another fungal macrolide but has a different mode of action, i.e., it inhibits T cell growth factor signaling pathways, preventing the response to IL-2 and other cytokines. Sirolimus can be used in conjunction with cyclosporine or tacrolimus, or with MMF, to avoid calcineurin inhibitors. Its use with tacrolimus alone shows promise as a steroid-sparing regimen, especially in patients who would benefit from pancreatic islet cell transplantation, where steroids have an adverse effect on islet survival.

ANTIBODIES TO LYMPHOCYTES

When serum from animals made immune to host lymphocytes is injected into the recipient, a marked suppression of cellular immunity to the tissue graft results. The action on cell-mediated immunity is greater than on humoral immunity. A globulin fraction of serum [antilymphocyte globulin (ALG)] is the agent generally employed. For use in humans, peripheral human lymphocytes, thymocytes, or lymphocytes from spleens or thoracic duct fistulas have been injected into horses, rabbits, or goats to produce antilymphocyte serum, from which the globulin fraction is then separated. A rabbit antithymocyte globulin (Thymoglobulin) is the most common agent currently in use. Monoclonal antibodies against defined lymphocyte subsets offer a more precise and standardized form of therapy. OKT3 is directed to the CD3 molecules that form a portion of the T cell antigen-receptor complex and is thus expressed on all mature T cells.

Another approach to more selective therapy is to target the 55-kDa alpha chain of the IL-2 receptor, expressed only on T cells that have been recently activated. Two such antibodies to the IL-2 receptor, in which either a chimeric protein has been made between mouse Fab with human Fc (basiliximab) or the antibody has been "humanized" by splicing the combining sites of the mouse into a molecule that is 90% human IgG (daclizumab), are in use for prophylaxis of acute rejection in the immediate posttransplant period. They are effective at decreasing the acute rejection rate and have few adverse side effects.

More recently, two new strategies have involved administration of engineered biologic agents: a depleting T cell antibody (alemtuzumab) as induction therapy to minimize maintenance immunosuppression, and a fusion protein (LEA29Y) to block B7 T cell co-stimulatory signals. The latter has shown promise in phase 2 trials and is currently being tested in phase 3 trials in kidney transplantation.

CLINICAL COURSE AND MANAGEMENT OF THE RECIPIENT

Adequate hemodialysis should be performed within 48 h of surgery, and care should be taken that the serum potassium level is not markedly elevated so that intraoperative cardiac arrhythmias can be averted. The diuresis that commonly occurs postoperatively must be carefully monitored; in some instances, it may be massive, reflecting the inability of ischemic tubules to regulate sodium and water excretion; with large diureses, massive potassium losses may occur. Most chronically uremic patients have some excess of extracellular fluid, and it is useful to maintain an expanded fluid volume in the immediate postoperative period. Acute tubular necrosis (ATN) may cause immediate oliguria or may follow an initial short period of graft function. ATN is most likely when cadaveric donors have been underperfused or if the interval between cessation of blood flow and organ harvest (warm ischemic time) is more than a few minutes. Recovery usually occurs within 3 weeks, although periods as long as 6 weeks have been reported. Superimposition of rejection on ATN is common, and the differential diagnosis may be difficult without a graft biopsy. Cyclosporine therapy prolongs ATN, and some patients do not diurese until the dose is drastically reduced. Many centers avoid starting cyclosporine for the first several days, using ALG or a monoclonal antibody along with MMF and prednisone until renal function is established. Figure 276-2 illustrates an algorithm followed by many transplant centers for early posttransplant management of recipients at high or low risk of early renal dysfunction.

THE REJECTION EPISODE

Early diagnosis of rejection allows prompt institution of therapy to preserve renal function and to prevent irreversible damage. Clinical evidence of rejection is rarely characterized by fever, swelling, and tenderness over the allograft. Rejection may present only with a rise in serum creatinine, with or without a reduction in urine volume. The focus should be on ruling out other causes of functional deterioration.

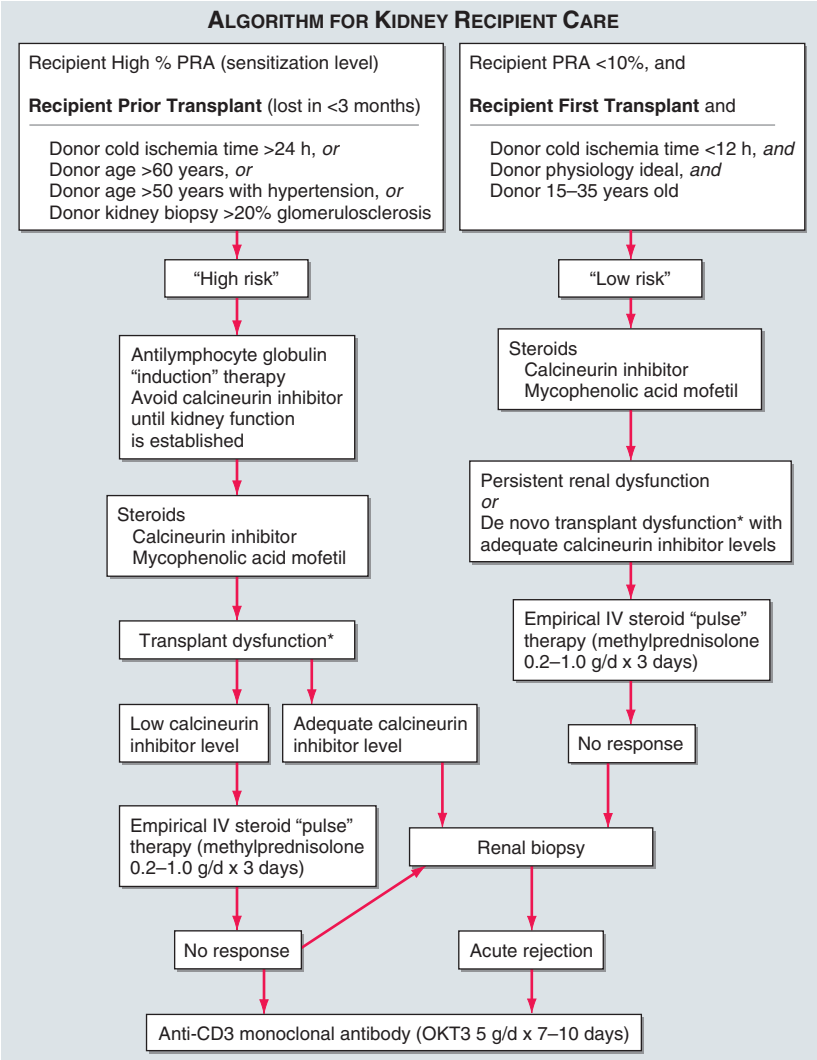

FIGURE 276-2 A typical algorithm for early posttransplant care of the kidney recipient. If any of the recipient or donor "high-risk" factors exist, more aggressive management is called for. Low-risk patients can be treated with a standard immunosuppressive regimen. Patients at higher risk of rejection or early ischemic and nephrotoxic transplant dysfunction are often induced with an antilymphocyte globulin to provide more potent early immunosuppression or to spare calcineurin nephrotoxicity. *When there is early transplant dysfunction, prerenal, obstructive, and vascular causes must be ruled out by ultrasonographic examination. The panel reactive antibody (PRA) is a quantitation of how much antibody is present in a candidate against a panel of cells representing the distribution of antigens in the donor pool.

Doppler ultrasonography or magnetic resonance angiography may be useful in ascertaining changes in the renal vasculature and in renal blood flow, even in the absence of changes in urinary flow. Thrombosis of the renal vein occurs rarely; it may be reversible if caused by technical factors and intervention is prompt. Diagnostic ultrasound is the procedure of choice to rule out urinary obstruction or to confirm the presence of perirenal collections of urine, blood, or lymph. When renal function has been good initially, a rise in the serum creatinine level is the most sensitive and reliable indicator of possible rejection and may be the only sign.

Calcineurin inhibitors (cyclosporine or tacrolimus) may cause deterioration in renal function in a manner similar to a rejection episode. In fact, rejection processes tend to be more indolent with these inhibitors, and the only way to make a diagnosis may be by renal biopsy. Calcineurin inhibitors have an afferent arteriolar constrictor effect on the kidney and may produce permanent vascular and interstitial injury after sustained high-dose therapy. Addition of angiotensin-converting enzyme (ACE) inhibitors or nonsteroidal anti-inflammatory drugs are likely to raise serum creatinine levels. The former are generally safe to use after the early months, while the latter are best avoided in all renal transplant patients. There is no universally accepted lesion that makes a diagnosis of calcineurin inhibitor toxicity, although interstitial fibrosis, isometric tubular vacuolization, and thickening of arteriolar walls have been noted by some. Basically, if the biopsy does not reveal moderate and active cellular rejection activity, the serum creatinine will most likely respond to a reduction in dose. Blood levels of drug can be useful if they are very high or very low but do not correlate precisely with renal function, although serial changes in a patient can be useful. If rejection activity is present in the biopsy, appropriate therapy is indicated. The first rejection episode is usually treated with IV administration of methylprednisolone, 500–1000 mg daily for 3 days. Failure to respond is an indication for antibody therapy, usually with OKT3 or antithymocyte globulin.

Biopsy may be necessary to confirm the presence of rejection; when evidence of antibody-mediated injury is present with endothelial injury and deposition of complement component C4d is detected by fluorescence labeling, one can usually detect the antibody in recipient blood. The prognosis is poor, and aggressive use of plasmapheresis, immunoglobulin infusions, or anti-CD20 monoclonal antibody (rituximab) that targets B lymphocytes is indicated.

MANAGEMENT PROBLEMS

The usual clinical manifestations of infection in the posttransplant period are blunted by immunosuppressive therapy. The major toxic effect of azathioprine is bone marrow suppression, which is less likely with MMF, while calcineurin inhibitors have no marrow effects. All drugs predispose to unusual opportunistic infections, however. The typical times after transplantation when the most common opportunistic infections occur are tabulated in Table 276-5. The signs and symptoms of infection may be masked or distorted. Fever without obvious cause is common, and only after days or weeks may it become apparent that it has a viral or fungal origin. Bacterial infections are most common during the first month after transplantation. The importance of blood cultures in such patients cannot be overemphasized because systemic infection without obvious foci is frequent, although wound infections with or without urinary fistulas are most common. Particularly ominous are rapidly occurring pulmonary lesions, which may result in death within 5 days of onset. When these become apparent, immunosuppressive agents should be discontinued, except for maintenance doses of prednisone.

Aggressive diagnostic procedures, including transbronchial and open lung biopsy, are frequently indicated. In the case of *Pneumocystis carinii*

TABLE 276-5 THE MOST COMMON OPPORTUNISTIC INFECTIONS IN THE RENAL TRANSPLANT RECIPIENT

Peritransplant (<1 month)	Late (>6 months)
Wound infections	*Aspergillus*
Herpesvirus	*Nocardia*
Oral candidiasis	BK virus (polyoma)
Urinary tract infection	Herpes zoster
Early (1–6 months)	Hepatitis B
Pneumocystis carinii	Hepatitis C
Cytomegalovirus	
Legionella	
Listeria	
Hepatitis B	
Hepatitis C	

(Chap. 200) infection, trimethoprim-sulfamethoxazole (TMP-SMX) is the treatment of choice; amphotericin B has been used effectively in systemic fungal infections. Prophylaxis against *P. carinii* with daily or alternate-day low-dose TMP-SMX is very effective. Involvement of the oropharynx with *Candida* (Chap. 196) may be treated with local nystatin. Tissue-invasive fungal infections require treatment with systemic agents such as fluconazole. Small doses (a total of 300 mg) of amphotericin given over a period of 2 weeks may be effective in fungal infections refractory to fluconazole. Macrolide antibiotics, especially ketoconazole and erythromycin, and some calcium channel blockers (diltiazem, verapamil) compete with calcineurin inhibitors for P450 catabolism and cause elevated levels of these immunosuppressive drugs. Analeptics, such as phenytoin and carbamazepine, will increase catabolism to result in low levels. *Aspergillus* (Chap. 197), *Nocardia* (Chap. 155), and especially cytomegalovirus (CMV) (Chap. 175) infections also occur.

CMV is a common and dangerous DNA virus in transplant recipients. It does not generally appear until the end of the first posttransplant month. Active CMV infection is sometimes associated, or occasionally confused, with rejection episodes. Patients at highest risk for severe CMV disease are those without anti-CMV antibodies who receive a graft from a CMV antibody–positive donor (15% mortality). Valganciclovir is a cost-effective and bioavailable oral form of ganciclovir that has been proven effective in both prophylaxis and treatment of CMV disease. Early diagnosis in a febrile patient with clinical suspicion of CMV disease can be made by determining CMV viral load in the blood. A rise in IgM antibodies to CMV is also diagnostic. Culture of CMV from blood may be less sensitive. Tissue invasion of CMV is common in the gastrointestinal tract and lungs. CMV retinopathy occurs late in the course, if untreated. Treatment of active CMV disease with valganciclovir is always indicated. In many patients immune to CMV, viral activation can occur with major immunosuppressive regimens.

The polyoma group (BK, JC, SV40) is another class of DNA viruses that can become dormant in kidneys and can be activated by immunosuppression. When reactivation occurs with BK there is a 50% chance of progressive fibrosis and loss of the graft within 1 year by the activated virus. The use of tacrolimus has been associated with the highest risk.

Renal biopsy is necessary for the diagnosis. There are promising results with leflunomide and cidofovir, but it is most important to reduce the immunosuppressive load.

The complications of glucocorticoid therapy are well known and include gastrointestinal bleeding, impairment of wound healing, osteoporosis, diabetes mellitus, cataract formation, and hemorrhagic pancreatitis. The treatment of unexplained jaundice in transplant patients should include cessation or reduction of immunosuppressive drugs if hepatitis or drug toxicity is suspected. Therapy in such circumstances often does not result in rejection of a graft, at least for several weeks. Acyclovir is effective in therapy of herpes simplex virus infections.

CHRONIC LESIONS OF THE TRANSPLANTED KIDNEY

While 1-year transplant survival is excellent, most recipients experience progressive decline in kidney function over time thereafter. Chronic renal transplant dysfunction can be caused by recurrent disease, hypertension, cyclosporine or tacrolimus nephrotoxicity, chronic immunologic rejection, secondary focal glomerulosclerosis, or a combination of these pathophysiologies. Chronic vascular changes with intimal proliferation and medial hypertrophy are commonly found. Control of systemic and intrarenal hypertension with ACE inhibitors is thought to have a beneficial influence on the rate of progression of chronic renal transplant dysfunction. Renal biopsy can distinguish subacute cellular rejection from recurrent disease or secondary focal sclerosis.

MALIGNANCY

The incidence of tumors in patients on immunosuppressive therapy is 5–6%, or approximately 100 times greater than that in the general population of the same age range. The most common lesions are cancer of the skin and lips and carcinoma in situ of the cervix, as well as lymphomas such as non-Hodgkin's lymphoma. The risks are increased in proportion to the total immunosuppressive load administered and time elapsed since transplantation. Surveillance for skin and cervical cancers is necessary.

OTHER COMPLICATIONS

Hypercalcemia after transplantation may indicate failure of hyperplastic parathyroid glands to regress. Aseptic necrosis of the head of the femur is probably due to preexisting hyperparathyroidism, with aggravation by glucocorticoid treatment. With improved management of calcium and phosphorus metabolism during chronic dialysis, the incidence of parathyroid-related complications has fallen dramatically. Persistent hyperparathyroid activity may require subtotal parathyroidectomy.

Hypertension may be caused by (1) native kidney disease; (2) rejection activity in the transplant; (3) renal artery stenosis, if an end-to-end anastomosis was constructed with an iliac artery branch; and (4) renal calcineurin inhibitor toxicity. This toxicity may improve with reduction in dose. Whereas ACE inhibitors may be useful, calcium channel blockers are more frequently used initially. Amelioration of hypertension to the range of 120–130/70–80 mmHg should be the goal in all patients.

While most transplant patients have a robust production of erythropoietin and normalization of hemoglobin, *anemia* is commonly seen in the posttransplant period. Often the anemia is attributable to bone marrow–suppressant immunosuppressive medications such as azathioprine, MMF, or sirolimus. Gastrointestinal bleeding is a common side effect of high-dose and long-term steroid administration. Many transplant patients have creatinine clearances of 30–50 mL/min and can be considered in the same way as other patients with chronic renal insufficiency for anemia management, including supplemental erythropoietin.

Chronic hepatitis, particularly when due to hepatitis B virus, can be a progressive, fatal disease over a decade or so. Patients who are persistently hepatitis B surface antigen–positive are at higher risk, according to some studies, but the presence of hepatitis C virus is also a concern when one embarks on a course of immunosuppression in a transplant recipient.

Both chronic dialysis and renal transplant patients have a higher incidence of death from myocardial infarction and stroke than does the population at large, and this is particularly true in diabetic patients. Contributing factors are the use of glucocorticoids and sirolimus, as well as hypertension. Recipients of renal transplants have a high prevalence of coronary artery and peripheral vascular diseases. The percentage of deaths from these causes has been slowly rising as the numbers of transplanted diabetic patients and the average age of all recipients increase. More than 50% of renal recipient mortality is attributable to cardiovascular disease. In addition to strict control of blood pressure and blood lipid levels, close monitoring of patients for indications of further medical or surgical intervention is an important part of management.

277 Glomerular Diseases

Julia B. Lewis, Eric G. Neilson

Two human kidneys harbor nearly 1.8 million glomerular capillary tufts. Each glomerular tuft resides within Bowman's space. The capsule circumscribing this space is lined by parietal epithelial cells that transition into tubular epithelia forming the proximal nephron. The glomerular capillary tuft derives from an afferent arteriole that forms a branching capillary bed embedded in mesangial matrix (Fig. 277-1). This capillary network funnels into an efferent arteriole, which passes filtered blood into cortical peritubular capillaries or medullary vasa recta that supply and exchange with a folded tubular architecture. Hence the glomerular capillary tuft, fed and drained by arterioles, represents an arteriolar portal system. Fenestrated endothelial cells resting on a glomerular basement membrane (GBM) line glomerular capillaries. Delicate foot processes extending from epithelial podocytes shroud the outer surface of these capillaries, and podocytes interconnect to each other by slit-pore membranes forming a selective filtration barrier.

The glomerular capillaries filter 120–180 L/d of plasma water containing various solutes for reclamation or discharge by downstream tubules. Most large proteins and all cells are excluded from filtration by a physicochemical barrier governed by pore size and negative electrostatic charge. The mechanics of filtration and reclamation are quite complicated for many solutes (Chap. 271). For example, in the case of serum albumin, the glomerulus is an imperfect barrier. Although albumin has a negative charge, which would tend to repel the negatively charged GBM, it only has a physical radius of 3.6 nm, while pores in the GBM and slit-pore membranes have a radius of 4 nm. Consequently, considerable amounts of albumin (estimates range from 4000 to 9000 mg/d) inevitably cross the filtration barrier to be reclaimed by megalin and cubilin receptors along the proximal tubule. Remarkably, humans with normal nephrons do not excrete more than 8–10 mg of albumin in daily voided urine. This amount of albumin, and other proteins, can rise to gram quantities following glomerular injury.

The breadth of diseases affecting the glomerulus is expansive because the glomerular capillaries can be injured in a variety of ways, producing many different lesions and several unique changes to the urinalysis. Some order to this vast subject is brought by grouping all of these diseases into a smaller number of clinical syndromes.

PATHOGENESIS OF GLOMERULAR DISEASE

There are many forms of glomerular disease with pathogenesis variably linked to the presence of genetic mutations, infection, toxin exposure, autoimmunity, atherosclerosis, hypertension, emboli, thrombosis, or diabetes mellitus. Even after careful study, however, the cause often remains unknown, and the lesion is called *idiopathic*. Specific or unique features of pathogenesis are mentioned with the description of each of the glomerular diseases later in this chapter.

Some glomerular diseases result from genetic mutations producing familial disease. (1) Congenital nephrotic syndrome from mutations in *NPHS1* (nephrin) and *NPHS2* (podocin) affect the slit-pore mem-

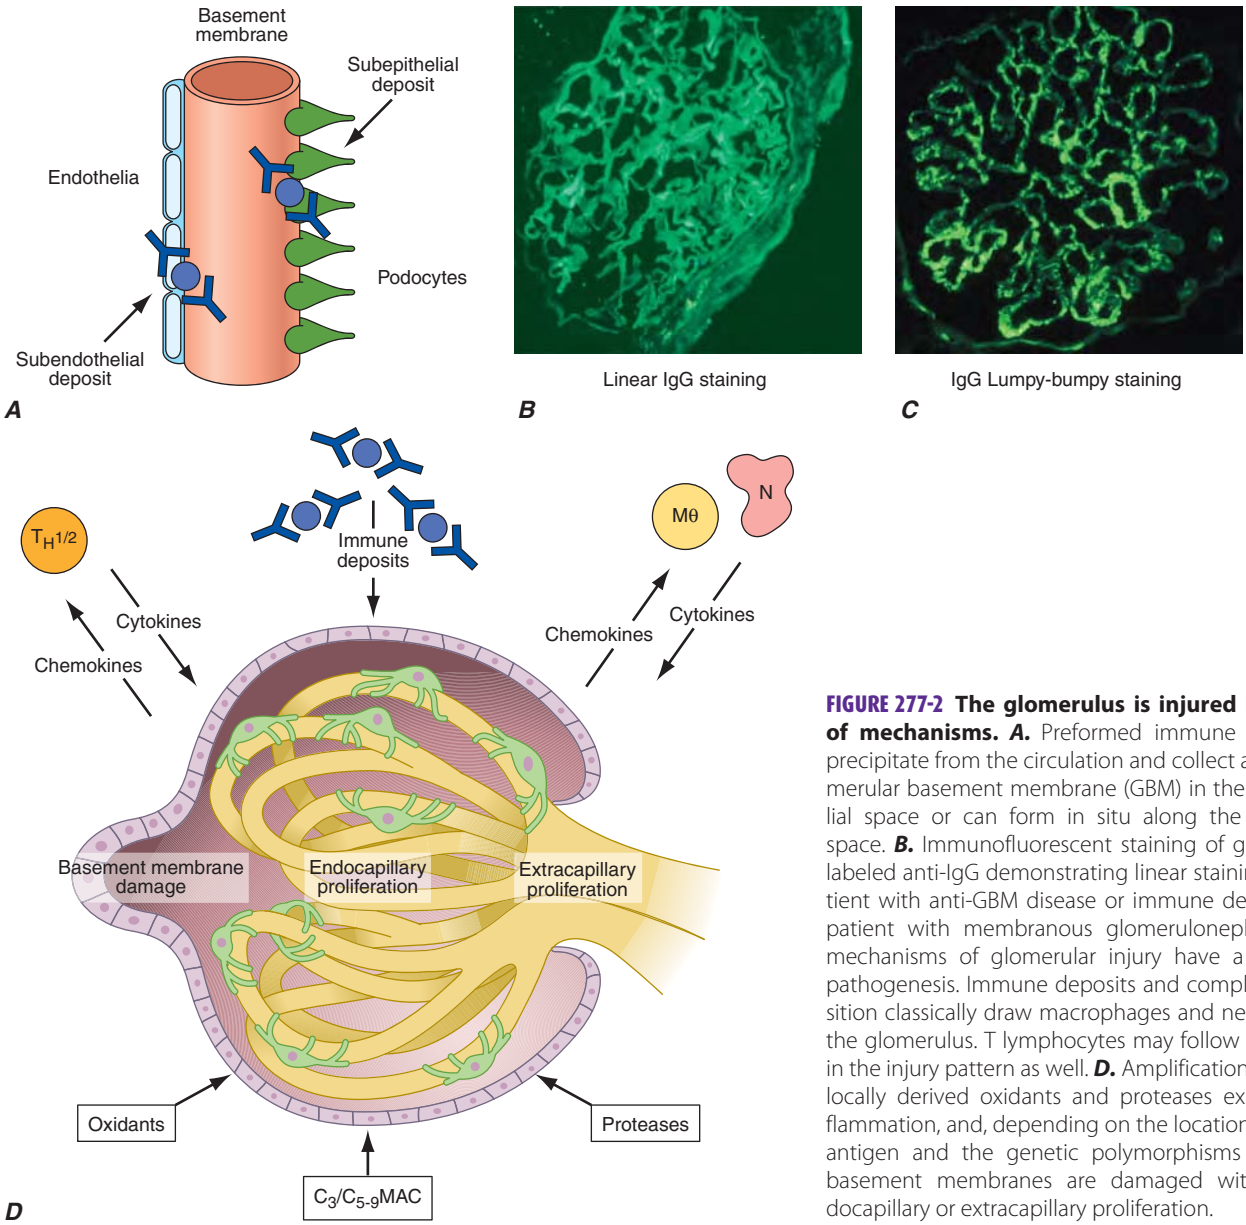

FIGURE 277-2 The glomerulus is injured by a variety of mechanisms. ***A.*** Preformed immune deposits can precipitate from the circulation and collect along the glomerular basement membrane (GBM) in the subendothelial space or can form in situ along the subepithelial space. ***B.*** Immunofluorescent staining of glomeruli with labeled anti-IgG demonstrating linear staining from a patient with anti-GBM disease or immune deposits from a patient with membranous glomerulonephritis. ***C.*** The mechanisms of glomerular injury have a complicated pathogenesis. Immune deposits and complement deposition classically draw macrophages and neutrophils into the glomerulus. T lymphocytes may follow to participate in the injury pattern as well. ***D.*** Amplification mediators as locally derived oxidants and proteases expand this inflammation, and, depending on the location of the target antigen and the genetic polymorphisms of the host, basement membranes are damaged with either endocapillary or extracapillary proliferation.

brane at birth, and *TRPC6* cation channel mutations in adulthood produce *focal segmental glomerulosclerosis* (FSGS). (2) Partial lipodystrophy from mutations in genes encoding lamin A/C or PPARγ cause a metabolic syndrome that can be associated with *membranoproliferative glomerulonephritis* (MPGN), which is sometimes accompanied by dense deposits and C3 nephritic factor. (3) Alport's syndrome, from mutations in the genes encoding for the α3, α4, or α5 chains of type IV collagen, produces *split-basement membranes* with *glomerulosclerosis*. (4) Lysosomal storage diseases, such as α-galactosidase A deficiency causing Fabry's disease and *N*-acetylneuraminic acid hydrolase deficiency causing nephrosialidosis, produce FSGS.

Systemic hypertension and atherosclerosis can produce pressure stress, ischemia, or lipid oxidants that lead to *chronic glomerulosclerosis. Malignant hypertension* can quickly complicate glomerulosclerosis with fibrinoid necrosis of arterioles and glomeruli, thrombotic microangiopathy, and acute renal failure. *Diabetic nephropathy* is an acquired sclerotic injury associated with thickening of the GBM secondary to the long-standing effects of hyperglycemia, advanced glycosylation endproducts, and reactive oxygen species.

Inflammation of the glomerular capillaries is called *glomerulonephritis*. Most glomerular or mesangial antigens involved in *immune-mediated glomerulonephritis* are unknown (Fig. 277-2). Glomerular epithelial or mesangial cells may shed them or express epitopes that mimic other immunogenic proteins made elsewhere in the body. Bacteria, fungi, and viruses can directly infect the kidney producing their own antigens. Autoimmune diseases like idiopathic *membranous glomerulonephritis* (MGN) or MPGN are confined to the kidney, while systemic inflammatory diseases like *lupus nephritis* or *Wegener's granulomatosis* spread to the kidney, causing secondary glomerular injury. *Antiglomerular basement membrane disease* producing Goodpasture's syndrome primarily injures both the lung and kidney because of the narrow distribution of the α3 NC1 domain of type IV collagen that is the target antigen.

While the adaptive immune response is similar to that of other tissues, early T cell activation plays an important role in the mechanism of glomerulonephritis. Antigens presented by class II major histocompatibility complex (MHC) molecules on macrophages and dendritic cells in conjunction with associative recognition molecules engage the CD4/8 T cell repertoire. Local activation of Toll-like receptors on glomerular cells, deposition of immune complexes, or complement injury to glomerular structures induces mononuclear cell infiltration, which subsequently leads to an adaptive immune response attracted to the kidney by local release of chemokines. Neutrophils, macrophages, and T cells are drawn by chemokines into the glomerular tuft, where they react with antigens and epitopes on or near somatic cells or their structures, producing more cytokines and proteases that damage the mesangium, capillaries, and/or the GBM.

Mononuclear cells by themselves can injure the kidney, but autoimmune events that damage glomeruli classically produce a humoral immune response. *Poststreptococcal glomerulonephritis*, *lupus nephritis*, and idiopathic *membranous nephritis* typically are associated with immune deposits along the GBM, while anti-GBM antibodies are produced in anti-GBM disease. Preformed circulating immune complexes can precipitate along the subendothelial side of the GBM, while other immune deposits form in situ on the subepithelial side. These latter deposits accumulate when circulating autoantibodies find their antigen trapped along the subepithelial edge of the GBM. Immune deposits in the glomerular mesangium may result from the deposition of preformed circulating complexes or in situ antigen-antibody interactions. Immune deposits can stimulate the release of local proteases and activate the complement cascade, producing $C_{5\text{-}9}$ attack complexes. In addition, local oxidants can damage glomerular structures, producing proteinuria and effacement of the podocytes. Overlapping etiologies or pathophysiologic mechanisms can produce similar glomerular lesions, suggesting that downstream molecular and cellular responses often converge towards common patterns of injury.

PROGRESSION OF GLOMERULAR DISEASE

Persistent glomerulonephritis that worsens renal function is always accompanied by interstitial nephritis, renal fibrosis, and tubular atrophy (**Fig. e9-25**). What is not so obvious, however, is that renal failure in glomerulonephritis best correlates histologically with the appearance of tubulointerstitial nephritis rather than with the type of inciting glomerular injury.

Loss of renal function due to interstitial damage can be explained hypothetically by several mechanisms. The simplest explanation is that urine flow is impeded by tubular obstruction as a result of interstitial inflammation and fibrosis. Thus, obstruction of the tubules with debris or by extrinsic compression results in aglomerular nephrons. A second mechanism suggests that interstitial changes, including interstitial edema or fibrosis, alter tubular and vascular architecture and thereby compromise the normal tubular transport of solutes and water from tubular lumen to vascular space. This failure increases the solute and water content of the tubule fluid, resulting in isothenuria and polyuria. Adaptive mechanisms related to tubuloglomerular feedback also fail, resulting in a reduction of renin output from the juxtaglomerular apparatus of glomeruli trapped by interstitial inflammation. Consequently, the local vasoconstrictive influence of angiotensin II on the glomerular arterioles decreases, and filtration drops owing to a generalized decrease in arteriolar tone. A third mechanism involves changes in vascular resistance due to damage of peritubular capillaries. The cross-sectional volume of these capillaries is decreased in areas of interstitial inflammation, edema, or fibrosis. These structural alterations in vascular resistance affect renal function through two mechanisms. First, tubular cells are very metabolically active, and, as a result, decreased perfusion could lead to ischemic injury. Second, impairment of glomerular arteriolar outflow leads to increased intraglomerular hypertension in less involved glomeruli; this selective intraglomerular hypertension aggravates and extends *mesangial sclerosis* and *glomerulosclerosis* to less-involved glomeruli. Regardless of the exact mechanism, early *acute tubulointerstitial nephritis* suggests potentially recoverable renal function, while the development of *chronic interstitial fibrosis* prognosticates a permanent loss.

Persistent damage to glomerular capillaries spreads to the tubulointerstitium in association with proteinuria. There is an untested hypothesis that efferent arterioles leading from inflamed glomeruli carry forward inflammatory mediators, which induces downstream interstitial nephritis, resulting in fibrosis. Glomerular filtrate from injured glomerular capillaries adherent to Bowman's capsule may also be misdirected to the periglomerular interstitium. Most nephrologists believe, however, that proteinuric glomerular filtrate forming tubular fluid is the primary route to downstream tubulointerstitial injury, although none of these hypotheses are mutually exclusive.

The simplest explanation for the effect of proteinuria on the development of interstitial nephritis is that increasingly severe proteinuria, carrying activated cytokines and lipoproteins producing reactive oxygen species, triggers a downstream inflammatory cascade in and around epithelial cells lining the tubular nephron. These effects induce T lymphocyte and macrophage infiltrates in the interstitial spaces along with fibrosis and tubular atrophy. **The details of this process are described in Chap. 272.**

Tubules disappear following direct damage to their basement membranes, leading to decondensation and epithelial-mesenchymal transitions forming more interstitial fibroblasts at the site of injury. Transforming growth factor β (TGF-β), fibroblast growth factor 2, and platelet-derived growth factor (PDGF) are particularly active in this transition. With persistent nephritis, fibroblasts multiply and lay down tenascin and a fibronectin scaffold for the polymerization of new interstitial collagens I/III. These events form scar tissue through a process called fibrogenesis. In experimental studies, bone morphogenetic protein 7 and hematopoietic growth factor can reverse early fibrogenesis and preserve tubular architecture. When fibroblasts outdistance their survival factors, they apoptose, and the permanent renal scar becomes acellular, leading to irreversible renal failure.

APPROACH TO THE PATIENT: Glomerular Disease

HEMATURIA, PROTEINURIA, AND PYURIA Patients with glomerular disease usually have some hematuria with varying degrees of proteinuria. Hematuria is typically asymptomatic. As little as 3–5 red blood cells in the spun sediment from first voided morning urine is suspicious. The diagnosis of glomerular injury can be delayed because patients will not realize they have *microscopic hematuria*, and only rarely with the exception of IgA nephropathy and sickle cell disease is *gross hematuria* present. When working up microscopic hematuria, perhaps accompanied by minimal proteinuria (<500 mg/24 h), it is important to exclude anatomic lesions, such as malignancy of the urinary tract, particularly in older men. Microscopic hematuria may also appear with the onset of benign prostatic hypertrophy, interstitial nephritis, papillary necrosis, renal stones, cystic kidney diseases, or renal vascular injury. However, when red blood cell casts (**Fig. e9-31**) or dysmorphic red blood cells are found in the sediment, glomerulonephritis is likely.

Sustained proteinuria >1–2 g/24 h is also commonly associated with glomerular disease. Patients often will not know they have proteinuria unless they become edematous or notice foamy urine on voiding. *Sustained proteinuria* has to be distinguished from lesser amounts of so-called *benign proteinuria* in the normal population (**Table 277-1**). This latter class of proteinuria is nonsustained, generally <1 g/24 h, and is sometimes called *functional* or *transient proteinuria.* Fever, exercise, obesity, sleep apnea, emotional stress, and congestive heart failure can explain transient proteinuria. Proteinuria only seen with upright posture is called *orthostatic proteinuria.* Occasionally, isolated proteinuria sustained over multiple clinic visits is found in diabetic nephropathy, *nil lesion, mesangioproliferative glomerulonephritis,* and FSGS. Proteinuria in most adults with glomerular disease is *nonselective,* containing albumin and a mixture of other serum proteins, while in children with nil

TABLE 277-1 URINE ASSAYS FOR ALBUMINURIA/PROTEINURIA

	24-Hour Albumin[a] (mg/24 h)	Albumin[a]/ Creatinine Ratio (mg/G)	Dipstick Proteinuria	24-Hour Urine Protein[b] (mg/ 24 h)
Normal	8–10	<30	–	<150

Proteinuria	>300	>300	Trace–3+	>150

[a]Albumin detected by radioimmunoassay.
[b]Albumin represents 30–70% of the total protein excreted in the urine.

lesion from *minimal change disease*, the proteinuria is *selective* and largely composed of albumin.

Some patients with inflammatory glomerular disease, such as acute poststreptococcal glomerulonephritis or MPGN, may have *pyuria* caused by the presence of considerable numbers of leukocytes in the urine. This latter finding has to be distinguished from urine infected with bacteria.

CLINICAL SYNDROMES Various forms of glomerular injury can also be parsed into several distinct syndromes on clinical grounds (Table 277-2). These syndromes, however, are not always mutually exclusive. There is an *acute nephritic syndrome* producing 1–2 g/24 h of proteinuria, hematuria with red blood cell casts, pyuria, hypertension, fluid retention, and a rise in serum creatinine associated with a reduction in glomerular filtration. If glomerular inflammation develops slowly, the serum creatinine will rise gradually over many weeks, but if the serum creatinine rises quickly, particularly over a few days, acute nephritis is sometimes called *rapidly progressive glomerulonephritis* (RPGN); the histopathologic term *crescentic glomerulonephritis* refers to the clinical occurrence of RPGN in a patient with this characteristic glomerular lesion. When patients with RPGN present with lung hemorrhage from Goodpasture's syndrome, antineutrophil cytoplasmic antibodies (ANCA) small-vessel vasculitis, lupus erythematosus, or cryoglobulinemia, they are often diagnosed as having a *pulmonary-renal syndrome*. *Nephrotic syndrome* describes the onset of heavy proteinuria (>3.0 g/24 h), hypertension, hypercholesterolemia, hypoalbuminemia, edema/anasarca, and microscopic hematuria; if only large amounts of proteinuria are present without clinical manifestations, the condition is sometimes called *nephrotic-range proteinuria*. The glomerular filtration rate (GFR) in these patients may initially be normal or, rarely, higher than normal, but with persistent hyperfiltration and continued nephron loss, it typically declines over months to years. Patients with a *basement membrane syndrome* either have genetically abnormal basement membranes or an autoimmune response to basement membrane collagen IV associated with microscopic hematuria, mild to heavy proteinuria, and hypertension with variable elevations in serum creatinine. *Glomerular-vascular syndrome* describes patients with vascular injury producing hematuria and moderate proteinuria. Affected individuals can have vasculitis, thrombotic microangiopathy, antiphospholipid syndrome, or, more commonly, a systemic disease such as atherosclerosis, cholesterol emboli, hypertension, sickle cell anemia, and autoimmunity. *Infectious diseases-asso-*

[a]Can present as rapidly progressive glomerulonephritis (RPGN); sometimes called crescentic glomerulonephritis.
[b]Can present as a malignant hypertensive crisis producing an aggressive fibrinoid necrosis in arterioles small arteries with microangiopathic hemolytic anemia.
[c]Can present with gross hematuria.
Abbreviations: ANCA, antineutrophil cytoplasmic antibodies; AL, amyloid L; AA, amyloid A; GBM, glomerular basement membrane.

ciated syndrome is most important if one has an international perspective. Save for subacute bacterial endocarditis in the Western Hemisphere, malaria and schistosomiasis may be the most common causes of glomerulonephritis throughout the world, closely followed by HIV and chronic hepatitis B and C. These infectious diseases produce a variety of inflammatory reactions in glomerular capillaries, ranging from nephrotic syndrome to acute nephritic injury, and yield urinalyses that demonstrate a combination of hematuria and proteinuria.

These six general categories of syndromes are usually determined at the bedside with the help of a history and physical examination, blood chemistries, renal ultrasound, and urinalysis. These initial studies help frame further diagnostic work up that typically involves some testing of the serum for the presence of various proteins (HIV and hepatitis B and C antigens), antibodies [anti-GBM, antiphospholipid, ASO, anti-DNAase, antihyaluronidase, ANCA, anti-DNA, cryoglobulins, anti-HIV, and anti-hepatitis B and C antibodies] or depletion of complement components (C_3 and C_4). The bedside history and physical examination can also help determine whether the glomerulonephritis is isolated to the kidney (*primary glomerulonephritis*) or is part of a systemic disease (*secondary glomerulonephritis*). When confronted with an abnormal urinalysis and elevated serum creatinine, with or without edema or congestive heart failure, one must consider whether the glomerulonephritis is *acute* or *chronic*. This assessment is best made by careful history (last known urinalysis or serum creatinine during pregnancy or insurance physical, evidence of infection, or use of medication or recreational drugs); the size of the kidneys on renal ultrasound examination; and how the patient feels at presentation. Chronic glomerular disease often presents with decreased kidney size. Patients who quickly develop renal failure are fatigued and weak; feel miserable; often have uremic symptoms associated with nausea, vomiting, fluid retention, and somnolence. Primary glomerulonephritis presenting with renal failure that has progressed slowly, however, can be remarkably asymptomatic, as are patients with acute glomerulonephritis without much loss in renal function. Once this initial information is collected, selected patients who are clinically stable, have adequate blood clotting parameters, and are willing to receive treatment are encouraged to have a renal biopsy. Biopsies can be done safely with an ultrasound-guided biopsy gun.

RENAL PATHOLOGY

A renal biopsy in the setting of glomerulonephritis can quickly identify the type of glomerular injury and often suggests a course of treatment. The biopsy is processed for light microscopy using stains for *hematoxylin and eosin* (H&E) to assess cellularity and architecture, *periodic acid-Schiff* (PAS) to stain carbohydrate moieties in the membranes of the glomerular tuft and tubules, *Jones-methenamine silver* to enhance basement membrane structure, *Congo red* for amyloid deposits, and *Masson's trichrome* to identify collagen deposition and assess the degree of glomerulosclerosis and interstitial fibrosis. Biopsies are also processed for direct immunofluorescence using conjugated antibodies against IgG, IgM, and IgA to detect the presence of "lumpy-bumpy" immune deposits or "linear" IgG or IgA antibodies bound to GBM, antibodies against trapped complement proteins (C_3 and C_4), or specific antibodies against a relevant antigen. High-resolution electron microscopy can clarify the principal location of immune deposits and the status of the basement membrane.

Each region of a renal biopsy is assessed separately. By light microscopy, glomeruli (at least 10 and ideally 20) are reviewed individually for discrete lesions; <50% involvement is considered *focal*, and >50% is *diffuse*. Injury in each glomerular tuft can be *segmental*, involving a portion of the tuft, or *global*, involving most of the glomerulus. Glomeruli can have *proliferative* characteristics, showing increased cellularity. When cells in the capillary tuft proliferate, it is called *endocapillary*, and when cellular proliferation extends into Bowman's space, it is called *extracapillary*. *Synechiae* are formed when epithelial podocytes attach to Bowman's capsule in the setting of glomerular injury; *crescents*, which in some cases may be the extension of synechiae, develop when fibrocellular/fibrin collections fill all or part of Bowman's space; and *sclerotic* glomeruli show acellular, amorphous accumulations of proteinaceous material throughout the tuft with loss of functional capillaries and normal mesangium. Since *age-related glomerulosclerosis* is common in adults, one can estimate the background percentage of sclerosis by dividing the patient's age in half and subtracting 10. Immunofluorescent and electron microscopy can detect the presence and location of *subepithelial, subendothelial, or mesangial* immune deposits, or *reduplication* or *splitting* of the basement membrane. In the other regions of the biopsy, the vasculature surrounding glomeruli and tubules can show *angiopathy, vasculitis*, the presence of *fibrils*, or *thrombi*. The tubules can be assessed for adjacency to one another; separation can be the result of edema, tubular dropout, or collagen deposition resulting from interstitial fibrosis. Interstitial fibrosis is an ominous sign of irreversibility and progression to renal failure.

ACUTE NEPHRITIC SYNDROMES

Acute nephritic syndromes classically present with hypertension, hematuria, red blood cell casts, pyuria, and mild to moderate proteinuria. Extensive inflammatory damage to glomeruli can cause a fall in GFR and eventually produce uremic symptoms with salt and water retention, leading to edema and hypertension.

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Poststreptococcal glomerulonephritis is prototypical for *acute endocapillary proliferative glomerulonephritis*. The incidence of poststreptococcal glomerulonephritis is decreasing in Western countries, and it is typically sporadic. Epidemic cases are still seen, though less commonly. Acute poststreptococcal glomerulonephritis typically affects children between the ages of 2 and 14 years, but 10% of cases are patients older than 40. It is more common in males, and the familial or cohabitant incidence is as high as 40%. Skin and throat infections with particular M types of streptococci (nephritogenic strains) antedate glomerular disease; M types 47, 49, 55, 2, 60, and 57 are seen following impetigo and M types 1, 2, 4, 3, 25, 49, and 12 with pharyngitis. Poststreptococcal glomerulonephritis due to impetigo develops 2–6 weeks after skin infection and 1–3 weeks after streptococcal pharyngitis.

The renal biopsy in poststreptococcal glomerulonephritis demonstrates hypercellularity of mesangial and endothelial cells, glomerular infiltrates of polymorphonuclear leukocytes, granular subendothelial immune deposits of IgG, IgM, C_3, C_4, and $C_{5\text{-}9}$, and subepithelial deposits (which appear as "humps") (**Fig. e9-4**). Poststreptococcal glomerulonephritis is an immune-mediated disease involving putative streptococcal antigens, circulating immune complexes, and activation of complement in association with cell-mediated injury. Many candidate antigens have been proposed over the years; three such candidates from nephritogenic streptococci are zymogen, a precursor of exotoxin B; glyceraldehyde phosphate dehydrogenase, also known as presorbing antigen (PA-Ag); and streptokinase. All have a biochemical affinity for GBMs, and in this location they may act as a target for antibodies.

The classic presentation is an acute nephritic picture with hematuria, pyuria, red blood cell casts, edema, hypertension, and oliguric renal failure, which may be severe enough to appear as RPGN. Systemic symptoms of headache, malaise, anorexia, and flank pain (due to swelling of the renal capsule) are reported in as many as 50% of cases. Five percent of children and 20% of adults have proteinuria in the nephrotic range. In the first week of symptoms, 90% of patients will have a depressed CH_{50} and decreased levels of C_3 with normal levels of C_4. Positive rheumatoid factor (30–40%), cryoglobulins and circulating immune complexes (60–70%), and ANCA against myeloperoxidase (10%) are also reported. Positive cultures for streptococcal infection are inconsistently present (10–70%), but increased titers of ASO (30%), anti-DNAase (70%) or antihyaluronidase antibodies (40%) can help confirm the diagnosis. Consequently, the diagnosis of

poststreptococcal glomerulonephritis rarely requires a renal biopsy. A subclinical disease is reported in some series to be four to five times as common as clinical nephritis, and these latter cases are characterized by asymptomatic microscopic hematuria with low serum complement levels. Treatment is supportive, with control of hypertension, edema, and dialysis as needed. Antibiotic treatment for streptococcal infection should be given to all patients and their cohabitants. There is no role for immunosuppressive therapy, even in the setting of crescents. Recurrent poststreptococcal glomerulonephritis is rare despite repeated streptococcal infections. Early death is rare in children but does occur in the elderly. Overall, the prognosis is good, with permanent renal failure being very uncommon (1–3%), and even less so in children. Complete resolution of the hematuria and proteinuria in children occurs within 3–6 weeks of the onset of nephritis.

SUBACUTE BACTERIAL ENDOCARDITIS

Endocarditis-associated glomerulonephritis is typically a complication of subacute bacterial endocarditis, particularly in patients who remain untreated for a long time, have negative blood cultures, or have right-sided endocarditis. Glomerulonephritis is unusual in acute bacterial endocarditis because it takes 10–14 days to develop immune complex–mediated injury, by which time the patient has been treated, often with emergent surgery. Grossly, the kidneys in subacute bacterial endocarditis have subcapsular hemorrhages with a "flea-bitten" appearance, and microscopy on renal biopsy reveals a focal proliferation around foci of necrosis associated with abundant mesangial, subendothelial, and subepithelial immune deposits of IgG, IgM, and C_3. Patients who present with a clinical picture of RPGN have crescents. Embolic infarcts or septic abscesses may also be present. The pathogenesis hinges on the renal deposition of circulating immune complexes in the kidney with complement activation. Patients present with gross or microscopic hematuria, pyuria, and mild proteinuria or, less commonly, RPGN with rapid loss of renal function. A normocytic anemia, elevated erythrocyte sedimentation rate, hypocomplementemia, high titers of rheumatoid factor, type III cryoglobulins, and circulating immune complexes are often present. Levels of serum creatinine may be elevated at diagnosis, but with modern therapy there is little progression to chronic renal failure. Primary treatment is eradication of the infection with 4–6 weeks of antibiotics, and if accomplished expeditiously, the prognosis for renal recovery is good.

As variants of persistent bacterial infection in blood, glomerulonephritis can occur in patients with ventriculoatrial and ventriculoperitoneal shunts; pulmonary, intra-abdominal, pelvic, or cutaneous infections; and infected vascular prostheses. The clinical presentation of these conditions is variable and includes proteinuria, microscopic hematuria, and acute renal failure. Blood cultures are usually positive and serum complement levels low, and there may be elevated levels of C-reactive proteins, rheumatoid factor, antinuclear antibodies, and cryoglobulins. Renal lesions include membranoproliferative glomerulonephritis (MPGN), diffuse proliferative glomerulonephritis (DPGN), or mesangioproliferative glomerulonephritis, sometimes leading to RPGN. Treatment focuses on eradicating the infection, with most patients treated as if they have endocarditis.

LUPUS NEPHRITIS

Lupus nephritis is a common and serious complication of systemic lupus erythematosus (SLE) and most severe in African-American female adolescents. Thirty to fifty percent of patients will have clinical manifestations of renal disease at the time of diagnosis, and 60% of adults and 80% of children develop renal abnormalities at some point in the course of their disease. Lupus nephritis results from the deposition of circulating immune complexes, which activate the complement cascade leading to complement-mediated damage, leukocyte infiltration, activation of procoagulant factors, and release of various cytokines. In situ immune complex formation following glomerular binding of nuclear antigens may also play a role in renal injury. The presence of antiphospholipid antibodies may trigger a thrombotic microangiopathy in a minority of patients.

TABLE 277-3 CLASSIFICATION FOR LUPUS NEPHRITIS

Class I	Minimal mesangial	Normal histology with mesangial deposits
Class II	Mesangial proliferation	Mesangial hypercellularity with expansion of the mesangial matrix
Class III	Focal nephritis	Focal endocapillary ± extracapillary proliferation with focal subendothelial immune deposits and mild mesangial expansion
Class IV	Diffuse nephritis	Diffuse endocapillary ± extracapillary proliferation with diffuse subendothelial immune deposits and mesangial alterations
Class V	Membranous nephritis	Thickened basement membranes with diffuse subepithelial immune deposits; may occur with Class III or IV lesions and is sometimes called mixed membranous and proliferative nephritis
Class VI	Sclerotic nephritis	Global sclerosis of nearly all glomerular capillaries

Note: Revised in 2004 by the International Society of Nephrology-Renal Pathology Society Study Group.

The clinical manifestations, course of disease, and treatment of lupus nephritis are closely linked to the renal pathology. The most common clinical sign of renal disease is proteinuria, but hematuria, hypertension, varying degrees of renal failure, and an active urine sediment with red blood cell casts can all be present. Although significant renal pathology can be found on biopsy even in the absence of major abnormalities in the urinalysis, most nephrologists do not biopsy patients until the urinalysis is convincingly abnormal. The extrarenal manifestations of lupus are important in establishing a firm diagnosis of systemic lupus because, while serologic abnormalities are common in lupus nephritis, they are not diagnostic. Anti-dsDNA antibodies that fix complement correlate best with the presence of renal disease. Hypocomplementemia is common in patients with acute lupus nephritis (70–90%) and declining complement levels may herald a flare. Renal biopsy, however, is the only reliable method of identifying the morphologic variants of lupus nephritis.

The World Health Organization (WHO) workshop in 1974 first outlined several distinct patterns of lupus-related glomerular injury; these were modified in 1982. In 2004 the International Society of Nephrology in conjunction with the Renal Pathology Society again updated the classification. This latest version of lesions seen on biopsy (Table 277-3) best defines clinicopathologic correlations, provides valuable prognostic information, and forms the basis for modern treatment recommendations. Class I nephritis describes normal glomerular histology by any technique or normal light microscopy with minimal mesangial deposits on immunofluorescent or electron microscopy. Class II designates mesangial immune complexes with *mesangial proliferation.* Both Class I and II lesions are typically associated with minimal renal manifestation and normal renal function; nephrotic syndrome is rare. Patients with lesions limited to the renal mesangium have an excellent prognosis and generally do not need therapy for their lupus nephritis.

The subject of lupus nephritis is presented under acute nephritic syndromes because of the aggressive and important proliferative lesions seen in Class III–V renal disease. Class III describes *focal lesions with proliferation or scarring*, often involving only a segment of the glomerulus (Fig. e9-10). Class III lesions have the most varied course. Hypertension, an active urinary sediment, and proteinuria are common with nephrotic-range proteinuria in 25–33% of patients. Elevated serum creatinine is present in 25% of patients. Patients with mild proliferation involving a small percentage of glomeruli respond well to therapy with steroids alone, and fewer than 5% progress to renal failure over 5 years. Patients with more severe proliferation involving a greater percentage of glomeruli have a far worse prognosis and may have lower remission rates. Treatment of those patients is the same as that for Class IV lesions, as some nephrologists believe that Class III le-

sions are simply an early presentation of Class IV disease. Class IV describes *global, diffuse proliferative lesions* involving the vast majority of glomeruli. Patients with Class IV lesions commonly have high anti-DNA antibody titers, low serum complement, hematuria, red blood cell casts, proteinuria, hypertension, and decreased renal function; 50% of patients have nephrotic-range proteinuria. Patients with crescents on biopsy may have a rapidly progressive decline in renal function. Without treatment, this aggressive lesion has the worst renal prognosis. However, if a remission—defined as a return to near-normal renal function and proteinuria ≤330 mg/dL per day—is achieved with treatment, renal outcomes are excellent. Treatment must combine high-dose steroids with either cyclophosphamide or mycophenolate mofetil. Current evidence suggests that inducing a remission with administration of steroids and either cyclophosphamide or mycophenolate mofetil for 2–6 months, followed by maintenance therapy with lower doses of steroids and mycophenolate mofetil, may best balance the likelihood of successful remission with the side effects of therapy. There is no consensus on use of high-dose intravenous methylprednisolone versus oral prednisone, monthly intravenous cyclophosphamide versus daily oral cyclophosphamide, or other immunosuppressants such as cyclosporine or azathioprine. Nephrologists tend to avoid prolonged use of cyclophosphamide in patients of childbearing age without first banking eggs or sperm.

The Class V lesion describes subepithelial immune deposits producing a *membranous pattern;* a subcategory of Class V lesions is associated with proliferative lesions and is sometimes called *mixed membranous and proliferative disease;* this category of injury is treated like Class IV glomerulonephritis. Sixty percent of patients present with nephrotic syndrome or lesser amounts of proteinuria. Patients with lupus nephritis Class V, like patients with *idiopathic membranous nephropathy*, are predisposed to renal-vein thrombosis and other thrombolic complications. A minority of patients with Class V will present with hypertension and renal dysfunction. There are conflicting data on the clinical course, prognosis, and appropriate therapy for patients with Class V disease, which may reflect the heterogeneity of this group of patients. Patients with severe nephrotic syndrome, elevated serum creatinine, and a progressive course will probably benefit from therapy with steroids in combination with other immunosuppressive agents. Therapy with inhibitors of the renin-angiotensin system also may attenuate the proteinuria.

Patients with any of the above lesions also can transform to another lesion; hence patients often require reevaluation, including repeat renal biopsy. Lupus patients with Class VI lesions have greater than 90% *sclerotic glomeruli* and end-stage renal disease with interstitial fibrosis. As a group, approximately 20% of patients with lupus nephritis will reach end-stage disease, requiring dialysis or transplantation. Systemic lupus tends to become quiescent once there is renal failure, perhaps due to the immunosuppressant effects of uremia. Renal transplantation in renal failure from lupus, usually performed after approximately 6 months of inactive disease, results in allograft survival rates comparable to patients transplanted for other reasons.

ANTIGLOMERULAR BASEMENT MEMBRANE DISEASE

Patients who develop autoantibodies directed against glomerular basement antigens frequently develop a glomerulonephritis termed *antiglomerular basement membrane (anti-GBM) disease.* When they present with lung hemorrhage and glomerulonephritis, they have a pulmonary-renal syndrome called *Goodpasture's syndrome.* The target epitopes for this autoimmune disease lie in the quaternary structure of α3 NC1 domain of collagen IV. MHC-restricted T cells initiate the autoantibody response because humans are not tolerant to the epitopes created by this quaternary structure. The epitopes are normally sequestered in the collagen IV hexamer and can be exposed by infection, smoking, oxidants, or solvents. Goodpasture's syndrome appears in two age groups: in young men in their late 20s and in men and women in their 60–70s. Disease in the younger age group is usually explosive, with hemoptysis, a sudden fall in hemoglobin, fever, dyspnea, and hematuria. Hemoptysis is largely confined to smokers, and those who present with lung hemorrhage as a group do better than older populations who have prolonged, asymptomatic renal injury; presentation with oliguria is often associated with a particularly bad outcome. The performance of an urgent kidney biopsy is important in suspected cases of Goodpasture's syndrome to confirm the diagnosis and assess prognosis. Renal biopsies typically show *focal or segmental necrosis* that later, with aggressive destruction of the capillaries by cellular proliferation, leads to crescent formation in Bowman's space (**Fig. e9-12**). As these lesions progress, there is concomitant interstitial nephritis with fibrosis and tubular atrophy. The presence of anti-GBM antibodies and complement is recognized on biopsy by linear immunofluorescent staining for IgG (rarely IgA). In testing serum for anti-GBM antibodies, it is particularly important that the α3 NC1 domain of collagen IV alone be used as the target. This is because nonnephritic antibodies against the α1 NC1 domain are seen in paraneoplastic syndromes and cannot be discerned from assays that use whole basement membrane fragments as the binding target. Between 10–15% of sera from patients with Goodpasture's syndrome also contain ANCA antibodies against myeloperoxidase. This subset of patients has a vasculitis-associated variant, which has a surprisingly good prognosis with treatment. Prognosis at presentation is worse if there are >50% crescents on renal biopsy with advanced fibrosis, if serum creatinine is >5–6 mg/dL, if oliguria is present, or if there is a need for acute dialysis. Although frequently attempted, most of these latter patients will not respond to plasmapheresis and steroids. Patients with advanced renal failure who present with hemoptysis should still be treated for their lung hemorrhage, as it responds to plasmapheresis and can be lifesaving. Treated patients with less severe disease typically respond to 8–10 treatments of plasmapheresis accompanied by oral prednisone and cyclophosphamide in the first 2 weeks. Kidney transplantation is possible, but because there is risk of recurrence, experience suggests that patients should wait for 6 months and until serum antibodies are undetectable.

IgA NEPHROPATHY

Berger first described the glomerulonephritis termed *IgA nephropathy*. It is classically characterized by episodic hematuria associated with the deposition of IgA in the mesangium. IgA nephropathy is one of the most common forms of glomerulonephritis worldwide. There is a male preponderance, a peak incidence in the second and third decades of life, and rare familial clustering. There are geographic differences in the prevalence of IgA nephropathy, with 30% prevalence along the Asian and Pacific Rim and 20% in southern Europe, compared to lower prevalence in northern Europe and North America. It was initially hypothesized that variation in detection, in part, reflected regional differences in the recognition of asymptomatic microscopic hematuria or the frequency of renal biopsies. With clinical care in nephrology becoming more uniform and regional reports coming largely from larger cities, however, this variation in prevalence more likely reflects true differences among racial and ethnic groups. Clinical and laboratory evidence suggests close similarities between Henoch-Schönlein purpura and IgA nephropathy. Henoch-Schönlein purpura is distinguished clinically from IgA nephropathy by prominent systemic symptoms, a younger age (<20 years old), preceding infection, and abdominal complaints. Deposits of IgA are also found in the glomerular mesangium in a variety of systemic diseases, including chronic liver disease, Crohn's disease, gastrointestinal adenocarcinoma, chronic obstructive bronchiectasis, idiopathic interstitial pneumonia, dermatitis herpetiformis, mycosis fungoides, leprosy, ankylosing spondylitis, relapsing polychondritis, and Sjögren's syndrome. IgA deposition in these entities is not usually associated with clinically significant glomerular inflammation or renal dysfunction and thus is not called IgA nephropathy.

IgA nephropathy is an immune complex-mediated glomerulonephritis defined by the presence of diffuse mesangial IgA deposits often associated with mesangial hypercellularity. IgM, IgG, C_3, or immunoglobulin light chains may be codistributed with IgA. IgA deposited in the mesangium is typically polymeric and of the IgA1 subclass, the pathogenic significance of which is not clear. Abnormalities have been described in IgA production by plasma cells, particularly secretory

IgA; in IgA *O*-glycosylation; in IgA clearance, predominately by the liver; in mesangial IgA clearance and receptors for IgA; and in growth factor and cytokine-mediated events. Despite the presence of elevated serum IgA levels in 20–50% of patients, IgA deposition in skin biopsies in 15–55% of patients, or elevated levels of secretory IgA and IgA-fibronectin complexes, a renal biopsy is necessary to make the diagnosis. Although the immunofluorescent pattern of IgA on renal biopsy defines IgA nephropathy in the proper clinical context, a variety of histologic lesions may be seen on light microscopy (**Fig. e9-6**), including DPGN; *segmental sclerosis*; and, rarely, *segmental necrosis with cellular crescent formation*, which typically presents as RPGN.

The two most common presentations of IgA nephropathy are recurrent episodes of macroscopic hematuria during or immediately following an upper respiratory infection in children (Henoch-Schönlein purpura) or asymptomatic microscopic hematuria most often seen in adults. Between episodes, the urinalysis is normal. When the hematuria persists, one finds increasing amounts of proteinuria; nephrotic syndrome, however, is uncommon. The presence or absence of proteinuria at the time of diagnosis often determines whether patients with asymptomatic hematuria are biopsied, which reflects the bias in habits of clinical practice. Proteinuria can occur late in the course of the disease. Rarely, patients can present with acute renal failure and a rapidly progressive clinical picture. IgA nephropathy is a benign disease for the majority of patients, with progression to renal failure seen in only 25–30% over 20–25 years; in fact, 5–30% of patients go into complete remission. Risk factors for the loss of renal function include the presence of hypertension or proteinuria, the absence of episodes of macroscopic hematuria, male age, older age of onset, and more severe changes on renal biopsy.

There is no agreement on optimal treatment. Both large studies that include patients with multiple glomerular diseases or small studies of patients with IgA nephropathy support the use of angiotensin-converting enzyme (ACE) inhibitors in patients with proteinuria or declining renal function. Tonsillectomy, steroid therapy, and fish oil have all been suggested in small studies to benefit select patients with IgA nephropathy. When presenting as RPGN, patients typically receive steroids, cytotoxic agents, and plasmapheresis.

ANCA SMALL VESSEL VASCULITIS

A group of patients with small-vessel vasculitis (arterioles, capillaries, and venules; rarely small arteries) and glomerulonephritis have serum ANCA; the antibodies are of two types, anti-proteinase 3 (PR3) or anti-myeloperoxidase (MPO) (Chap. 319). ANCA are produced with the help of T cells and activate leukocytes and monocytes, which together damage the walls of small vessels. Endothelial injury also attracts more leukocytes and extends the inflammation. Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome belong to this group because they are ANCA-positive and have a *pauci-immune glomerulonephritis* with few immune complexes in small vessels and glomerular capillaries. Patients with any of these three diseases can have any combination of the above serum antibodies, but anti-PR3 antibodies are more common in Wegener's and anti-MPO antibodies are more common in microscopic polyangiitis or Churg-Strauss. While each of these diseases have some unique clinical features, most features do not predict relapse or progression, and as a group they are generally treated in the same way. Only the presence of upper-airway involvement, persistent pulmonary injury, and anti-PR3 antibodies suggests that the course of disease will be more difficult. Induction therapy usually includes some combination of plasmapheresis, methylprednisolone, and cyclophosphamide. The benefit of plasmapheresis in this setting is uncertain. The steroids are tapered soon after acute inflammation subsides, and patients are maintained on cyclophosphamide or azathioprine for up to a year to minimize the risk of relapse.

Wegener's Granulomatosis Patients with this disease classically present with fever, purulent rhinorrhea, nasal ulcers, sinus pain, polyarthralgias/arthritis, cough, hemoptysis, shortness of breath, microscopic hematuria, and 0.5–1 g/24 h of proteinuria; occasionally there may be cutaneous purpura and mononeuritis multiplex. Presentation without renal involvement is termed *limited Wegener's granulomatosis*, although some of these patients will show signs of renal injury later. Chest x-ray often reveals nodules and persistent infiltrates, sometimes with cavities. Biopsy of involved tissue will show a small-vessel vasculitis and adjacent noncaseating granulomas. Renal biopsies during active disease demonstrate *segmental necrotizing glomerulonephritis* without immune deposits (**Fig. e9-11**). The cause of Wegner's granulomatosis is unknown. In case-controlled studies there is greater risk associated with exposure to silica dust. The disease is also more common in patients with α_1 antitrypsin deficiency, which is an inhibitor of PR3.

Microscopic Polyangiitis Clinically, these patients look somewhat similar to those with Wegener's granulomatosis, except they rarely have significant lung disease or destructive sinusitis. The distinction is made on biopsy where the vasculitis in microscopic polyangiitis is without granulomas. Some patients will also have injury limited to the capillaries and venules.

Churg-Strauss Syndrome When small-vessel vasculitis is associated with peripheral eosinophilia, cutaneous purpura, mononeuritis, asthma, and allergic rhinitis, a diagnosis of Churg-Strauss syndrome is considered. Hypergammaglobulinemia, elevated levels of serum IgE, or the presence of rheumatoid factor sometimes accompanies the allergic state. Lung inflammation, including fleeting cough and pulmonary infiltrates, often precedes the systemic manifestations of disease by years; lung manifestations are rarely absent. A third of patients may have exudative pleural effusions associated with eosinophils. Small-vessel vasculitis and *focal segmental necrotizing glomerulonephritis* can be seen on renal biopsy, usually absent eosinophils or granulomas. The cause of Churg-Strauss syndrome is autoimmune, but the inciting factors are unknown. Interestingly, some asthma patients treated with leukotriene receptor antagonists will develop this vasculitis.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

MPGN is sometimes called *mesangiocapillary glomerulonephritis* or *lobar glomerulonephritis.* It is an immune-mediated glomerulonephritis characterized by thickening of the GBM with mesangioproliferative changes; 70% of patients have hypocomplementemia. MPGN is rare in African Americans, and idiopathic disease usually presents in childhood or young adulthood. MPGN is subdivided pathologically into Type I, Type II, and Type III disease. *Type I MPGN* is commonly associated with persistent hepatitis C infections, autoimmune diseases like lupus or cryoglobulinemia, or neoplastic diseases (**Table 277-4**). *Types II and III MPGN* are usually idiopathic, except in the presence of C_3 nephritic factor and/or in partial lipodystrophy producing Type II disease or complement receptor deficiency in Type III disease.

Type I MPGN, the most proliferative of the three types, shows mesangial proliferation with lobular segmentation on renal biopsy and

mesangial interposition between the capillary basement membrane and endothelial cells, producing a double contour sometimes called *tram-tracking* (**Figs. e9-7** and **e9-9**). Subendothelial deposits with low serum levels of C_3 are typical, although 50% of patients have normal levels of C_3 and occasional intra-mesangial deposits. Low serum C_3 and a dense thickening of the GBM containing ribbons of dense deposits and C_3 characterize Type II MPGN, sometimes called *dense deposit disease* (**Fig. e9-8**). Classically, the glomerular tuft has a lobular appearance; intramesangial deposits are rarely present and subendothelial deposits are generally absent. Proliferation in Type III MPGN is less common than the other two types and is often focal; mesangial interposition is rare, and subepithelial deposits can occur along widened segments of the GBM that appear laminated and disrupted.

Type I MPGN is secondary to glomerular deposition of circulating immune complexes or their in situ formation. Types II and III MPGN may be related to "nephritic factors," which are autoantibodies that stabilize C_3 convertase and allow it to activate serum C_3. Patients with MPGN present with proteinuria, hematuria, and pyuria (30%), systemic symptoms of fatigue and malaise that are most common in children with Type I disease, or an acute nephritic picture with RPGN and a speedy deterioration in renal function in up to 25% of patients. Low serum C_3 levels are common. Fifty percent of patients with MPGN develop end-stage disease 10 years after diagnosis, and 90% have renal insufficiency after 20 years. Nephrotic syndrome, hypertension, and renal insufficiency all predict poor outcome. In the presence of proteinuria, treatment with inhibitors of the renin-angiotensin system is prudent. Evidence for treatment with dipyridamole, coumadin, or cyclophosphamide is not strongly established nor recommended. There is some evidence supporting the efficacy of treatment of *primary MPGN* with steroids, particularly in children. In *secondary MPGN*, treating the associated infection, autoimmune disease, or neoplasms is of demonstrated benefit. Although all primary renal diseases can recur over time in transplanted renal allografts, patients with MPGN are well known to be at risk for this adverse event.

MESANGIOPROLIFERATIVE GLOMERULONEPHRITIS

Mesangioproliferative glomerulonephritis is characterized by expansion of the mesangium, sometimes associated with mesangial hypercellularity; thin, single contoured capillary walls; and mesangial immune deposits. Clinically, it can present with varying degrees of proteinuria and, commonly, hematuria. Mesangioproliferative disease may be seen in IgA nephropathy, *P. falciparum* malaria, resolving postinfectious glomerulonephritis, and Class II nephritis from lupus, all of which can have a similar histologic appearance. With these secondary entities excluded, the diagnosis of *primary mesangioproliferative glomerulonephritis* is made in less than 15% of renal biopsies. As an immune-mediated renal lesion with deposits of IgM, C1q, and C_3, the clinical course is variable. Patients with isolated hematuria may have a very benign course, and those with heavy proteinuria occasionally progress to renal failure. There is little agreement on treatment, but some clinical reports suggest benefit from use of inhibitors of the renin-angiotensin system, steroid therapy, and even cytotoxic agents.

NEPHROTIC SYNDROME

Nephrotic syndrome classically presents with heavy proteinuria, minimal hematuria, hypoalbuminemia, hypercholesterolemia, edema, and hypertension. If left undiagnosed or untreated, some of these syndromes will progressively damage enough glomeruli to cause a fall in GFR, producing renal failure.

Therapies for various causes of nephrotic syndrome are noted under individual disease headings below. In general, all patients with hypercholesterolemia secondary to nephrotic syndrome should be treated with lipid-lowering agents since they are at increased risk for cardiovascular disease. Edema secondary to salt and water retention can be controlled with the judicious use of diuretics, avoiding intravascular volume depletion. Venous complications secondary to the hypercoagulable state associated with nephrotic syndrome can be treated with anticoagulants. The losses of various serum binding proteins, such as thyroid-binding globulin, lead to alterations in functional tests. Lastly, proteinuria itself is hypothesized to be nephrotoxic, and treatment of proteinuria with inhibitors of the renin-angiotensin system can lower urinary protein excretion.

MINIMAL CHANGE DISEASE

MCD, sometimes known as *nil lesion*, causes 70–90% of nephrotic syndrome in childhood but only 10–15% of nephrotic syndrome in adults. MCD usually presents as a primary renal disease but can be associated with several other conditions, including Hodgkin's disease, allergies, or use of nonsteroidal anti-inflammatory agents; significant interstitial nephritis often accompanies cases associated with nonsteroidal use. MCD on renal biopsy shows no obvious glomerular lesion by light microscopy and is negative for deposits by immunofluorescent microscopy, or occasionally shows small amounts of IgM in the mesangium (**Fig. e9-1**). Electron microscopy, however, consistently demonstrates an effacement of the foot process supporting the epithelial podocytes with weakening of slit-pore membranes. The pathophysiology of this lesion is uncertain. Most agree there is a circulating cytokine, perhaps related to a T cell response that alters capillary charge and podocyte integrity. The evidence for cytokine-related immune injury is circumstantial and is suggested by the presence of preceding allergies, altered cell-mediated immunity during viral infections, and the high frequency of remissions with steroids.

MCD presents clinically with the abrupt onset of edema and nephrotic syndrome accompanied by acellular urinary sediment. Less common clinical features include hypertension (30% in children, 50% in adults), microscopic hematuria (20% in children, 33% in adults), atopy or allergic symptoms (40% in children, 30% in adults), and decreased renal function (<5% in children, 30% in adults). The appearance of acute renal failure in adults is usually caused by intrarenal edema (nephrosarca) that is responsive to intravenous albumin and diuretics. This presentation must be distinguished from acute renal failure secondary to hypovolemia. In children, the abnormal urine principally contains albumin with minimal amounts of higher molecular weight proteins, and is sometimes called *selective proteinuria*. Although up to 30% of children have a spontaneous remission, all children today are treated with steroids; only children who are nonresponders are biopsied in this setting. Primary responders are patients who have a complete remission (<0.2 mg/24 h of proteinuria) after a single course of prednisone; steroid-dependent patients relapse as their steroid dose is tapered. Frequent relapsers have two or more relapses in the 6 months following taper, and steroid-resistant patients fail to respond to steroid therapy. Ninety to 95% of children will develop a complete remission after 8 weeks of steroid therapy, and 80–85% of adults will achieve complete remission, but only after a longer course of 20–24 weeks. Patients with steroid resistance can develop FSGS on repeat biopsy. Some hypothesize that if the first renal biopsy does not have a sample of deeper glomeruli, then the correct early diagnosis of FSGS may be missed.

Relapses occur in 70–75% of children after the first remission, and early relapse predicts multiple subsequent relapses. The frequency of relapses decreases after puberty, although there is an increased risk of relapse following the rapid tapering of steroids in all groups. Relapses are less common in adults but are more resistant to subsequent therapy. Prednisone is first-line therapy, and other immunosuppressive drugs, such as cyclophosphamide, chlorambucil, and mycophenolate mofetil, are saved for frequent relapsers, steroid-dependent, or steroid-resistant patients. Cyclosporine can induce remission, but relapse is also common when cyclosporine is withdrawn. The long-term prognosis in adults is less favorable when acute renal failure or steroid resistance occurs.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

FSGS refers to a pattern of renal injury characterized by segmental glomerular scars that involve some but not all glomeruli; the clinical findings of FSGS largely manifest as proteinuria. When the secondary causes of FSGS are eliminated (**Table 227-5**), the remaining patients

TABLE 277-6 MEMBRANOUS GLOMERULONEPHRITIS

Primary/idiopathic membranous glomerulonephritis
Secondary membranous glomerulonephritis
Infection: Hepatitis B and C, syphilis, malaria, schistosomiasis, leprosy, filariasis
Cancer: Breast, colon, lung, stomach, kidney, esophagus, neuroblastoma
Drugs: gold, mercury, penicillamine, nonsteroidal anti-inflammatory agents, probenecid
Autoimmune diseases: systemic lupus erythematosus, rheumatoid arthritis, primary biliary cirrhosis, dermatitis herpetiformis, bullous pemphigoid, myasthenia gravis, Sjögren's syndrome, Hashimoto's thyroiditis
Other systemic diseases: Fanconi's syndrome, sickle cell anemia, diabetes, Crohn's disease, sarcoidosis, Guillain-Barré syndrome, Weber-Christian disease, angiofollicular lymph node hyperplasia

are considered to have FSGS. The incidence of this disease is increasing, and it now represents up to one-third of cases of nephrotic syndrome in adults and one-half of cases of nephrotic syndrome in African Americans, in whom it is seen more commonly. The pathogenesis of FSGS is probably multifactorial. Possible mechanisms include a T cell–mediated circulating permeability factor, TGF-β–mediated cellular proliferation and matrix synthesis, and podocyte abnormalities associated with genetic mutations.

The pathologic changes of FSGS are most prominent in glomeruli located at the corticomedullary junction (**Fig. e9-2**), so if the renal biopsy specimen is from superficial tissue, the lesions can be missed, which sometimes leads to a misdiagnosis of MCD. In addition to focal and segmental scarring, other variants have been described, including cellular lesions with *endocapillary hypercellularity* and heavy proteinuria; *collapsing glomerulopathy* (**Fig. e9-3**) with segmental or global glomerular collapse and a rapid decline in renal function; or the *glomerular tip lesion*, which seems to have a better prognosis.

FSGS can present with any level of proteinuria, hematuria, hypertension, or renal insufficiency. Nephrotic range proteinuria, African-American race, and renal insufficiency are associated with a poor outcome, with 50% of patients reaching renal failure in 6–8 years. FSGS rarely remits spontaneously, but treatment-induced remission of proteinuria significantly improves prognosis. Treatment of patients with *primary FSGS* should include inhibitors of the renin-angiotensin system. Based on retrospective studies, patients with nephrotic range proteinuria can be treated with steroids but respond far less often than patients with MCD. Proteinuria remits in only 20–45% of patients receiving a course of steroids over 6–9 months. Limited evidence suggests that the use of cyclosporine in steroid-responsive patients helps ensure remissions, while other cytotoxic agents confer little added benefit over steroid therapy. Primary FSGS recurs in 25–40% of patients given allografts at end-stage disease, leading to graft loss in half of those cases. The treatment of *secondary FSGS* typically involves treating the underlying cause and controlling proteinuria. There is no role for steroids or other immunosuppressive agents in secondary FSGS.

MEMBRANOUS GLOMERULONEPHRITIS

MGN, or *membranous nephropathy* as it is sometimes called, accounts for approximately 30% of cases of nephrotic syndrome in adults, with a peak incidence between the ages of 30–50 years and a male to female ratio of 2:1. It is rare in childhood and by far the most common cause of nephrotic syndrome in the elderly. In 25–30% of cases, MGN is secondary to malignancy (solid tumors of the breast, lung, colon), infection (hepatitis B, malaria, schistosomiasis), or rheumatologic disorders like lupus or rarely rheumatoid arthritis (**Table 277-6**).

Uniform thickening of the basement membrane along the peripheral capillary loops is seen by light microscopy on renal biopsy (**Fig. e9-5**); this thickening needs to be distinguished from that seen in diabetes and amyloidosis. Immunofluorescence demonstrates diffuse granular deposits of IgG and C_3, and electron microscopy typically reveals electron-dense subepithelial deposits. While different stages (I–V) of progressive membranous lesions have been described, some published analyses indicate the degree of tubular atrophy or interstitial fibrosis is more predictive of progression than is the stage of glomerular disease. The presence of subendothelial deposits or the presence of tubuloreticular inclusions strongly points to a diagnosis of membranous lupus nephritis, which may precede the extrarenal manifestations of lupus. Work in Heyman nephritis, an animal model of MGN, suggests that glomerular lesions result from in situ formation of immune complexes with megalin receptor–associated protein as the putative antigen. This antigen is not found in human podocytes, but human antibodies have been described against neutral endopeptidase expressed by podocytes, hepatitis antigens B/C, *Helicobacter pylori* antigens, tumor antigens, and thyroglobulin.

Eighty percent of patients with MGN present with nephrotic syndrome and nonselective proteinuria. Microscopic hematuria is seen in up to 50% of patients. Spontaneous remissions occur in 20–33% of patients and often occur late in the course after years of nephrotic syndrome. One-third of patients continue to have relapsing nephrotic syndrome but maintain normal renal function, and approximately another third of patients develop renal failure or die from the complications of nephrotic syndrome. Male gender, older age, hypertension, and the persistence of proteinuria are associated with worse prognosis. Although thrombotic complications are a feature of all nephrotic syndromes, MGN has the highest reported incidences of renal vein thrombosis, pulmonary embolism, and deep vein thrombosis. Prophylactic anticoagulation is controversial but has been recommended for patients with severe or prolonged proteinuria in the absence of risk factors for bleeding.

In addition to the treatment of edema, dyslipidemia, and hypertension, inhibition of the renin-angiotensin system is recommended. Therapy with immunosuppressive drugs is also recommended for patients with primary MGN and persistent proteinuria (>3.0 g/24 h). The choice of immunosuppressive drugs for therapy is controversial, but current recommendations based on small clinical studies are to treat with steroids and cyclophosphamide, chlorambucil, or cyclosporine. Experience with mycophenolate mofetil or anti-CD20 antibody is even more limited.

DIABETIC NEPHROPATHY

Diabetic nephropathy is the single most common cause of chronic renal failure in the United States, accounting for 45% of patients receiving renal replacement therapy, and is a rapidly growing problem worldwide. The dramatic increase in the number of patients with diabetic nephropathy reflects the epidemic increase in obesity, metabolic syndrome, and Type 2 diabetes mellitus. Approximately 40% of patients with Types 1 or 2 diabetes develop nephropathy, but due to the higher prevalence of Type 2 diabetes (90%) compared to Type 1 (10%), the majority of patients with diabetic nephropathy have Type 2 disease. Renal lesions are more common in African-American, Native American, Polynesian, and Maori populations. Risk factors for the de-

velopment of diabetic nephropathy include hyperglycemia, hypertension, dyslipidemia, smoking, a family history of diabetic nephropathy, and gene polymorphisms affecting the activity of the renin-angiotensin-aldosterone axis.

Within 1–2 years after the onset of clinical diabetes, morphologic changes appear in the kidney. Thickening of the GBM is a sensitive indicator for the presence of diabetes but correlates poorly with the presence or absence of clinically significant nephropathy. The composition of the GBM is altered notably with a loss of heparan sulfate moieties that form the negatively charged filtration barrier. This change results in increased filtration of serum proteins into the urine, predominately negatively charged albumin. The expansion of the mesangium due to the accumulation of extracellular matrix correlates with the clinical manifestations of diabetic nephropathy. This expansion in mesangial matrix can be associated with the development of *mesangial sclerosis.* Some patients also develop eosinophilic, PAS^+ nodules called *nodular glomerulosclerosis* or *Kimmelstiel-Wilson nodules*. Immunofluorescence microscopy often reveals the nonspecific deposition of IgG (at times in a linear pattern) or complement staining without immune deposits on electron microscopy. Prominent vascular changes are frequently seen with hyaline and hypertensive arteriosclerosis. This is associated with varying degrees of chronic glomerulosclerosis and tubulointerstitial changes. Renal biopsies from patients with Types 1 and 2 diabetes are largely indistinguishable.

These pathologic changes are the result of a number of postulated factors. Multiple lines of evidence support an important role for increases in glomerular capillary pressure (intraglomerular hypertension) in alterations in renal structure and function. Direct effects of hyperglycemia on the actin cytoskeleton of renal mesangial and vascular smooth-muscle cells as well as diabetes-associated changes in circulating factors such as atrial naturetic factor, angiotensin II, and insulin-like growth factor (IGF) may account for this. Sustained glomerular hypertension increases matrix production, alterations in the GBM with disruption in the filtration barrier (and hence proteinuria) and glomerulosclerosis. A number of factors have also been identified which alter matrix production, including the accumulation of advanced glycosylation end products, circulating factors including growth hormone, IGF-I, angiotensin II, connective tissues growth factor, TGF-β, and dyslipidemia.

The natural history of diabetic nephropathy in patients with Types 1 and 2 diabetes is similar. However, since the onset of Type 1 diabetes is readily identifiable and the onset of Type 2 diabetes is not, a patient newly diagnosed with Type 2 diabetes may have renal disease for many years before nephropathy is discovered and presents as *advanced diabetic nephropathy.* At the onset of diabetes, renal hypertrophy and glomerular hyperfiltration are present. The degree of glomerular hyperfiltration correlates with the subsequent risk of clinically significant nephropathy. In the approximately 40% of patients with diabetes who develop diabetic nephropathy, the earliest manifestation is an increase in albuminuria detected by sensitive radioimmunoassay (Table 277-1). Albuminuria in the range of 30–300 mg/24 h is called *microalbuminuria*. In patients with Types 1 or 2 diabetes, microalbuminuria appears 5–10 years after the onset of diabetes. It is currently recommended to test patients with Type 1 disease for microalbuminuria 5 years after diagnosis of diabetes and yearly thereafter, and, because the time of onset of Type 2 diabetes is often unknown, to test Type 2 patients at the time of diagnosis of diabetes and yearly thereafter.

Patients with small rises in albuminuria increase their levels of urinary albumin excretion, typically reaching dipstick positive levels of proteinuria (>300 mg albuminuria) 5–10 years after the onset of early albuminuria. Microalbuminuria is a potent risk factor for cardiovascular events and death in patients with Type 2 diabetes. Many patients with Type 2 diabetes and microalbuminuria succumb to cardiovascular events before they progress to proteinuria or renal failure. Proteinuria in frank diabetic nephropathy can be variable, ranging from 500 mg to 25 g/24 h, and is often associated with nephrotic syndrome. More than 90% of patients with Type 1 diabetes and nephropathy have diabetic retinopathy, so the absence of retinopathy in Type 1 patients with proteinuria should prompt consideration of a diagnosis other than diabetic nephropathy; only 60% of patients with Type 2 diabetes with nephropathy have diabetic retinopathy. There is a highly significant correlation between the presence of retinopathy and the presence of Kimmelstiel-Wilson nodules (**Fig. e9-18**). Also, characteristically, patients with advanced diabetic nephropathy have normal to enlarged kidneys, in contrast to other glomerular diseases where kidney size is usually decreased. Using the above epidemiologic and clinical data, and in the absence of other clinical or serologic data suggesting another disease, diabetic nephropathy is usually diagnosed without a renal biopsy. After the onset of proteinuria >500 mg/24 h, renal function inexorably declines, with 50% of patients reaching renal failure in 5–10 years; thus, from the earliest stages of microalbuminuria, it usually takes 10–20 years to reach end-stage renal disease. Hypertension may predict which patients develop diabetic nephropathy, as the presence of hypertension accelerates the rate of decline in renal function. Once renal failure appears, however, survival on dialysis is far shorter for patients with diabetes compared to other dialysis patients; some diabetics do better clinically if they are started on dialysis before they reach advanced renal failure. Survival is best for patients with Type 1 diabetes who receive a transplant from a living related donor.

Good evidence supports the benefits of blood sugar and blood pressure control as well as inhibition of the renin-angiotensin system in retarding the progression of diabetic nephropathy. In patients with Type 1 diabetes, intensive control of blood sugar clearly prevents the development or progression of diabetic nephropathy. The evidence in patients with Type 2 disease, although less compelling, also supports intensive control of blood sugar. Controlling systemic blood pressure to levels of 130/80 mmHg or less decreases renal and cardiovascular adverse events in this high-risk population. The vast majority of patients with diabetic nephropathy require three or more antihypertensive drugs to achieve this goal. Drugs that inhibit the renin-angiotensin system, independent of their effects on systemic blood pressure, have been repeatedly shown to slow the progression of diabetic nephropathy at early (microalbuminuria) and late (proteinuria with reduced glomerular filtration) stages, independent of any effect they may have on systemic blood pressure.

Since angiotensin II increases efferent arteriolar resistance and, hence, glomerular capillary pressure, one key mechanism for the efficacy of ACE inhibitors or angiotensin receptor blockers (ARBs) is reducing glomerular hypertension. Patients with Type 1 diabetes for 5 years who develop albuminuria or declining renal function should be treated with ACE inhibitors. Patients with Type 2 diabetes and microalbuminuria or proteinuria may be treated with ACE inhibitors or ARBs.

GLOMERULAR DEPOSITION DISEASES

Plasma cell dyscrasias producing excess light chain immunoglobulin sometimes lead to the formation of glomerular and tubular deposits that cause heavy proteinuria and renal failure; the same is true for the accumulation of serum amyloid A protein fragments seen in several inflammatory diseases. This broad group of proteinuric patients has *glomerular deposition disease.*

Light Chain Deposition Disease The biochemical characteristics of nephrotoxic light chains produced in light chain malignancies typically confers a specific pattern of renal injury in each individual patient; that of either cast nephropathy (**Fig. e9-15**), which causes renal failure but not heavy proteinuria, amyloidosis, or *light chain deposition disease* (**Fig. e9-14**), which produce nephrotic syndrome with renal failure. These latter patients produce kappa light chains that do not have the biochemical features necessary to form amyloid fibrils. Instead, they self-aggregate and form granular deposits along the glomerular capillary and mesangium, tubular basement membrane, and Bowman's capsule. When predominant in glomeruli, nephrotic syndrome develops, and about 70% of patients progress to dialysis. Light-chain deposits are not fibrillar and do not stain with Congo red, but they are easily detected with anti-light–chain antibody using immunofluorescence, or as granular deposits on electron microscopy. A combination

of the light-chain rearrangement, self-aggregating properties at neutral pH, and abnormal metabolism probably contribute to the deposition. Treatment for light-chain deposition disease is treatment of the primary disease. As so many patients with light-chain deposition disease progress to renal failure, the overall prognosis is grim.

Renal Amyloidosis Most *renal amyloidosis* is either the result of primary fibrillar deposits of immunoglobulin light chains [amyloid L (AL)], or secondary to fibrillar deposits of serum amyloid A (AA) protein fragments (Chap. 324). Even though both occur for different reasons, their clinicopathophysiology is quite similar and will be discussed together. Amyloid infiltrates the liver, heart, peripheral nerves, carpal tunnel, upper pharynx, and kidney, producing restrictive cardiomyopathy, hepatomegaly, macroglossia, and heavy proteinuria sometimes associated with renal vein thrombosis. In systemic AL amyloidosis, also called *primary amyloidosis*, light chains produced in excess by clonal plasma cell dyscrasias are made into fragments by macrophages so they can self-aggregate at acid pH. A disproportionate number of these light chains (75%) are of the *lambda* class. About 10% of these patients have overt myeloma with lytic bone lesions and infiltration of the bone marrow with >30% plasma cells; nephrotic syndrome is common, and about 20% of patients progress to dialysis. AA amyloidosis is sometimes called *secondary amyloidosis* and also affects the kidney with nephrotic syndrome. It is due to deposition of β-pleated sheets of serum amyloid A protein, an acute phase reactant whose physiologic function is unknown. Forty percent of patients with AA amyloid have rheumatoid arthritis, and another 10% have ankylosing spondylitis or psoriatic arthritis; the rest derive from other lesser causes. Less common in Western countries but more common in Mediterranean regions, particularly in Sephardic and Iraqi Jews, is familial Mediterranean fever (FMF). FMF is caused by a mutation in the gene encoding pyrin, while Muckle-Wells syndrome, a related disorder, results from a mutation in cryopyrin; both proteins are important in the apoptosis of leukocytes early in inflammation. Receptor mutations in TNFR1–associated periodic syndrome also produce chronic inflammation and secondary amyloidosis. Fragments of serum amyloid A protein increase and self-aggregate by attaching to receptors for advanced glycation end products in the extracellular environment; nephrotic syndrome is common, and about 40–60% of patients progress to dialysis. AA and AL amyloid fibrils are detectable with Congo red or in more detail with electron microscopy (**Fig. e9-13**). Biopsy of involved liver or kidney is diagnostic 90% of the time when the pretest probability is high; abdominal fat pad aspirates are positive about 70% of the time, but apparently less so when looking for AA amyloid. Amyloid deposits are distributed along blood vessels and in the mesangial regions of the kidney. The treatment for primary amyloidosis is not particularly effective; melphalan and autologous hematopoietic stem cell transplantation can delay the course of disease in about 30% of patients. Secondary amyloidosis is also relentless unless the primary disease can be controlled. Some new drugs in development that disrupt the formation of fibrils may be available in the future.

Fibrillary-Immunotactoid Glomerulopathy There is no agreement on whether *fibrillary glomerulonephritis* and *immunotactoid glomerulonephritis* are different or one and the same. Both are hard to distinguish by clinical presentation but have some apparent differences with electron microscopy. Fibrillar/microtubular deposits of oligoclonal or oligotypic immunoglobulins and complement appear in the mesangium and along the glomerular capillary wall. In fibrillary glomerulonephritis the fibrils are smaller and more randomly distributed than in immunotactoid glomerulonephritis. Congo red stains are negative in both disorders. The cause of this "nonamyloid" glomerulopathy is mostly idiopathic; reports of immunotactoid glomerulonephritis describe an occasional association with chronic lymphocytic leukemia or B cell lymphoma. Both disorders appear in adults in the fourth decade with moderate to heavy proteinuria, hematuria, and a wide variety of histologic lesions, including DPGN, MPGN, MGN, or mesangioproliferative glomerulonephritis. Nearly half of patients will develop renal failure over a few years. There is no consensus on treatment of this uncommon disorder.

FABRY'S DISEASE

Fabry's disease is an X-linked inborn error of globotriaosylceramide metabolism secondary to deficient lysosomal α-galactosidase A activity, resulting in excessive intracellular storage of globotriaosylceramide. Affected organs include the vascular endothelium, heart, brain, and kidneys. Classically, Fabry's disease presents in childhood in males with multi-organ involvement. Hemizygotes with hypomorphic mutations sometimes present in the fourth to sixth decade with single organ involvement. Rarely, dominant-negative α-galactosidase A mutations or female heterozygotes with unfavorable X inactivation present with mild single-organ involvement. Renal biopsy reveals enlarged glomerular visceral epithelial cells packed with small clear vacuoles containing globotriaosylceramide; vacuoles may also be found in parietal and tubular epithelia (**Fig. e9-16**). These vacuoles of electron-dense materials in parallel arrays (zebra bodies) are easily seen on electron microscopy. Ultimately, glomeruli develop FSGS. The nephropathy of Fabry's disease typically presents in the third decade as mild to moderate proteinuria, sometimes with microscopic hematuria or nephrotic syndrome. Urinalysis may reveal oval fat bodies and birefringent glycolipid globules under polarized light (Maltese cross). Renal biopsy is necessary for definitive diagnosis. Progression to renal failure occurs by the fourth or fifth decade. Treatment with recombinant α-galactosidase A has been demonstrated to clear microvascular endothelial deposits of globotriaosylceramide from the kidneys, heart, and skin.

PULMONARY-RENAL SYNDROMES

Several diseases can present with catastrophic hemoptysis and glomerulonephritis associated with varying degrees of renal failure. The usual causes include Goodpasture's syndrome, Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss vasculitis, and, rarely, Henoch-Schönlein purpura or cryoglobulinemia. Each of these diseases can also present without hemoptysis and are discussed in detail in "Acute Nephritic Syndromes," above. Pulmonary bleeding in this setting is life-threatening and often results in airway intubation, and acute renal failure requires dialysis in the intensive care unit. Diagnosis is difficult initially because biopsies and serologic testing take time. Treatment with plasmapheresis and methylprednisolone is often empiric and temporizing until results of testing are available.

BASEMENT MEMBRANE SYNDROMES

All kidney epithelia, including podocytes, rest on basement membranes assembled into a planar surface through the interweaving of collagen IV with laminins, nidogen, and sulfated proteoglycans. Structural abnormalities in GBMs associated with hematuria are characteristic of several familial disorders related to the expression of collagen IV genes. The extended family of collagen IV contains six chains, which are expressed in different tissues at different stages of embryonic development. All epithelial basement membranes early in human development are composed of interconnected triple-helical protomers rich in α1.α1.α2(IV) collagen. Some specialized tissues undergo a developmental switch replacing α1.α1.α2(IV) protomers with an α3.α4.α5(IV) collagen network; this switch occurs in the kidney (glomerular and tubular basement membrane), lung, testis, cochlea, and eye, while an α5.α5.α6(IV) network appears in skin, smooth muscle, and esophagus and along Bowman's capsule in the kidney. This switch probably occurs because the α3.α4.α5(IV) network is more resistant to proteases and ensures the structural longevity of critical tissues. When basement membranes are the target of glomerular disease, they produce moderate proteinuria, some hematuria, and progressive renal failure.

ANTI-GBM DISEASE

Autoimmune disease where antibodies are directed against the α3 NC1 domain of collagen IV produces an *anti-GBM disease* often asso-

ciated with RPGN and/or a pulmonary-renal syndrome called *Goodpasture's syndrome.* Discussion of this disease is covered in "Acute Nephritic Syndromes," above.

ALPORT'S SYNDROME

Classically, patients with Alport's syndrome develop hematuria, thinning and splitting of the GBMs, mild proteinuria (<1–2 g/24 h), and chronic glomerulosclerosis, leading to renal failure in association with sensorineural deafness. Some patients develop lenticonus of the anterior lens capsule and, rarely, mental retardation or leiomyomatosis. Approximately 85% of patients with Alport's syndrome have an X-linked inheritance of mutations in the α5(IV) collagen chain on chromosome Xq22–24. Female carriers have variable penetrance depending on the type of mutation or the degree of mosaicism created by X inactivation. Fifteen percent of patients have autosomal recessive disease of the α3(IV) or α4(IV) chains on chromosome 2q35–37. Rarely, some kindred have an autosomal dominant inheritance of dominant-negative mutations in α3(IV) or α4(IV) chains.

Pedigrees with this syndrome are quite variable in their rate and frequency of tissue damage leading to organ failure. Patients with nonsense or missense mutations, reading frame shifts, or large deletions generally develop renal failure and sensorineural deafness by age 30 (juvenile form), while patients with splice variants, exon skipping, or missense mutations of α-helical glycines generally deteriorate after the age of 30 (adult form) with mild or late deafness. Early severe deafness or lenticonus suggest a poorer prognosis.

Alport's patients early in their disease typically have thin basement membranes on renal biopsy (**Fig. e9-17**), which thicken over time into multilamellations surrounding lucent areas that often contain granules of varying density—the so-called split basement membrane. In any Alport kidney there are areas of thinning mixed with splitting of the GBM. Tubules drop out, glomeruli scar, and the kidney eventually succumbs to interstitial fibrosis. Primary treatment is control of systemic hypertension and use of ACE inhibitors to slow renal progression. Although patients who receive renal allografts usually develop anti-GBM antibodies directed toward the collagen epitopes absent in their native kidney, overt Goodpasture's syndrome is uncommon and graft survival is good.

THIN BASEMENT MEMBRANE DISEASE

Some variants of Alport's syndrome are now recognized as a subpopulation of patients with *thin basement membrane disease.* Thin basement membranes are found in 5–10% of the so-called normal population. These subclinical patients have normal blood pressure and little proteinuria, and they rarely progress to renal failure. If they present with hematuria, they are often given the diagnosis of *benign familial hematuria.* Many of these patients have mutations in the same α3(IV) or α4(IV) collagen genes associated with autosomal recessive or dominant Alport's syndrome. Clearly, the boundary between nonprogressive Alport's syndrome and benign familial hematuria is quite variable, as there is a spectrum of clinical penetrance.

NAIL-PATELLA SYNDROME

Patients with nail-patella syndrome develop iliac horns on the pelvis and dysplasia of the dorsal limbs involving the patella, elbows, and nails, variably associated with neural-sensory hearing impairment, glaucoma, and abnormalities of the GBM and podocytes, leading to hematuria, proteinuria, and FSGS. The syndrome is autosomal-dominant, with haploinsufficiency for the LIM homeodomain transcription factor LMX1B; pedigrees are extremely variable in the penetrance for all features of the disease. LMX1B regulates the expression of genes encoding α3 and α4 chains of collagen IV, interstitial type III collagen, podocin, and CD2AP that help form the slit-pore membranes connecting podocytes. Mutations in the LIM domain region of LMX1B are associated with glomerulopathy, and renal failure appears in as many as 30% of patients. Proteinuria or isolated hematuria is discovered throughout life, but usually by the third decade, and is inexplicably more common in females. On renal biopsy there is lucent damage to the lamina densa of the GBM, an increase in collagen III fibrils along glomerular capillaries and in the mesangium, and damage to the slit-pore membrane, producing heavy proteinuria not unlike that seen in congenital nephrotic syndrome. Patients with renal failure do well with transplantation.

GLOMERULAR-VASCULAR SYNDROMES

A variety of diseases result in classic vascular injury to the glomerular capillaries. Most of these processes also damage blood vessels elsewhere in the body. The group of diseases discussed here lead to vasculitis, renal endothelial injury, thrombosis, ischemia, and/or lipid-based occlusions.

ATHEROSCLEROTIC NEPHROPATHY

Aging in the developed world is commonly associated with the occlusion of coronary and systemic blood vessels. The reasons for this include obesity, insulin resistance, smoking, hypertension, and diets rich in lipids that deposit in the arterial and arteriolar circulation, producing local inflammation and fibrosis of small blood vessels. When the renal arterial circulation is involved, the glomerular microcirculation is damaged, leading to *chronic nephrosclerosis.* Patients with GFRs <60 mL/min have more cardiovascular events and hospitalizations than those with higher filtration rates. Several aggressive lipid disorders can accelerate this process, but most of the time atherosclerotic progression to chronic nephrosclerosis is associated with poorly controlled hypertension. Approximately 10% of glomeruli are normally sclerotic by age 40, rising to 20% by age 60 and 30% by age 80. Serum lipid profiles in humans are greatly affected by *apolipoprotein E* polymorphisms; the E4 allele is accompanied by increases in serum cholesterol and is more closely associated with atherogenic profiles in patients with renal failure. Mutations in E2 alleles, particularly in Japanese patients, produce a specific renal abnormality called *lipoprotein glomerulopathy* associated with glomerular lipoprotein thrombi and capillary dilation.

HYPERTENSIVE NEPHROSCLEROSIS

Uncontrolled systemic hypertension causes permanent damage to the kidneys in about 6% of patients with elevated blood pressure. As many as 27% of patients with end-stage kidney disease have hypertension as a primary cause. Although there is not a clear correlation between the extent or duration of hypertension and the risk of end-organ damage, *hypertensive nephrosclerosis* is fivefold more frequent in African Americans than Caucasians. Associated risk factors for progression to end-stage kidney disease include age, sex, race, smoking, hypercholesterolemia, duration of hypertension, low birth weight, and preexisting renal injury. Kidney biopsies in patients with hypertension, microhematuria, and moderate proteinuria demonstrate arteriolosclerosis, chronic nephrosclerosis, and interstitial fibrosis in the absence of immune deposits (**Fig. e9-19**). Today, based on a careful history, physical examination, urinalysis, and some serologic testing, the diagnosis of chronic nephrosclerosis is usually inferred without a biopsy. Treating hypertension is the best way to avoid progressive renal failure; most guidelines recommend lowering blood pressure to <130/80 mmHg if there is preexisting diabetes or kidney disease. In the presence of kidney disease, most patients begin therapy with two drugs, classically a thiazide diuretic and an ACE inhibitor; many will require three drugs. There is strong evidence in African Americans with hypertensive nephrosclerosis that therapy initiated with an ACE inhibitor can slow the rate of decline in renal function independent of systemic blood pressure. Patients with lower levels of hypertension are usually started on a thiazide diuretic or an ACE inhibitor alone. Malignant acceleration of hypertension can complicate the course of chronic nephrosclerosis, particularly in the setting of scleroderma (**Fig. e9-22**) or cocaine use. The hemodynamic stress of malignant hypertension causes fibrinoid necrosis of small blood vessels, thrombotic microangiography, a nephritic urinalysis, and acute renal failure. In the setting of renal failure, chest pain, or papilledema, the condition is treated as a hypertensive emergency. Slightly lowering the blood pressure often produces an immediate re-

duction in GFR that improves as the vascular injury attenuates and autoregulation of blood vessel tone is restored.

CHOLESTEROL EMBOLI

Aging patients with clinical complications from atherosclerosis sometimes shower cholesterol crystals into the circulation—either spontaneously or, more commonly, following an endovascular procedure with manipulation of the aorta—or with use of systemic anticoagulation. Spontaneous emboli may shower acutely or shower subacutely and somewhat more silently. Irregular emboli trapped in the microcirculation produce ischemic damage that induces an inflammatory reaction. Depending on the location of the atherosclerotic plaques releasing these cholesterol fragments, one may see cerebral transient ischemic attacks; livedo reticularis in the lower extremities; Hollenhorst plaques in the retina with visual field cuts; necrosis of the toes; and acute glomerular capillary injury leading to *focal glomerulosclerosis* sometimes associated with hematuria, mild proteinuria, and loss of renal function, which typically progresses over a few years. Occasional patients have fever, eosinophilia, or eosinophiluria. A skin biopsy of an involved area may be diagnostic. Since tissue fixation dissolves the cholesterol, one typically sees only residual, biconvex clefts in the vessel (**Fig. e9-20**). There is no therapy to reverse embolic occlusions, and steroids do not help. Controlling blood pressure and lipids and cessation of smoking are usually recommended for prevention.

SICKLE CELL DISEASE

Although individuals with SA-hemoglobin are usually asymptomatic, most will gradually develop hyposthenuria due to subclinical infarction of the renal medulla, thus predisposing them to volume depletion. Patients with homozygous SS-sickle cell disease develop chronic vasoocclusive disease in many organs. Polymers of deoxygenated SS-hemoglobin distort the shape of red blood cells. These cells attach to endothelia and obstruct small blood vessels, producing frequent, random, and painful sickle cell crises over time. Vessel occlusions in the kidney produce glomerular hypertension, FSGS, interstitial nephritis, and renal infarction associated with hyposthenuria, microscopic hematuria, and even gross hematuria; some patients also present with MPGN. By the second or third decade of life, persistent vasoocclusive disease in the kidney leads to varying degrees of renal failure, and some patients end up on dialysis. Treatment is directed to reducing the frequency of painful crises and administering ACE inhibitors in the hope of delaying a progressive decline in renal function. Sickle cell patients can have transplantations, and renal graft survival is comparable to African Americans given transplantations for other reasons.

THROMBOTIC MICROANGIOPATHIES

Thrombotic thrombocytopenic purpura (TTP) and *hemolytic-uremic syndrome* (HUS) represent a spectrum of thrombotic microangiopathies. TTP and HUS share the general features of idiopathic thrombocytopenic purpura, hemolytic anemia, fever, renal failure, and neurologic disturbances. When patients have more evidence of renal injury, their condition tends to be called HUS, and when there is more neurologic disease, it is considered to be TTP. In adults there is often a mixture of both, which is why they are often called TTP/HUS. On examination of kidney tissue there is evidence of *glomerular capillary endotheliosis* associated with platelet thrombi, damage to the capillary wall, and formation of fibrin material in and around glomeruli (**Fig. e9-21**). These tissue findings are similar to what is seen in preeclampsia/HELLP (hemolysis, elevated liver enzymes, and low platelet count syndrome), malignant hypertension, and the antiphospholipid syndrome. TTP/HUS is also seen in pregnancy; with the use of oral contraceptives or quinine; in renal transplant patients given OKT3 for rejection; in patients taking the calcineurin inhibitors cyclosporine and tacrolimus or in patients taking the antiplatelet agents ticlopidine and clopidogrel; or following HIV infection.

Although there is no agreement on how much they share a final common pathophysiology, two general groups of patients are recognized: childhood HUS associated with enterohemorrhagic diarrhea and TTP-HUS in adults. Childhood HUS is caused by a toxin released by *Escherichia coli* O157:H7 and occasionally by *Shigella dysenteriae*. This shiga toxin (veratoxin) directly injures endothelia, enterocytes, and renal cells, causing apoptosis, platelet clumping, and intravascular hemolysis by binding to the glycolipid receptors (Gb3). These receptors are more abundant along endothelia in children compared to adults. In familial cases of adult TTP/HUS, there is a genetic deficiency of the ADAMTS13 metalloprotease that cleaves large multimers of von Willebrand's factor. Absent ADAMTS13, these large multimers cause platelet clumping and intravascular hemolysis. An antibody to ADAMTS13 is found in many sporadic cases of adult TTP/HUS, but not all; many patients also have antibodies to the thrombospondin receptor on selected endothelial cells in small vessels or increased levels of plasminogen-activator inhibitor 1 (PAI-1). The treatment of childhood HUS or adult TTP/HUS is daily plasmapheresis, which can be lifesaving. Plasmapheresis is given until the platelet count rises, but in relapsing patients it may need to be continued well after the platelet count improves, and in resistant patients twice-daily exchange may be helpful. Most patients respond within 2 weeks of daily plasmapheresis. Since TTP/HUS often has an autoimmune basis, there is an anecdotal role in relapsing patients for using splenectomy, steroids, immunosuppressive drugs, or anti-CD20 antibody. Patients with childhood HUS from infectious diarrhea are not given antibiotics, as antibiotics are thought to accelerate the release of the toxin and the diarrhea is usually self-limited.

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome develops in patients expressing antibodies to anionic phospholipids, particularly β_2 glycoprotein 1. Half of the patients have no obvious cause, a few are pregnant, some are already receiving hemodialysis or have a renal allograft, and the rest have a primary glomerulonephritis (nil lesion or membranous nephropathy) or a rheumatologic disease such as SLE. Lupus patients also often coexpress a lupus anticoagulant, with elevation in the activated partial tissue thromboplastin time. Clinical presentation of the catastrophic form of antiphospholipid syndrome appears as mixed thrombosis of the arterial and venous circulation with varying degrees of thrombocytopenia, hemolytic anemia, deep vein thrombosis, transient ischemic attacks, pulmonary embolism, and spontaneous abortions; lesser degrees of disease are more common. The kidneys are injured in this syndrome in approximately 25% of patients, particularly those with IgG antibodies. Some patients develop acute renal failure, while others suffer subclinical damage over time. Patients who present with acute flank pain and renal vein thrombosis in the setting of proteinuria should always be checked for antiphospholipid antibodies. Clinically, the antiphospholipid syndrome can wax and wane, and many patients have recurrences; <10% present with catastrophic multi-organ involvement and acute renal failure. Dialysis patients with antiphospholipid syndrome experience frequent occlusion of their arteriovenous graft. The urinalysis in most patients typically shows a mixed picture of moderate proteinuria (1–2 g/24 h) and hematuria. Glomerular capillaries and large and small renal arteries and veins occlude, accompanied by ischemic mesangiolysis and vessel hyperplasia, leading eventually to chronic glomerulosclerosis and interstitial fibrosis. Evidence of antiphospholipid syndrome on biopsy can usually be distinguished as an added complication of an underlying renal disease, particularly lupus nephritis. The mainstay of treatment for antiphospholipid syndrome is warfarin. There is also evidence of vasculitis in many patients due to complement-fixing antiphospholipid antibodies, which responds to the addition of steroids. Acute renal failure sometimes responds to removal of antiphospholipid antibodies with plasmapheresis and adjustment of immunosuppression where clinically indicated.

INFECTIOUS DISEASE–ASSOCIATED SYNDROMES

A number of infectious diseases will injure the glomerular capillaries as part of a systemic reaction producing an immune response or from direct infection of renal tissue. Evidence of this immune response is

collected by glomeruli in the form of immune deposits that damage the kidney, producing moderate proteinuria and hematuria. Some of these infectious diseases represent the most common causes of glomerulonephritis worldwide.

POST-STREPTOCOCCAL GLOMERULONEPHRITIS

This form of glomerulonephritis is one of the classic complications of streptococcal infection. The discussion of this disease can be found in the section on *acute nephritic syndromes.*

SUBACUTE BACTERIAL ENDOCARDITIS

Renal injury from persistent bacteremia absent the continued presence of a foreign body, regardless of cause, is treated presumptively as if the patient has endocarditis. The discussion of this disease can be found in "Acute Nephritic Syndromes," above.

HUMAN IMMUNODEFICIENCY VIRUS

HIV-associated nephropathy is seen after an interval of approximately 2.5 years from discovery of HIV, and many patients have low CD4 counts. Most lesions on renal biopsy show FSGS followed by MPGN. Other less common renal lesions include DPGN, IgA nephropathy, MCD, and membranous or mesangioproliferative glomerulonephritis. The disease affects up to 10% of HIV-infected patients and is more commonly seen in African-American men than in Caucasians, and in intravenous drug users or homosexuals. The FSGS characteristically reveals collapse of the glomerular capillary tuft called *collapsing glomerulopathy*, visceral epithelial cell swelling, microcystic dilatation of renal tubules, and tubuloreticular inclusions. Renal epithelial cells express replicating HIV virus, but host immune responses also play a role in the pathogenesis. MPGN and DPGN have been reported more commonly in HIV-infected Caucasians and in patients co-infected with hepatitis B or C. HIV-associated TTP has also been reported.

HIV patients with FSGS typically present with nephrotic-range proteinuria and hypoalbuminemia, but unlike patients with other etiologies for nephrotic syndrome, they do not commonly have hypertension, edema, or hyperlipidemia. Renal ultrasound also reveals large, echogenic kidneys, and renal function in some patients declines rapidly. Treatment with inhibitors of the renin-angiotensin system decreases the proteinuria. Although evidence from large well-designed clinical trials is lacking, many feel that effective antiretroviral therapy benefits both the patient and the kidney. Dismal survival once renal failure is reached has improved, and many centers now offer renal allografts to select HIV patients.

HEPATITIS B AND C

Chronic hepatitis B infection can be associated with polyarteritis nodosa, more commonly in adults than children. Typically, however, infected patients only present with microscopic hematuria, nonnephrotic or nephrotic-range proteinuria, and hypertension. Alternatively, the hepatitis B carrier state can produce a MGN that is more common in children than adults or MPGN that is more common in adults than in children. Renal histology is indistinguishable from idiopathic MGN or Type I MPGN. There are no good treatment guidelines, but interferon α and lamivudine have been used to some effect in small studies. Children have a good prognosis, with 66% achieving spontaneous remission within 3 years. In contrast, 30% of adults have renal insufficiency and 10% have renal failure 5 years after diagnosis.

Up to 30% of patients with chronic hepatitis C infection have some renal manifestations. Patients often present with cryoglobulinemia and nephrotic syndrome, microscopic hematuria, abnormal liver function tests, depressed C3 levels, anti-HCV antibodies, and viral RNA in the blood. The renal lesions most commonly seen, in order of decreasing frequency, are *cryoglobulinemic glomerulonephritis, MGN, and Type I MPGN.* Treatment aims at reducing the level of the infection.

OTHER VIRUSES

Other viral infections are occasionally associated with glomerular lesions, but cause and effect are not well-established. These viral infections and their respective glomerular lesions include: cytomegalovirus producing MPGN; influenza and anti-GBM disease; measles-associated endocapillary proliferative glomerulonephritis, with measles antigen in the capillary loops and mesangium; parvovirus causing mild proliferative or mesangioproliferative glomerulonephritis; mumps and mesangioproliferative glomerulonephritis; Epstein-Barr virus producing MPGN, diffuse proliferative nephritis, or IgA nephropathy; dengue hemorrhagic fever causing endocapillary proliferative glomerulonephritis; and coxsackie virus producing *focal glomerulonephritis* or DPGN.

SYPHILIS

Secondary syphilis, with rash and constitutional symptoms, develops weeks to months after the chancre first appears and occasionally presents with the nephrotic syndrome from MGN caused by subepithelial immune deposits containing treponemal antigens. The diagnosis is confirmed with non-treponemal and treponemal tests for *Treponema pallidum.* The renal lesion responds to treatment with penicillin or an alternative drug, if allergic. Additional testing for other sexually transmitted diseases is an important part of disease management.

LEPROSY

Despite aggressive eradication programs, approximately 400,000 new cases of leprosy appear annually worldwide. The diagnosis is best made in patients with multiple skin lesions accompanied by sensory loss in affected areas, using skin smears showing paucibacillary or multibacillary infection (WHO criteria). Leprosy is caused by infection with *Mycobacterium leprae* and can be classified by Ridley-Jopling criteria into various types: tuberculoid, borderline tuberculoid, mid-borderline and borderline lepromatous, and lepromatous. In some series, all cases with borderline lepromatous and lepromatous types of leprosy have various forms of glomerulonephritis. Most common is focal glomerulonephritis followed by mesangioproliferative glomerulonephritis or renal amyloidosis; much less common are the renal lesions of DPGN and MPGN. Treatment with dapsone, rifampicin, and clofazimine can irradiate the infection in nearly all patients.

MALARIA

There are 300–500 million incident cases of malaria each year worldwide, and the kidney is commonly involved. Glomerulonephritis is due to immune complexes containing malarial antigens that are implanted in the glomerulus. In malaria from *P. falciparum,* mild proteinuria is associated with subendothelial deposits, mesangial deposits, and mesangioproliferative glomerulonephritis that usually resolve with treatment. In quartian malaria from infection with *P. malariae,* children are more commonly affected and renal involvement is more severe. Transient proteinuria and microscopic hematuria can resolve with treatment of the infection. However, resistant nephrotic syndrome with progression to renal failure over 3–5 years does happen, as <50% of patients respond to steroid therapy. Affected patients with nephrotic syndrome have thickening of the glomerular capillary walls, with subendothelial deposits of IgG, IgM, and C_3 associated with a sparse membranoproliferative lesion. The rare mesangioproliferative glomerulonephritis reported with *P. vivax* or *P. ovale* typically has a benign course.

SCHISTOSOMIASIS

Schistosomiasis affects more than 300 million people worldwide and primarily involves the urinary and gastrointestinal tracts. Glomerular involvement varies with the specific strain of schistosomiasis; *Schistosoma mansoni* is most commonly associated with clinical renal disease, and the glomerular lesions can be classified: Class I is a *mesangioproliferative glomerulonephritis*; Class II is an *extracapillary proliferative glomerulonephritis;* Class III is a *membranoproliferative glomerulonephritis*; Class IV is a *focal segmental glomerulonephritis;* and Class V lesions have *amyloidosis*. Classes I–II often remit with

treatment of the infection, but Classes III and IV lesions are associated with IgA immune deposits and progress despite antiparasitic and/or immunosuppressive therapy.

OTHER PARASITES

Renal involvement with toxoplasmosis infections is rare. When it occurs, patients present with nephrotic syndrome and have a histologic picture of MPGN. Fifty percent of patients with leishmaniasis will have mild to moderate proteinuria and microscopic hematuria, but renal insufficiency is rare. Acute DPGN, MGN, and mesangioproliferative glomerulonephritis have all been observed on biopsy. The nematodes, filariasis and trichinosis, can be associated with glomerular injury presenting with proteinuria, hematuria, and a variety of histologic lesions that typically resolve with eradication of the infection.

278 Polycystic Kidney Disease and Other Inherited Tubular Disorders

David J. Salant, Parul S. Patel

INTRODUCTION

The polycystic kidney diseases are among the most common life-threatening inherited diseases worldwide. They are equally prevalent in all ethnic and racial groups. Progressive expansion of numerous fluid-filled cysts results in massive enlargement of the kidneys (Fig. 278-1) and frequently causes kidney failure. Autosomal dominant polycystic kidney disease (ADPKD) is seen predominantly in adults, whereas autosomal recessive polycystic kidney disease (ARPKD) is mainly a disease of childhood. As shown in Table 278-1, renal cysts are also seen in several other hereditary kidney diseases, some of which may have defects in a common signaling pathway with ADPKD and ARPKD. Table 278-2 summarizes the gene defects and functional abnormalities in inherited tubular diseases that manifest primarily with alterations in fluid, electrolyte, acid-base, and mineral balance.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Etiology And Pathogenesis ADPKD is a systemic disorder resulting from mutations in either the *PKD-1* or *PKD-2* gene. The *PKD-1* encoded protein, polycystin-1, is a large receptor-like molecule, whereas the *PKD-2* gene product, polycystin-2, has features of an ion-channel protein. Both are transmembrane proteins present throughout all segments of the nephrin and are localized to the luminal surface of tubular cells in primary cilia, on the basal surface in focal adhesion complexes, and on the lateral surface in adherens junctions. The proteins are thought to function independently, or as a complex, to regulate fetal and adult epithelial cell gene transcription, apoptosis, differentiation, and cell-matrix interactions. Disruption of these processes leads to epithelial dedifferentiation, unregulated proliferation and apoptosis, altered cell polarity, disorganization of surrounding extracellular matrix, excessive fluid secretion, and abnormal expression of several genes, including some that encode growth factors. Vasopressin-mediated elevation of cyclic AMP (cAMP) levels in cyst epithelia plays a major role in cystogenesis by stimulating cell proliferation and fluid secretion into the cyst lumen through apical chloride and aquaporin channels. Cyst formation begins in utero from any point along the nephron, although <5% of total nephrons are thought to be involved. As the cysts accumulate fluid, they enlarge, separate entirely from the nephron, compress the neighboring renal parenchyma, and progressively compromise renal function.

GENETIC CONSIDERATIONS ADPKD occurs in 1:400–1:1,000 individuals worldwide and accounts for ~4% of end-stage renal disease (ESRD) in the United States. Over 90% of cases are inherited as an autosomal dominant trait, with the remainder likely representing spontaneous mutations. Mutations in the *PKD-1* gene on chromosome 16 (ADPKD-1) account for 85% of cases, whereas mutations in the *PKD-2* gene on chromosome 4 (ADPKD-2) represent the remainder. A few families appear to have a defect at a site that is different from either of these loci. Direct mutation analysis of isolated cysts suggests there is loss of heterozygosity, whereby a somatic mutation in the normal "wild-type" allele of a small number of tubular epithelial cells leads to unregulated clonal proliferation of the cells that ultimately form the cyst lining.

Clinical Features Phenotypic heterogeneity is a hallmark of ADPKD, as evidenced by family members who share the same mutation but have a different clinical course. Affected individuals are often asymptomatic

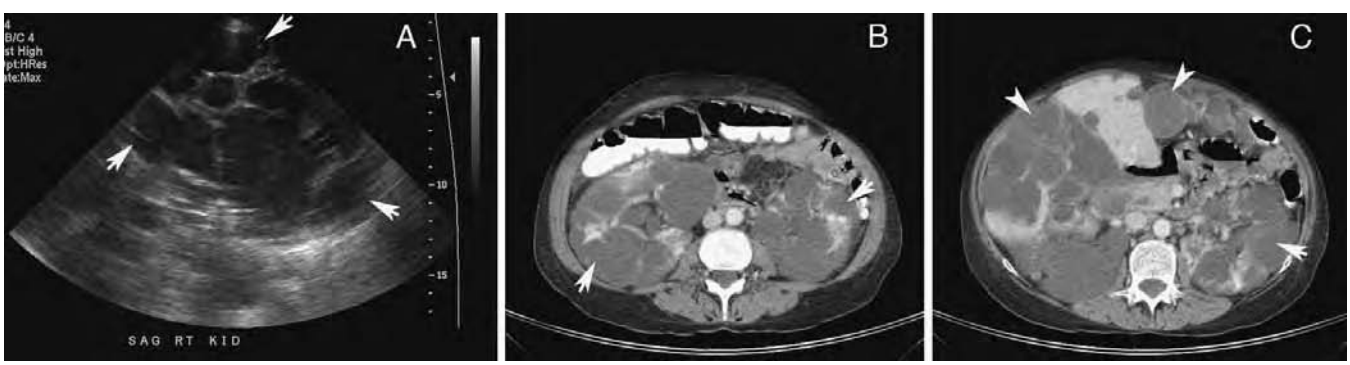

FIGURE 278-1 Renal ultrasonogram and contrast-enhanced abdominal CT scan in a 56-year-old woman with autosomal dominant polycystic kidney disease. ***A.*** Sonogram of the right kidney showing numerous cysts of varying sizes (*arrows*). ***B.*** Abdominal CT scan demonstrating bilaterally enlarged kidneys with large cysts (*arrows*). ***C.*** Multiple liver cysts (*arrowheads*) and renal cysts (*arrow*) are seen in an upper abdominal image.

TABLE 278-1 INHERITED CYSTIC KIDNEY DISEASES

Disease (OMIM)	Mode of Inheritance	Locus	Gene	Protein	Renal Abnormalities	Extra-Renal Abnormalities
Autosomal dominant polycystic kidney disease (601313, 173910)	AD	16p13	*PKD1*	polycystin-1	Cortical and medullary cysts	Cerebral aneurysms; liver cysts, other[a]
	AD	4q21	*PKD2*	polycystin-2	Cortical and medullary cysts	Cerebral aneurysms; liver cysts, other[a]
Autosomal recessive polycystic kidney disease (263200)	AR	6p21	*PKDH1*	fibrocystin	Distal tubule and collecting duct cysts	Hepatic fibrosis; Caroli syndrome
Nephronophthisis I (Juvenile/ adolescent, 256100)	AR	2q13	*NPHP1*	nephrocystin	Small fibrotic kidneys; medullary cysts	Retinitis pigmentosa
Nephronophthisis II (Infantile, 602088)	AR	9q31	*INVS*	inversin	Large kidneys; widespread cysts	Situs inversus
Nephronophthisis III (Juvenile/ Adolescent, 604387)	AR	3q22	*NPHP3*	nephrocystin-3	Small fibrotic kidneys; medullary cysts	Retinitis pigmentosa; hepatic fibrosis
Nephronophthisis IV (Juvenile/ Adolescent, 606966)	AR	1p36	*NPHP4*	nephrocystin-4	Small fibrotic kidneys; medullary cysts	Retinitis pigmentosa
Nephronophthisis V (Juvenile/ adolescent)	AR	3q13	*NPHP5*	nephrocystin-5	Small fibrotic kidneys; medullary cysts	Amaurosis
Medullary cystic kidney disease (174000, 603860)	AD	1q21	*MCKD1*	unknown	Small fibrotic kidneys; medullary cysts	None
	AD	16p12	*UMOD*	uromodulin (Tamm-Horsfall protein)	Small fibrotic kidneys; medullary cysts	Hyperuricemia and gout
Tuberous sclerosis (191100)	AD	9q34	*TSC1*	tuberin	Renal cysts; angiomyolipomas; renal cell carcinoma	Adenoma sebaceum; CNS hamartomas
	AD	16p13	*TSC1*	hamartin	Renal cysts; angiomyolipomas; renal cell carcinoma	Adenoma sebaceum; CNS hamartomas
Von Hippel-Lindau disease (608537)	AD	3p26-p25	*VHL*	pVHL	Renal cysts; renal cell carcinoma	Retinal angiomas; CNS hemangioblastomas; pheochromocytomas

Note: AD, autosomal dominant; AR, autosomal recessive; OMIM, online Mendelian inheritance in man.
[a]See text for details.

into the fourth or fifth decade. Presenting symptoms and signs include abdominal discomfort, hematuria, urinary tract infection, incidental discovery of hypertension, abdominal mass, elevated serum creatinine, or cystic kidneys on imaging studies (Fig. 278-1*A* and *B*). Frequently the diagnosis is made prior to the onset of symptoms, when asymptomatic members in affected families request screening. In most patients, renal function declines progressively over the course of 10–20 years from the time of diagnosis, but not everyone with ADPKD develops ESRD; it occurs in about 60% of patients by age 70. Those with ADPKD-2 tend to have later onset and slower progression. Hypertension is common and often precedes renal dysfunction, perhaps mediated by increased activity of the renin-angiotensin system. There is only mild proteinuria, and impaired urinary concentrating ability manifests early as polyuria and nocturia. Risk factors for progressive kidney disease include younger age at diagnosis, black race, male gender, presence of polycystin-1 mutation, and hypertension. There is a close correlation between the rate of kidney expansion and the rate of decline in kidney function. Dull, persistent flank and abdominal pain and early satiety and gastroesophageal reflux symptoms are common due to the mass effect of the enlarged kidneys. Cyst rupture or hemorrhage into a cyst may produce acute flank pain or symptoms and signs of localized peritonitis. Hematuria may result from cyst rupture into the collecting system or from uric acid or calcium oxalate kidney stones. Nephrolithiasis occurs in about 20% of patients. Urinary tract infection, including acute pyelonephritis, occurs with increased frequency in ADPKD. Infection in a kidney or liver cyst is a particularly serious complication. It is most often due to Gram-negative bacteria and presents with pain, fever, and chills. Blood cultures are frequently positive, but urine culture may be negative because infected kidney cysts do not communicate directly with the collecting system. Distinguishing between infection and cyst hemorrhage is often a challenge, and the diagnosis relies mainly on clinical and bacteriological findings. Radiological and nuclear imaging studies are generally not helpful.

Numerous extrarenal manifestations of ADPKD highlight the systemic nature of the disease and likely reflect a generalized abnormality in collagen and extracellular matrix. Patients with ADPKD have a fourfold increased risk of subarachnoid or cerebral hemorrhage from a ruptured intracranial aneurysm as compared to the general population. Saccular aneurysms of the anterior cerebral circulation may be detected in up to 10% of asymptomatic patients on MRA screening, but most are small, have a low risk of spontaneous rupture, and do not merit the risk of intervention. In general, hemorrhage tends to occur before the age of 50 years, in patients with a family history of intracranial hemorrhage, those who have survived a previous bleed, have aneurysms larger than 10 mm and have uncontrolled hypertension. Other vascular abnormalities include aortic root and annulus dilatation. Cardiac valvular abnormalities occur in 25% of patients, most commonly mitral valve prolapse and aortic regurgitation. Although most valvular lesions are asymptomatic, some may progress over time and warrant valve replacement. The incidence of hepatic cysts rises progressively up to 40% in patients over the age of 60 years. Most patients are asymptomatic with normal liver function tests, but hepatic cysts may bleed, become infected, rupture, and cause pain. Although the frequency of liver cysts is equal between genders, women are more likely to have massive cysts (Fig. 278-1*C*). Colonic diverticulae are common, with a higher incidence of perforation in patients with ADPKD. Abdominal wall and inguinal hernias also occur with a higher frequency than in the general population.

Diagnosis and Screening The sensitivity of renal ultrasonography for the detection of ADPKD is 100% for subjects 30 years or older with a positive family history. Diagnostic criteria require two or more cysts in one kidney and at least one cyst in the contralateral kidney in young subjects, but four or more in subjects older than 60 years because of the increased frequency of benign simple cysts. Most often, the diagnosis is made from a positive family history and imaging studies showing large

kidneys with multiple bilateral cysts and possibly liver cysts (Fig. 278-1). Before the age of 30 years, CT scan or T2-weighted MRI is more sensitive for detecting presymptomatic disease because the sensitivity of ultrasound falls to 95% for ADPKD type 1 and <70% for ADPKD type 2. Genetic linkage analysis and mutational screening for *ADPKD-1* and *ADPKD-2* is available for equivocal cases, especially when a young adult from an affected family is being considered as a potential kidney donor. Genetic counseling is essential for those being screened. It is recommended that screening for asymptomatic intracranial aneurysms should be restricted to patients with a personal or family history of intracranial hemorrhage and those in high-risk occupations. Intervention should be limited to aneurysms larger than 10 mm.

℞ AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

At present, treatment is largely supportive, as there is no single therapy that has been shown to prevent the decline in kidney function. Hypertension control with a target blood pressure of 130/85 or less is recommended according to Joint National Committee (JNC) VII guidelines; however, lower levels have been reported to slow the rate of loss of kidney function. A multidrug approach that includes agents to inhibit the renin-angiotensin system is frequently required. There is no compelling evidence to recommend a low-protein diet, especially in patients with advanced kidney dysfunction where optimizing nutritional status is important. Lipid-soluble antimicrobials, such as trimethoprim-sulfamethoxazole and quinolone antibiotics that have good tissue permeation, are the preferred therapy for infected kidney and liver cysts. Pain management occasionally requires cyst drainage by percutaneous aspiration, sclerotherapy with alcohol or, rarely, surgical drainage. Patients with ADPKD appear to have a survival advantage on either peritoneal or hemodialysis compared to patients with other causes of ESRD. Those undergoing kidney transplantation may require bilateral nephrectomy if the kidneys are massively enlarged or have been the site of infected cysts. Posttransplantation survival rates are similar to those of patients with other causes of kidney failure, but patients remain at risk for the extrarenal complications of ADPKD. Studies in animal models of inherited cystic diseases have identified promising therapeutic strategies, including vasopressin V2 receptor antagonists that suppress cyst growth by lowering intracellular cAMP and inhibitors of cell signaling that target the epidermal growth factor receptor tyrosine kinase to control cell proliferation.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

GENETIC CONSIDERATIONS ARPKD is primarily a disease of infants and children. The incidence is 1:20,000 births. The kidneys are enlarged, with small cysts, <5 mm, limited to the collecting tubules.

The ARPKD gene on chromosome 6p21, *PKHD1* (polycystic kidney and hepatic disease 1), encodes several alternatively spliced transcripts (Table 278-1). The largest transcript produces a multidomain transmembrane protein termed *fibrocystin* (*polyductin*) that is found in the cortical and medullary collecting ducts and thick ascending limb of Henle's loop in the kidney as well as in biliary and pancreatic duct epithelia. Like the polycystins, fibrocystin has receptor-like features and may be involved in cell-cell and cell-matrix interactions. Fibrocystin, the polycystins, and several proteins involved in animal models of PKD are located in association with primary cilia on the tubular epithelial cell apical surface, which suggests that they may cooperate in a mechanosensory pathway. A large number of different mutations have been identified throughout *PKHD1* and are unique to individual families. Most patients are compound heterozygotes. Those with two truncating mutations frequently die shortly after birth, whereas those that survive beyond the neonatal period generally have at least one missense mutation. Mutations in *PKHD1* have also been identified in about 30% of children with congenital hepatic fibrosis (Caroli syndrome) without evident kidney involvement.

Clinical Features The clinical presentation of ARPKD is highly variable. Up to 50% of affected neonates die of pulmonary hypoplasia, the result of oligohydramnios from severe intrauterine kidney disease. About 80% of those who survive the neonatal period are still alive after 10 years; however, one-third of them will have developed ESRD. Enlarged kidneys may be detected soon after birth as bilateral abdominal masses. Impaired urinary concentrating ability and metabolic acidosis ensue as tubular function deteriorates. Hypertension often occurs in the first few years of life. Kidney function deteriorates progressively from childhood into early adult life. Longer-term survivors frequently develop portal hypertension, esophageal varices, and hypersplenism from periportal fibrosis.

Diagnosis Ultrasonography reveals large, echogenic kidneys. The diagnosis can be made in utero after 24 weeks of gestation in severe cases, but cysts generally become visible only after birth. The absence of renal cysts in either parent on ultrasonography helps to distinguish ARPKD from ADPKD in older patients. The wide range of different mutations and the large size of the gene complicate molecular diagnosis, although prenatal diagnosis is possible by gene linkage to the *PKHD1* locus in families with a previous confirmed ARPKD birth.

℞ AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

No specific therapy exists for ARPKD. Improvements in mechanical ventilation, neonatal support, blood pressure management, dialysis, and kidney transplantation have led to survival well into adulthood. Complications of hepatic fibrosis may necessitate liver transplantation. Future therapies may target aberrant cell signaling mechanisms, as in ADPKD.

NEPHRONOPHTHISIS

Genetics and Pathogenesis Nephronophthisis (NPHP) is the most common genetic cause of ESRD in childhood and adolescence. Five distinct genetic mutations with autosomal recessive inheritance have been identified (Table 278-1). Although their precise functions are unclear, the defective protein products, named nephrocystins and inversin, localize to the primary cilium and associated basal body of renal epithelial cells, similar to the polycystins and fibrocystin. NPHP is classified into infantile, juvenile, and adolescent forms based on the age of ESRD onset. In juvenile NPHP, the most common form, the kidneys are shrunken and histology shows tubular atrophy, thickening of tubular basement membranes, diffuse interstitial fibrosis, and microscopic medullary cysts. In the infantile form, the kidneys are large and histology is similar to the juvenile form, except that medullary cysts are more prominent and develop earlier.

Clinical Features In juvenile NPHP, symptoms typically appear after one year of age. Impaired tubular function causes salt wasting and defective urinary concentration and acidification. Patients may present with polyuria, polydipsia, volume depletion, or systemic acidosis. Progressive kidney failure leads to growth retardation, anemia, and symptoms of uremia. On average, ESRD occurs by age 5 in the infantile form, age 13 in the juvenile form, and age 19 in the adolescent form. Up to 15% of patients with juvenile NPHP have extrarenal manifestations (Table 278-1), most commonly retinitis pigmentosa (Senior-Loken syndrome). Other abnormalities include blindness from amaurosis, oculomotor apraxia, cerebellar ataxia, mental retardation, hepatic fibrosis, and ventricular septal defect. Situs inversus is seen in some cases of infantile NPHP, consistent with mutation in *INVS*, a gene that is critical for left-right patterning in the embryo.

Diagnosis The diagnosis of NPHP should be considered in patients with a family history of kidney disease, early-onset progressive renal failure, and a bland urine sediment with minimal proteinuria. Ultrasonography reveals small hyperechoic kidneys in juvenile NPHP and large kidneys with cysts in the infantile form.

℞ NEPHRONOPHTHISIS

No specific therapy exists to prevent loss of kidney function in NPHP. Salt and water replacement are required for patients with salt wasting and

polyuria. Therapy should include sodium bicarbonate or citrate for acidosis, control of secondary hyperparathyroidism, erythropoietin for anemia, and timely institution of dialysis and transplantation.

MEDULLARY CYSTIC KIDNEY DISEASE

GENETIC CONSIDERATIONS The medullary cystic kidney diseases (MCKD) generally present in young adults. Two genetic loci have been defined, both with autosomal dominant transmission (Table 278-1). The locus for MCKD1 has been mapped to chromosome 1q21. Mutations in the uromodulin gene (*UMOD*) that encodes the Tamm-Horsfall mucoprotein on chromosome 16p12 have been identified in MCKD2.

Clinical Features Like NPHP, patients with MCKD have atrophic kidneys with diffuse interstitial fibrosis, cysts restricted to the renal medulla, salt wasting, and polyuria. Disease onset is later than NPHP. Consequently, there is no growth retardation, salt wasting is milder, and ESRD occurs later, usually between the ages of 20 and 60. There are no extrarenal manifestations in MCKD1. Most patients with MCKD2 and the genetically related familial juvenile hyperuricemic nephropathy also have severe hyperuricemia and precocious onset of gout.

Diagnosis The diagnosis of MCKD should be considered in young adults presenting with a family history suggesting dominant inheritance of kidney disease, progressive renal failure, bland urinalysis with little or no proteinuria, and small dense kidneys with medullary cysts on ultrasonography or CT. The presence of hyperuricemia and gout are further clues to the diagnosis of MCKD2. MCKD2 can be confirmed by mutation analysis of *UMOD*.

℞ MEDULLARY CYSTIC KIDNEY DISEASE

There is no specific therapy for MCKD. Allopurinol is indicated for patients with gout and makes sense for those with presymptomatic hyperuricemia, although there is no evidence that it prevents progressive renal failure in MCKD2. Dialysis and transplantation outcomes appear to be favorable.

TUBEROUS SCLEROSIS

Tuberous sclerosis (TS) is an autosomal dominant disorder affecting 1 out of 6000 people. It results from inactivating mutations in either the *TSC1* gene encoding tuberin or the *TSC2* gene encoding hamartin (Table 278-1). Hamartin and tubulin form a complex that is thought to negatively regulate the cell cycle. The presence of either mutation produces uncontrolled proliferation in numerous tissues, including the skin, central nervous system (CNS), heart, skeleton, and kidneys. CNS hamartomas can cause seizures, mental retardation, and autism. Expressivity is highly variable, but the kidneys are affected in 80% of patients. Renal TS occurs in three forms: renal cysts, renal angiomyolipomas, and renal cell carcinoma. Cysts are usually asymptomatic and are not evident on imaging studies until adulthood. Cysts may be large and numerous, sometimes leading to ESRD and producing a clinical scenario that can be confused with ADPKD, especially if there are few other systemic manifestations of TS. Angiomyolipomas are the most common renal abnormality, occur bilaterally, are often multiple, and are usually asymptomatic. Spontaneous bleeding can produce flank pain, nausea and vomiting, hematuria, and even life-threatening retroperitoneal hemorrhage. Large lesions, >4 cm, are most likely to cause pain and bleeding, and may require surgical excision. Multicentric renal cell carcinomas have been reported to occur with increased frequency in TS. Patients with TS should be screened for renal involvement at initial diagnosis with ultrasound or CT. Those with cysts or angiomyolipomas require regular imaging to monitor for the development of renal cell carcinoma.

VON HIPPEL-LINDAU DISEASE

Von Hippel-Lindau disease (VHL) is a rare autosomal dominant disease characterized by abnormal angiogenesis with benign and malignant tumors affecting multiple tissues. The disease is inherited as a mutation in one allele of the *VHL* tumor suppressor gene. Somatic mutation of the normal allele leads to retinal angiomas, CNS hemangioblastomas, pheochromocytomas and multicentric clear cell cysts, hemangiomas, and adenomas of the kidney. The kidneys are affected in three-quarters of patients, and half develop clear cell carcinomas in the renal cysts. Ten percent of patients present with symptoms of clear cell carcinoma. It is noteworthy that *VHL* mutations also account for 60% of spontaneous clear cell carcinomas of the kidney. The diagnosis of renal cell carcinoma in VHL disease is made at a mean age of 44 years, while 70% of patients who survive to age 60 develop renal carcinoma. The high risk of renal cell carcinoma mandates periodic surveillance (usually yearly in adults) by either CT or MRI. Routine screening and awareness of the natural history of lesions has enabled renal-sparing approaches to disease management. Tumors <3 cm in size require careful monitoring for growth, while partial nephrectomy is indicated in those >3 cm in the absence of metastasis. Nonsurgical renal-sparing strategies, including percutaneous radiofrequency ablation and selective arterial embolization, have shown promise in short-term trials.

MEDULLARY SPONGE KIDNEY

Pathology and Clinical Features Medullary sponge kidney (MSK) is a common, benign condition of unknown cause characterized by ectasia of the papillary collecting ducts of one or both kidneys. Urinary stasis in the dilated ducts, hypocitraturia, and, occasionally, incomplete distal renal tubular acidosis (dRTA) contribute to the formation of small calcium-containing calculi. Most cases are asymptomatic or are discovered during investigation of asymptomatic hematuria. Symptomatic patients typically present as young adults with renal colic and the passage of stones or recurrent urinary tract infections; however, MSK may cause hematuria and nephrolithiasis in children. Most cases are sporadic, although MSK has been found rarely in association with other congenital anomalies of the urinary tract and with congenital hepatic ductal ectasia and fibrosis (Caroli disease).

Diagnosis In patients with nephrolithiasis, MSK is characteristically seen as hyperdense papillae with clusters of small stones on renal ultrasonography or abdominal X-ray (Fig. 278-2). The classical "paintbrush-like" features of MSK, representing the ectatic collecting ducts, are best seen on intravenous urography. However, this procedure has been supplanted in many radiology departments by contrast-enhanced, high-resolution helical CT with digital reconstruction (Fig. 278-2).

℞ MEDULLARY SPONGE KIDNEY

No treatment is necessary in asymptomatic individuals aside from maintaining high fluid intake to reduce the risk of nephrolithiasis. Recurrent stone formation should prompt a metabolic evaluation and treatment as in any stone former (Chap. 281). In those patients with hypocitraturia and incomplete distal renal tubular acidosis, treatment with potassium citrate helps prevent new stone formation. Urinary tract infections should be treated promptly.

HEREDITARY DISORDERS OF SODIUM, POTASSIUM, AND MAGNESIUM HANDLING WITHOUT HYPERTENSION

Inherited forms of hypochloremic metabolic alkalosis and hypokalemia without hypertension are due to genetic mutations of various ion transporters and channels of the thick ascending limb (TAL) of Henle's loop and distal convoluted tubule (DCT) (Table 278-2 and Fig. 278-3). In 1962 Bartter and colleagues described two African-American patients with a syndrome of metabolic alkalosis, hypovolemia, hyposthenuria, and failure to thrive associated with juxtaglomerular apparatus hyperplasia, hyperaldosteronism, and normal blood pressure. Subsequently, Gitelman and colleagues identified a similar but milder syndrome accompanied by severe hypomagnesemia from urinary magnesium wasting and presenting in later childhood and adolescence. These disorders are now known to occur sporadically or

In addition to the stone (*arrow*), a blush of contrast is seen filling the ectatic collecting ducts (*arrowheads*).

from genetically heterogenous loss-of-function autosomal recessive mutations that cause salt-losing tubulopathy.

BARTTER'S SYNDROME AND GITELMAN'S SYNDROME

Genetics and Pathogenesis

Bartter's syndrome may result from mutations affecting any of four ion transport proteins in the TAL. The proteins affected include the apical loop-diuretic sensitive sodium-potassium-chloride co-transporter NKCC2 (type 1), the apical potassium channel ROMK (type 2), and the basolateral chloride channel ClC-Kb (type 3). Bartter type 4 results from mutations in barttin, an essential subunit of ClC-Ka and ClC-Kb that enables transport of the chloride channels to the cell surface. Barttin is also expressed in the inner ear, which accounts for the deafness invariably associated with Bartter type 4. The TAL transporters function in an integrated manner to maintain both the electrical potential difference and sodium gradient between the lumen and the cell (Fig. 278-3). Loss of the lumen-positive electrical transport potential that normally drives the paracellular reabsorption of sodium, calcium, and magnesium causes NaCl wasting, hypercalciuria, and mild hypomagnesemia. As expected, the clinical syndrome mimics a state induced by chronic ingestion of a loop diuretic.

Gitelman's syndrome is due to mutations in the thiazide-sensitive Na-Cl co-transporter (NCCT) in the DCT. Defects in NCCT in Gitelman's syndrome impair sodium and chloride reabsorption in the DCT (Fig. 278-3) and, thus, resemble the effects of thiazide diuretics. It remains unclear how this defect leads to severe magnesium wasting. A Bartter-like phenotype (type 5) with associated hypocalcemia has also been described in a few patients with autosomal dominant gain-of-function mutations in the extracellular calcium-sensing receptor (CaSR). Unregulated activation of this G-protein–coupled receptor inhibits sodium reabsorption in the TAL.

In both Bartter's and Gitelman's syndromes, hypovolemia from impaired sodium and chloride reabsorption in either the TAL or DCT activates the renin-angiotensin-aldosterone system (RAS). The consequent hyperaldosteronism, together with increased distal flow and sodium delivery, stimulates increased sodium reabsorption in the collecting tubules via the epithelial sodium channel (ENaC). This promotes increased potassium and hydrogen ion secretion, causing hypokalemia and metabolic alkalosis. Additionally, in Bartter's syndrome, RAS activation causes increased levels of cyclooxygenase 2 (COX-2) and marked overproduction of renal prostaglandins (PGE2), which exacerbates the polyuria and electrolyte abnormalities.

Clinical Features

• ***BARTTER'S SYNDROME*** Bartter's syndrome is a rare disease that most often presents in the neonatal period or early childhood with polyuria, polydipsia, salt craving, and growth retardation. Blood pressure is normal or low. Metabolic abnormalities include hypokalemia, hypochloremic metabolic alkalosis, decreased urinary concentrating and diluting ability, hypercalciuria with nephrocalcinosis, mild hypomagnesemia, and increased urinary prostaglandin excretion. Hyperprostaglandin E syndrome is a particularly severe form of Bartter's syndrome in which neonates present with pronounced volume depletion and failure to thrive, as well as fever, vomiting, and diarrhea from PGE_2 overproduction. In the antenatal period, fetal polyuria may cause maternal polyhydramnios and premature labor. Sensorineural deafness occurs in those cases with barttin gene mutations. Patients with severe Bartter's syndrome that survive early childhood may develop chronic renal failure from nephrocalcinosis or from tubular atrophy and interstitial fibrosis from severe persistent hypokalemia. Patients with Bartter's syndrome type 3 have a phenotype intermediate between Bartter's and Gitelman's syndromes, consistent with mutation of the ClC-Kb chloride channel in both the TAL and DCT with preservation of the ClC-Ka chloride channel in the TAL. This disease occurs predominantly in African-American patients and resembles most closely the classical syndrome described by Bartter. Onset is generally later in childhood, patients have mild or no nephrocalcinosis, and prostaglandin excretion is normal.

GITELMAN'S SYNDROME Gitelman's syndrome is more common than Bartter's syndrome and has a generally milder clinical course with later age of presentation. It is characterized by hypocalciuria, severe hypomagnesemia, and prominent muscular symptoms and signs, including fatigue, weakness, carpopedal spasm, cramps, and tetany. Excess prostaglandin production does not typically occur in Gitelman's syndrome.

Diagnosis

Hypokalemia and hypochloremic metabolic alkalosis without hypertension is more often due to surreptitious vomiting or diuretic abuse rather than Bartter's or Gitelman's syndromes. In contrast to the salt-losing tubulopathies, urinary chloride levels are very low or undetectable in patients with surreptitious vomiting. Diuretic abuse can be excluded by screening the urine for the offending drugs. Gitelman's

syndrome is distinguished from most forms of Bartter's syndrome by the presence of severe hypomagnesemia and hypocalciuria.

℞ BARTTER'S SYNDROME AND GITELMAN'S SYNDROME

Both conditions require lifelong therapy with potassium and magnesium supplements and liberal salt intake. High doses of spironolactone or amiloride are necessary to treat the hypokalemia, alkalosis, and magnesium wasting. Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the polyuria and salt wasting in Bartter's syndrome but are ineffective in Gitelman's syndrome. They may be lifesaving in hyperprostaglandin E syndrome. COX-2 inhibitors are effective and justified because of the gastrointestinal complications that may arise from the long-term use of high doses of NSAIDs. In Gitelman's syndrome, magnesium repletion is essential to correct the hypokalemia and control

muscle weakness, tetany, and metabolic alkalosis; however, it may prove difficult in patients wasting large amounts of magnesium.

PSEUDOHYPOALDOSTERONISM TYPE I

Patients with type I pseudohypoaldosteronism present with severe renal salt wasting and hyperkalemia. Although these findings resemble mineralocorticoid deficiency, plasma renin activity and aldosterone levels are elevated. Defective salt handling is the result of autosomal recessive loss-of-function mutations of the α, β, or γ subunits of the ENaC or autosomal dominant mutations of one allele of the mineralocorticoid receptor (Table 278-2 and Fig. 278-3). The autosomal recessive form is a multisystem disorder with a severe phenotype, often manifesting in the neonatal period with renal salt wasting, vomiting, hyponatremia, hyperkalemia, acidosis, and failure to thrive. Impaired channel activity in the skin and lungs can produce excess sodium and chloride loss in sweat, excess fluid in the airways, and a propensity for lower respiratory tract infections mimicking cystic fibrosis. In contrast, the autosomal dominant form of type I pseudohypoaldosteronism has a more benign course that is limited mainly to renal salt wasting and hyperkalemia. Aggressive salt replacement and management of hyperkalemia can lead to survival into adulthood, and symptoms may become less severe with time, especially in the dominant form. In the latter, high-dose fludrocortisone or carbenoxolone provides additional benefit by raising intracellular mineralocorticoid activity and partly restoring the functional defect in the mutant receptor.

MAGNESIUM WASTING DISORDERS

In addition to Gitelman's syndrome, there are several hereditary disorders that cause urinary magnesium wasting (Table 278-2 and Fig. 278-3). These include autosomal recessive familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC), autosomal recessive hypomagnesemia with secondary hypocalcemia (HSH), autosomal dominant hypomagnesemia, and autosomal dominant hypoparathyroidism (Chap. 347). Common clinical features are the early onset of spasms, tetany, and seizures, as well as associated or secondary disturbances in calcium homeostasis.

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

FHHNC (also known as primary hypomagnesemia) is the first example of a disorder attributable to a defective protein involved in paracellular

ion transport. *CLDCN16* encodes claudin 16 (previously known as paracellin-1), a member of the claudin family of proteins that are involved in tight junction formation. Claudin 16 is expressed in the TAL of Henle's loop and the DCT. Claudin 16 is thought to be an essential component of the paracellular pathway for Mg, and Ca to a lesser extent, reabsorption in the TAL. Clinical manifestations begin in infancy and include hypomagnesemia that is refractory to oral supplementation, hypercalciuria and nephrocalcinosis. Recurrent urinary tract infections and nephrolithiasis have also been observed, and some patients manifest ocular defects, including corneal calcifications and chorioretinitis.

Hypomagnesemia with Secondary Hypocalcemia Hypomagnesemia in HSH results from a defect in the TRPM6 channel, a member of the transient receptor potential (TRP) family of proteins that are involved in cation transport. TRPM6 is expressed in intestinal epithelia and renal tubules and is thought to mediate transepithelial magnesium transport. Affected individuals have presented with symptoms attributable to hypomagnesemia with secondary impairment of parathyroid function and hypocalcemia. Seizures and muscle spasms occur in infancy, and restoration of magnesium and calcium levels requires high doses of oral magnesium supplementation.

Other Hereditary Hypomagnesemic Disorders Mutations of the sodium-potassium-ATPase gamma-subunit can cause an autosomal dominant form of hypomagnesemia. Activating mutations of the CaSR in autosomal dominant hypoparathyroidism primarily manifests as hypocalcemia, but hypomagnesemia has been reported in 50% of patients.

HEREDITARY TUBULAR DISORDERS CAUSING HYPERTENSION DUE TO SALT RETENTION

LIDDLE'S SYNDROME

Liddle's syndrome mimics a state of aldosterone excess by the presence of early and severe hypertension, often accompanied by hypokalemia and metabolic alkalosis, but plasma aldosterone and renin levels are low. This disorder is due to unregulated sodium reabsorption by an overactive ENaC in the cortical collecting duct (Fig. 278-3). Deletional mutations of the intracellular domain of the β or γ subunit of ENaC (Table 278-2) prevent recycling from the apical membrane and an inability to downregulate the number of channels despite a high intracellular sodium concentration. Increased potassium and hydrogen ion secretion follow the lumen-negative electrical potential that results from chloride-independent sodium reabsorption. Amiloride or triamterene block ENaC and, combined with salt restriction, provide effective therapy for hypertension and hypokalemia.

FAMILIAL HYPERKALEMIC HYPERTENSION (PSEUDOHYPOALDOSTERONISM TYPE II; GORDON SYNDROME)

Familial hyperkalemic hypertension (FHHt) is a rare autosomal dominant disease that manifests in adolescence or early adulthood with thiazide-responsive low-renin hypertension, hyperkalemia, and metabolic acidosis with normal renal function. In some families, mutations have been identified in the WNK kinases 1 and 4 that lead to increased activity of the thiazide-sensitive sodium chloride co-transporter, NCCT. This causes hypertension from enhanced salt reabsorption in the DCT and impaired distal secretion of potassium and hydrogen ion, all of which can be corrected with thiazide diuretics.

INHERITED DISORDERS OF WATER HANDLING

HEREDITARY NEPHROGENIC DIABETES INSIPIDUS

Hereditary nephrogenic diabetes insipidus (NDI) is a rare monogenic disease that usually presents in infancy with severe vasopressin-resistant polyuria, dehydration, failure to thrive, and dilute urine despite the presence of hypernatremia.

Genetics and Pathogenesis Vasopressin [antidiuretic hormone (ADH)]-stimulated water reabsorption in the collecting duct is mediated by the type 2 vasopressin receptor (V2R) on the basal surface of principal cells. Activation of the adenylyl cyclase-cAMP pathway phosphorylates vesicle-associated aquaporin-2 (AQP2) water channels and stimulates their insertion into the apical plasma membrane. Water enters the cells from the tubular lumen through AQP2 and exits along an osmotic gradient into the hypertonic medulla and vasa rectae via basal AQP3/4 channels (Fig. 278-3). X-linked mutations of V2R account for about 90% of cases of NDI, such that the expression of the receptor on the cell surface is impaired. The remaining cases are due to various autosomal recessive or dominant mutations of AQP2 that cause the water channels to be retained within the cytosol (Table 278-2). The effect of these mutations is an inability to concentrate the urine and conserve water despite high plasma levels of vasopressin. Penetrance is variable in heterozygous female carriers of X-linked NDI, and some have a moderate concentrating defect.

Clinical Features Whereas NDI in adults is most often acquired from conditions such as hypercalcemia, lithium therapy, and partial chronic urinary obstruction, hereditary NDI typically presents in infancy. Unlike other polyuric syndromes such as Bartter's and Gitelman's syndromes, conservation of electrolytes is normal, and hypernatremia is entirely from the loss of water. Recurrent episodes of dehydration and hypernatremia can lead to seizures and mental retardation. Although renal function is otherwise normal, chronically high urine flow causes dilatation of the ureters and bladder and may cause bladder dysfunction and obstructive uropathy.

Diagnosis The diagnosis in infants and children with hereditary NDI is usually apparent from the family history and clinical presentation. The diagnosis can be confirmed by the presence of high plasma levels of vasopressin in the face of polyuria and hypotonic urine. This may be especially useful in adults with partial NDI to distinguish the polyuric state from central diabetes insipidus or psychogenic polydipsia (Chap. 334). Genetic screening for mutations in *AVPR2* and *AQP2* is available in research centers and should be performed to identify affected infants from families at risk of NDI in order to begin treatment and avoid dehydration and its consequences.

℞ HEREDITARY NEPHROGENIC DIABETES INSIPIDUS

In families with high awareness of the condition, early diagnosis and treatment with abundant water intake has enabled many patients to live to adulthood with normal mental and physical development. Exogeneous vasopressin is ineffective, and because these patients can excrete up to 20 L of urine per day, maintaining adequate water intake is challenging. Thiazide diuretics and salt restriction can reduce urine output by inducing a state of mild volume contraction, thereby promoting increased proximal reabsorption of isotonic fluid and inhibiting the generation of free water. A combination thiazide-amiloride formulation will avoid thiazide-induced hypokalemia and alkalosis, and indomethacin may further reduce urine output by inhibiting prostaglandin synthesis.

NEPHROGENIC SYNDROME OF INAPPROPRIATE ANTIDIURESIS

Activating mutations of the V2R were recently described in two boys who presented with irritability and seizures within the first three months of life. Laboratory evaluation was significant for hyponatremia with inappropriately elevated urinary osmolality and undetectable vasopressin levels. Genomic analysis revealed missense mutations of *AVPR2* causing constitutive activation of V2R and inappropriate water reabsorption.

INHERITED RENAL TUBULAR ACIDOSIS

Nonanion gap (hyperchloremic) metabolic acidosis from proximal tubular bicarbonate wasting or impaired distal net acid excretion may be a primary (sporadic or inherited) tubular disorder or acquired secondary to a variety of conditions (Chap. 48). There are three forms of

renal tubular acidosis (RTA). Types 1 and 2 may be acquired or primary whereas the most common form, type 4 RTA, is usually acquired in association with moderate renal dysfunction and is characterized by hyperkalemia.

TYPE 1 (DISTAL) RTA

Clinical Features and Diagnosis In primary distal RTA (dRTA), the kidneys are unable to acidify the urine to pH <5.5 in the presence of systemic metabolic acidosis or after acid loading as a result of impaired hydrogen ion secretion or bicarbonate reabsorption in the distal nephron. Other features are hypokalemia, hypocitraturia, hypercalciuria, nephrocalcinosis, and/or nephrolithiasis. Chronic untreated acidosis may cause rickets or osteomalacia. Inheritance of primary dRTA includes autosomal dominant and autosomal recessive forms with a broad spectrum of clinical expression. Autosomal recessive dRTA most often presents in infancy with severe acidosis, failure to thrive, impaired growth, and impaired kidney function from nephrocalcinosis. Many patients with autosomal dominant dRTA, and some with recessive disease, are asymptomatic, and RTA is discovered incidentally in adolescence or adulthood during evaluation for kidney stones. In the absence of systemic acidosis, the diagnosis of incomplete dRTA is suggested by hypocitraturia and hypercalciuria and can be confirmed by failure of the urine to acidify to pH <5.5 after acid loading with oral ammonium chloride or calcium chloride.

Genetics and Pathophysiology Primary dRTA may be hereditary or sporadic. Several kindreds with hereditary dRTA have been identified in Southeast Asia and in areas of the world where parental consanguinity is high. The cellular basis for dRTA lies in dysfunction at the level of the α type intercalated cell of the cortical collecting duct (Fig. 278-3). Mutations affecting subunits of the H^+-ATPase proton pump on the luminal surface impair hydrogen ion secretion, account for most forms of autosomal recessive dRTA, and are often associated with early-onset sensorineural hearing loss (Table 278-2). Autosomal dominant dRTA results from mutations involving the chloride-bicarbonate exchanger AE1, the gateway for bicarbonate exit into the blood. Anion exchange by the mutant AE1 is normal, but aberrant targeting of AE1 from the basal to apical plasma membrane is believed to cause bicarbonate loss into the urine instead of recovery. Bi-allelic mutations of AE1 may impair transport activity and account for some cases of recessive disease, sometimes associated with late-onset hearing loss (Table 278-2). A syndrome of osteopetrosis, short stature, and mental retardation, so-called "marble-brain disease" with dRTA, is due to mutations in carbonic anhydrase II. Urinary potassium wasting and defective urinary concentration are characteristic of dRTA, but the precise mechanisms are unclear. Calcium is released from bone in the process of buffering of acid and results in hypercalciuria. Enhanced proximal citrate absorption accounts for hypocitraturia and, together with hypercalciuria, predisposes to nephrocalcinosis and calcium phosphate stone formation.

Rx TYPE 1 (DISTAL) RTA

Early initiation of alkali replacement at doses equivalent to 1–3 mmol/kg/day of bicarbonate in divided doses will usually correct the acidosis, hypokalemia, and hypocitraturia, maintaining growth and preventing bone disease in early-onset dRTA. Citrate is generally tolerated better than sodium bicarbonate and can be given as potassium or sodium salt, depending on the severity of hypokalemia. In patients who present later with kidney stones, large fluid intake and sufficient alkali to restore normal acid-base balance corrects the hypocitraturia and reduces hypercalciuria, thereby inhibiting the formation of new stones.

TYPE 2 (PROXIMAL) RTA

Proximal RTA (pRTA) is the result of impaired bicarbonate reabsorption in the proximal tubular where the bulk of filtered bicarbonate is recovered (Fig. 278-3). It is most often secondary to various autoimmune, drug-induced, infiltrative, or other tubulopathies (Chap. 48) or a result of tubular injury from inherited diseases in which endogenous metabolites accumulate and produce tubular injury. Such inherited disorders include Wilson's disease, cystinosis, tyrosinemia, galactosemia, hereditary fructose intolerance, glycogen storage disease type I, and Lowe's syndrome. In this situation pRTA is but one of several abnormalities that constitute Fanconi syndrome. Other features are hyperphosphaturia, hyperuricosuria, hypercalciuria, nonselective amino aciduria and glycosuria. In addition to hyperchloremic acidosis, rickets or osteomalacia are the predominant effects of Fanconi syndrome.

A rare infantile form of primary pRTA with isolated proximal tubular bicarbonate wasting is due to homozygous mutations of the proximal tubule basolateral sodium-bicarbonate exchanger NBC1 (Table 278-2). This exchanger is the main mechanism by which bicarbonate moves from the proximal tubule cell back into the blood. Other manifestations include short stature and mental retardation. An ocular phenotype that includes bilateral glaucoma, cataracts, and band keratopathy reflects a role of NBC1 in maintaining normal fluid balance in the eye and clarity of the lens.

Patients with pRTA have severe metabolic acidosis, and it is difficult to restore normal acid-base balance despite large amounts of alkali. This is a consequence of their continuing to waste bicarbonate (fractional excretion >15%) until the serum level falls below a threshold level, usually about 15–17 mmol/L, at which time bicarbonate is completely reabsorbed and the urine is maximally acidified with pH <5.5. When the serum bicarbonate is raised above the threshold with alkali therapy, bicarbonate wasting recurs and causes hypokalemia by flooding the distal nephron with a nonreabsorbable anion.

Rx TYPE 2 (PROXIMAL) RTA

Treatment of pRTA requires 5–15 mmol/kg/day of bicarbonate together with supplemental potassium and vitamin D.

OTHER MONOGENIC DISORDERS OF PROXIMAL TUBULAR FUNCTION (Fig. 278-3)

CYSTINURIA

Cystinuria is an autosomal recessive disorder of cystine and dibasic amino acid (ornithine, arginine, and lysine) transport in the proximal tubule and intestinal epithelial cells. With a prevalence of about 1 in 7000, it represents one of the more common heritable diseases. Impaired tubular absorption leads to high concentrations of cystine, which is insoluble in the acid environment of the renal tubules. Clinical severity varies from asymptomatic cystine crystalluria in heterozygous carriers to the frequent passage of gravel and cystine stones, ureteral obstruction, recurrent urinary infections, and progressive kidney failure in homozygotes. The disease is due to mutations in one of two genes, *SLC3A1* and *SLC7A9* (Table 278-2). *SLC3A1* encodes rBAT, a high-affinity, sodium-independent transporter for dibasic amino acids. The protein product of *SLC7A9*, $b^{0,+}$AT, is a catalytic subunit that associates with rBAT to form the active transporter. Diagnosis of cystinuria is established by a positive family history, the finding of hexagonal cystine crystals on urinalysis, and 24-hour urinary cystine excretion that exceeds 400 mg (normal less than 30 mg/d). Genetic analysis will probably become commonly available.

Rx CYSTINURIA

The mainstay of treatment is hydration to achieve a urine output of 2.5 L/day or more to reduce urine cystine concentration to <300mg/L, together with urine alkalinization to pH 7.0–7.5 with potassium citrate, and sodium restriction. Cystine is an oxidized dimer formed by linking two cysteine residues via a disulfide bond between the -SH groups. Thus, in intractable cases, thiol derivatives like penicillamine, captopril, and tiopronin may be added as second-line chelation therapy to dissociate the cystine molecule into more soluble disulfide compounds. Various stone removal and urinary drainage procedures are often required.

HARTNUP DISEASE

Hartnup disease is an autosomal recessive condition caused by a defect in intestinal and renal transport of neutral amino acids. The major clinical manifestations are cerebellar ataxia and pellagra-like skin lesions. Other than aminoaciduria, the kidneys are unaffected. The defective gene *SLC6A19* encodes a sodium-dependent and chloride-independent neutral amino acid transporter, which is expressed predominately in the intestine and renal tubules (Table 278-2). Amino acids such as tryptophan that are retained in the intestinal lumen are converted to indole compounds that are toxic to the CNS. Abnormal tryptophan metabolism also leads to niacin deficiency that accounts for the skin manifestations. Symptoms are aggravated by a protein-deficient diet and alleviated with a high-protein diet and nicotinamide supplements.

DENT'S DISEASE

Dent's disease and X-linked recessive nephrolithiasis are unusual forms of Fanconi syndrome due to X-linked recessive mutations of the gene encoding CLCN5, a channel belonging to a family of voltage-gated chloride channels (Table 278-2). The disorders are characterized by childhood onset of low-molecular-weight proteinuria, hypercalciuria, nephrocalcinosis and nephrolithiasis. Rickets or osteomalacia occurs in 30% of patients, and progressive renal failure from interstitial fibrosis, tubular atrophy, and glomerulosclerosis commonly develops in adulthood. CLCN5 serves to maintain the electrical gradient and acid environment established in proximal tubular cell endosomes by proton-ATPase, which is necessary for the degradation of low-molecular-weight proteins normally filtered by the glomerulus. Defects in CLCN5 appear to disrupt this process and lead to tubular cell dysfunction.

Rx DENT'S DISEASE

Treatment is directed at controlling hypercalciuria by dietary salt restriction and thiazide diuretics, which favor calcium reabsorption. Restriction of dietary calcium is not recommended.

RENAL GLUCOSURIA

Isolated glucosuria in the presence of a normal blood glucose concentration is due to mutations in *SLC5A2*, the gene encoding the high-capacity sodium-glucose co-transporter SGLT2 in the proximal renal tubule (Table 278-2). Subjects with this disorder are usually asymptomatic and do not have other features of proximal tubular dysfunction. Depending on the severity of the defect, the tubular maximum for glucose reabsorption may fall well within normal blood glucose levels and lead to >50 grams/day of glucosuria. Such patients may have polyuria from osmotic diuresis.

RENAL PHOSPHATE WASTING

Renal phosphate wasting resulting in hypophosphatemia and rickets or osteomalacia may be part of a generalized disorder of proximal tubular function, as in Fanconi syndrome, or an isolated phenomenon. Isolated phosphaturia is most often due to the inhibition of renal tubular phosphate reabsorption by one or other phosphaturic hormone (Chap. 346). An exception is hereditary hypophosphatemic rickets with hypercalciuria (HHRH). HHRH is an autosomal recessive disorder due to mutations in *SLC34A3*, the gene encoding the proximal tubule sodium-phosphate co-transporter (Table 278-2). Defective phosphate reabsorption causes renal phosphate wasting and leads to stunted growth from rickets. The low serum phosphorus levels appropriately stimulate 1-hydroxylation of vitamin D, which increases intestinal calcium absorption, suppresses parathyroid hormone (PTH) secretion and results in hypercalciuria. High levels of 1,25-dihydroxyvitamin D help distinguish HHRH from hormonal causes of hyperphosphaturia. Treatment is directed at phosphate repletion.

VITAMIN D–DEPENDENT RICKETS

Vitamin D–dependent rickets exists in two forms that manifest with hypocalcemia, hypophosphatemia, elevated PTH levels, and the skeletal abnormalities of rickets and osteomalacia. Tetany may be present in severe cases. Vitamin D–dependent rickets type I is an autosomal recessive disease resulting from mutations in *CYP27B1*, the gene that encodes 25(OH)D_3-1α-hydroxylase, an enzyme in the proximal tubule that catalyzes the hydroxylation and activation of 25(OH)D_3 into 1,25$(OH)_2D_3$ (Table 278-2). It can be treated with physiologic replacement doses of 1,25$(OH)_2D_3$. In contrast, vitamin D–dependent rickets type II is due to end-organ resistance to 1,25$(OH)_2D_3$ as a result of mutations in the vitamin D receptor (Chap. 347).

279 Tubulointerstitial Diseases of the Kidney

Alan S. L. Yu, Barry M. Brenner

Primary tubulointerstitial diseases of the kidney are characterized by histologic and functional abnormalities that involve the tubules and interstitium to a greater degree than the glomeruli and renal vasculature (Table 279-1). Secondary tubulointerstitial disease occurs as a consequence of progressive glomerular or vascular injury. Morphologically, acute forms of these disorders are characterized by interstitial edema, often associated with cortical and medullary infiltration by both mononuclear cells and polymorphonuclear leukocytes, and patchy areas of tubule cell necrosis. In more chronic forms, interstitial fibrosis predominates, inflammatory cells are typically mononuclear, and abnormalities of the tubules tend to be more widespread, as evidenced by atrophy, luminal dilatation, and thickening of tubule basement membranes. Because of the nonspecific nature of the histology, particularly in chronic tubulointerstitial diseases, biopsy specimens rarely provide a specific diagnosis. The urine sediment is also unlikely to be diagnostic, except in allergic forms of acute tubulointerstitial disease in which eosinophils may predominate in the urinary sediment.

Defects in renal function often accompany these alterations of tubule and interstitial structure (Table 279-2). Proximal tubule dysfunction may be manifested as selective reabsorptive defects leading to hypokalemia, aminoaciduria, glycosuria, phosphaturia, uricosuria, or

TABLE 279-1 PRINCIPAL CAUSES OF TUBULOINTERSTITIAL DISEASE OF THE KIDNEY

Acute Interstitial Nephritis
Drugs[a]
Antibiotics (β-lactams, sulfonamides, quinolones, vancomycin, erythromycin, minocycline, rifampin, ethambutol, acyclovir)
Nonsteroidal anti-inflammatory drugs, cyclooxygenase 2 inhibitors
Diuretics (thiazides, furosemide, triamterene)
Anticonvulsants (phenytoin, phenobarbital, carbamazepine, valproic acid)
Miscellaneous (captopril, H_2 receptor blockers, proton pump inhibitors, mesalazine, indinavir, allopurinol)
Infection
Bacteria (*Streptococcus*, *Staphylococcus*, *Legionella*, *Salmonella*, *Brucella*, *Yersinia*, *Corynebacterium diphtheriae*)
Viruses (Epstein-Barr virus, cytomegalovirus, Hantavirus, polyomavirus, HIV)
Miscellaneous (*Leptospira*, *Rickettsia*, *Mycoplasma*)
Idiopathic
Tubulointerstitial nephritis–uveitis syndrome
Anti-tubule basement membrane disease
Sarcoidosis
Chronic Tubulointerstitial Diseases
Hereditary renal diseases
Polycystic kidney disease[a] (Chap. 278)
Medullary cystic disease (Chap. 278)
Medullary sponge kidney (Chap. 278)

Radiation nephritis
Balkan nephropathy
Tubulointerstitial disease secondary to glomerular and vascular disease

[a]Common.

bicarbonaturia [proximal or type II renal tubular acidosis (RTA); Chap. 278]. In combination, these defects constitute the *Fanconi syndrome*. Proteinuria, predominantly of low-molecular-weight proteins, is usually modest, rarely > 2 g/d.

Defects in urinary acidification and concentrating ability often represent the most troublesome of the tubule dysfunctions encountered in patients with tubulointerstitial disease. Hyperchloremic metabolic acidosis often develops at a relatively early stage in the course. Patients with this finding generally elaborate urine of maximal acidity (pH ≤ 5.3). In such patients the defect in acid excretion is usually caused by a reduced capacity to generate and excrete ammonia due to the reduction in renal mass. Preferential damage to the collecting ducts, as in amyloidosis or chronic obstructive uropathy, may also predispose to distal or type I RTA, characterized by high urine pH (≥ 5.5) during spontaneous or NH_4Cl-induced metabolic acidosis. Patients with tubulointerstitial diseases affecting predominantly medullary and papillary structures (such as analgesic nephropathy and sickle cell disease) may also exhibit concentrating defects, with resultant nocturia and polyuria.

TOXINS

Although the kidney is vulnerable to toxic injury, renal damage by a variety of nephrotoxins often goes unrecognized because the manifestations of such injury are usually nonspecific in nature and insidious in onset. Diagnosis largely depends on a history of exposure to a certain toxin. Particular attention should be paid to the occupational history, as well as to an assessment of exposure—current and remote—to drugs, especially antibiotics and analgesics, and to dietary supplements or herbal remedies. The recognition of a potential association between a patient's renal disease and exposure to a nephrotoxin is crucial, because, unlike many other forms of renal disease, progression of the functional and morphologic abnormalities associated with toxin-induced nephropathies may be prevented, and even reversed, by eliminating additional exposure.

Exogenous Toxins • *ANALGESIC NEPHROPATHY*

A distinct syndrome has been described in heavy users of analgesic mixtures containing phenacetin (banned in the United States since 1983) in combination with aspirin, acetaminophen, or caffeine. Morphologically, analgesic nephropathy is characterized by papillary necrosis and tubulointerstitial inflammation. At an early stage, damage to the vascular supply of the inner medulla (vasa recta) leads to a local interstitial inflammatory reaction and, eventually, to papillary ischemia, necrosis, fibrosis, and calcification. The susceptibility of the renal papillae to damage by phenacetin is believed to be related to the establishment of a renal gradient for its acetaminophen metabolite, resulting in papillary tip concentrations tenfold higher than those in renal cortex.

In analgesic nephropathy, renal function usually declines gradually. Occasionally, papillary necrosis may be associated with hematuria and even renal colic owing to obstruction of a ureter by necrotic tissue. More than half of patients have sterile pyuria. Patients with analgesic nephropathy are usually unable to generate maximally concentrated urine, reflecting the underlying medullary and papillary damage. An acquired form of distal RTA (Chap. 278) may contribute to the development of *nephrocalcinosis*. The occurrence of anemia out of proportion to the degree of renal failure may also provide a clue to the diagnosis. When analgesic nephropathy has progressed to renal insufficiency, the kidneys usually appear bilaterally shrunken on intravenous pyelography, and the calyces are deformed. A "ring sign" on the pyelogram is pathognomonic of papillary necrosis and represents the radiolucent sloughed papilla surrounded by the radiodense contrast material in the calyx. CT may reveal papillary calcifications surrounding the central sinus complex in a "garland" pattern (Fig. 279-1). Transitional cell carcinoma may develop in the urinary pelvis or ureters as a late complication of analgesic abuse.

TABLE 279-2 FUNCTIONAL CONSEQUENCES OF TUBULOINTERSTITIAL DISEASE

Defect	Cause(s)
Reduced glomerular filtration rate[a]	Obliteration of microvasculature and obstruction of tubules
Fanconi syndrome	Damage to proximal tubular reabsorption of glucose, amino acids, phosphate, and bicarbonate
Hyperchloremic acidosis[a]	1. Reduced ammonia production 2. Inability to acidify the collecting duct fluid (distal renal tubular acidosis) 3. Proximal bicarbonate wasting
Tubular or small-molecular-weight proteinuria[a]	Failure of proximal tubule protein reabsorption
Polyuria, isosthenuria[a]	Damage to medullary tubules and vasculature
Hyperkalemia[a]	Potassium secretory defects including aldosterone resistance
Salt wasting	Distal tubular damage with impaired sodium reabsorption

[a]Common.

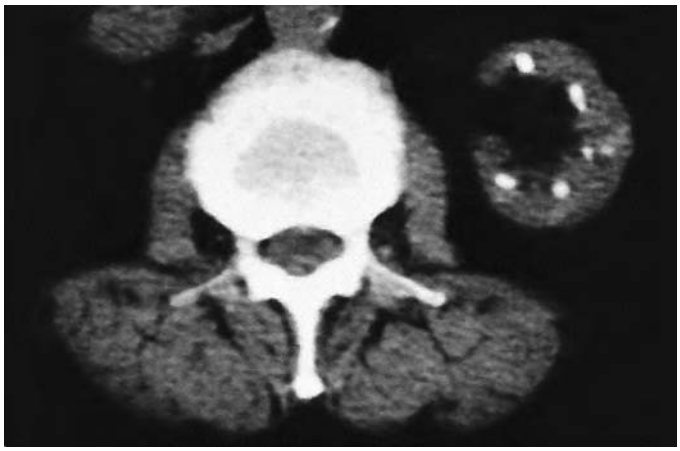

FIGURE 279-1 Radiologic appearance of analgesic nephropathy. A non-contrast CT scan shows an atrophic left kidney with papillary calcifications in a garland pattern. *(Reprinted by permission from Macmillan Publishers Ltd, MM Elseviers et al, Kidney International 48:1316, 1995.)*

Whether non-phenacetin analgesics, alone or in combination, cause renal disease is controversial. Recent cohort studies in individuals with normal baseline renal function suggest that the risk of moderate analgesic use, if any, is low. Until conclusive evidence is available, however, physicians should consider screening heavy users of acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) for evidence of renal disease and discouraging their use of these drugs.

LEAD NEPHROPATHY (See also **Chap. e33**) Lead intoxication may produce a chronic tubulointerstitial renal disease. Children who repeatedly ingest lead-based paints (pica) may develop kidney disease as adults. Significant occupational exposure may occur in workplaces where lead-containing metals or paints are heated to high temperatures, such as battery factories, smelters, salvage yards, and weapon firing ranges.

Tubule transport processes enhance the accumulation of lead within renal cells, particularly in the proximal convoluted tubule, leading to cell degeneration, mitochondrial swelling, and eosinophilic intranuclear inclusion bodies rich in lead. In addition, lead nephropathy is associated with ischemic changes in the glomeruli, fibrosis of the adventitia of small renal arterioles, and focal areas of cortical scarring. Eventually, the kidneys become atrophic. Urinary excretion of lead, porphyrin precursors such as δ-aminolevulinic acid and coproporphyrin, and urobilinogen may be increased. Patients with chronic lead nephropathy are characteristically *hyperuricemic*, a consequence of enhanced reabsorption of filtered urate. Acute gouty arthritis (so-called saturnine gout) develops in about 50% of patients with lead nephropathy, in striking contrast to other forms of chronic renal failure in which de novo gout is rare (Chap. 353). Hypertension is also a complication. Therefore, in any patient with slowly progressive renal failure, atrophic kidneys, gout, and hypertension, the diagnosis of lead intoxication should be considered. Features of acute lead intoxication (abdominal colic, anemia, peripheral neuropathy, and encephalopathy) are usually absent.

The diagnosis may be suspected by finding elevated serum levels of lead. However, because blood levels may not be elevated even in the presence of a toxic total-body burden of lead, the quantitation of lead excretion following infusion of the chelating agent calcium disodium edetate is a more reliable indicator of serious lead exposure. Urinary excretion of >0.6 mg/d of lead is indicative of overt toxicity, but even lead burdens of 0.08–0.6 mg/d may cause progressive loss of renal function.

℞ LEAD NEPHROPATHY

Treatment includes removing the patient from the source of exposure and augmenting lead excretion with a chelating agent such as calcium disodium edetate.

LITHIUM Use of lithium salts for bipolar disorder (Chap. 386) is associated with chronic tubulointerstitial nephropathy, generally manifest as the insidious development of chronic renal insufficiency. Nephrogenic diabetes insipidus, which may occur alone or in association with the renal insufficiency, is common. It manifests as polyuria and polydipsia and is due to lithium-induced downregulation of the vasopressin-regulated water channels in the collecting duct. Mild proteinuria and hypercalcemia due to lithium-induced hyperparathyroidism are common. The predominant finding on renal biopsy is tubular atrophy and interstitial fibrosis out of proportion to the extent of glomerular or vascular disease. Tubular cysts are common, and concomitant focal segmental glomerulosclerosis can be observed.

Renal function should be followed in patients taking this drug, and caution should be exercised if lithium is employed in patients with underlying renal disease. Once renal impairment occurs, lithium therapy should be stopped and an alternative agent substituted. Despite discontinuation of lithium, chronic renal disease in such patients is often irreversible and can progress to end-stage renal failure.

MISCELLANEOUS NEPHROTOXINS The immunosuppressant *cyclosporine* causes both acute and chronic renal injury. The acute injury and the use of cyclosporine in transplantation are discussed in Chap. 276. The chronic injury results in an irreversible reduction in glomerular filtration rate (GFR), with mild proteinuria and arterial hypertension. Hyperkalemia is a relatively common complication and results, in part, from tubule resistance to aldosterone. The histologic changes in renal tissue include patchy interstitial fibrosis and tubular atrophy. In addition, the intrarenal vasculature often demonstrates hyalinosis, and focal segmental glomerular sclerosis can be present as well. In patients receiving this drug for renal transplantation (Chap. 276), chronic graft dysfunction and recurrence of the primary disease may coincide with chronic cyclosporine injury, and, on clinical grounds, distinction among these may be difficult. Dose reduction appears to mitigate cyclosporine-associated renal fibrosis but may increase the risk of rejection and graft loss. Treatment of any associated arterial hypertension may lessen renal injury.

Chinese herbs nephropathy is characterized by rapidly progressive interstitial renal fibrosis in young women due to ingestion of weight-reduction pills containing Chinese herbs; at least one of the culprit ingredients is aristolochic acid. Clinically, patients present with progressive chronic renal insufficiency with sterile pyuria and anemia that is disproportionately severe relative to the level of renal function. The pathologic findings are interstitial fibrosis and tubular atrophy that affects the cortex in preference to the medulla, fibrous intimal thickening of the interlobular arteries, and a relative paucity of cellular infiltrates.

Metabolic Toxins • ***ACUTE URIC ACID NEPHROPATHY*** (See also Chap. 327) Acute overproduction of uric acid and extreme hyperuricemia often lead to a rapidly progressive renal insufficiency, so-called acute uric acid nephropathy. This tubulointerstitial disease is usually seen as part of the tumor lysis syndrome in patients given cytotoxic drugs for the treatment of lymphoproliferative or myeloproliferative disorders but may also occur in these patients before such treatment is begun. The pathologic changes are largely the result of deposition of uric acid crystals in the kidneys and their collecting systems, leading to partial or complete obstruction of collecting ducts, renal pelvis, or ureter. Since obstruction is often bilateral, patients typically follow the clinical course of acute renal failure, characterized by oliguria and rapidly rising serum creatinine concentration. In the early phase uric acid crystals can be found in urine, usually in association with microscopic or gross hematuria. Hyperuricemia can also be a consequence of renal failure of any etiology. The finding of a urine uric acid/creatinine ratio >1 mg/mg (0.7 mol/mol) distinguishes acute uric acid nephropathy from other causes of renal failure.

Prevention of hyperuricemia in patients at risk by treatment with allopurinol in doses of 200–800 mg/d prior to cytotoxic therapy reduces the danger of acute uric acid nephropathy. Once hyperuricemia develops, however, efforts should be directed to preventing deposition of uric acid within the urinary tract. Increasing urine volume with potent diuretics (furosemide or mannitol) effectively lowers intratubular

uric acid concentrations, and alkalinization of the urine to pH ≥ 7 with sodium bicarbonate and/or a carbonic anhydrase inhibitor (acetazolamide) enhances uric acid solubility. If these efforts, together with allopurinol therapy, are ineffective in preventing acute renal failure, dialysis should be instituted to lower the serum uric acid concentration as well as to treat the acute manifestations of uremia.

GOUTY NEPHROPATHY (See also Chap. 327) Patients with less severe but prolonged forms of hyperuricemia are predisposed to a more chronic tubulointerstitial disorder, often referred to as *gouty nephropathy*. The severity of renal involvement correlates with the duration and magnitude of the elevation of the serum uric acid concentration. Histologically, the distinctive feature of gouty nephropathy is the presence of crystalline deposits of uric acid and monosodium urate salts in kidney parenchyma. These deposits not only cause intrarenal obstruction but also incite an inflammatory response, leading to lymphocytic infiltration, foreign-body giant cell reaction, and eventual fibrosis, especially of medullary and papillary regions of the kidney. Since patients with gout frequently suffer from hypertension and hyperlipidemia, degenerative changes of the renal arterioles may constitute a striking feature of the histologic abnormality, often out of proportion to other morphologic defects. Clinically, gouty nephropathy is an insidious cause of renal insufficiency. Early in its course, GFR may be near normal, often despite focal morphologic changes in medullary and cortical interstitium, proteinuria, and diminished urinary concentrating ability. Whether reducing serum uric acid levels with allopurinol exerts a beneficial effect on the kidney remains to be demonstrated. Although such undesirable consequences of hyperuricemia as gout and uric acid stones respond well to allopurinol, use of this drug in asymptomatic hyperuricemia has not been shown to improve renal function consistently. Uricosuric agents such as probenecid, which may increase uric acid stone production, are clearly contraindicated.

HYPERCALCEMIC NEPHROPATHY (See also Chap. 347) Chronic hypercalcemia, as occurs in primary hyperparathyroidism, sarcoidosis, multiple myeloma, vitamin D intoxication, or metastatic bone disease, can cause tubulointerstitial damage and progressive renal insufficiency. The earliest lesion is a focal degenerative change in renal epithelia, primarily in collecting ducts, distal convoluted tubules, and loops of Henle. Tubule cell necrosis leads to nephron obstruction and stasis of intrarenal urine, favoring local precipitation of calcium salts and infection. Dilatation and atrophy of tubules eventually occur, as do interstitial fibrosis, mononuclear leukocyte infiltration, and interstitial calcium deposition (nephrocalcinosis). Calcium deposition may also occur in glomeruli and the walls of renal arterioles.

Clinically, the most striking defect is an inability to concentrate the urine maximally, resulting in polyuria and nocturia. Reduced collecting duct responsiveness to vasopressin and defective transport of NaCl in the ascending limb of Henle's loop are responsible for this. Reductions in GFR and renal blood flow also occur, both in acute severe hypercalcemia and with prolonged hypercalcemia of lesser severity. Eventually, uncontrolled hypercalcemia leads to severe tubulointerstitial damage and overt renal failure. Abdominal x-rays may demonstrate nephrocalcinosis as well as nephrolithiasis, the latter due to the hypercalciuria that often accompanies hypercalcemia.

℞ HYPERCALCEMIC NEPHROPATHY

Treatment consists of reducing the serum calcium concentration toward normal and correcting the primary abnormality of calcium metabolism. The management of hypercalcemia is discussed in Chap. 347. Renal dysfunction of acute hypercalcemia may be completely reversible. Gradual, progressive renal insufficiency related to chronic hypercalcemia, however, may not improve even with correction of the calcium disorder.

RENAL PARENCHYMAL DISEASE ASSOCIATED WITH EXTRARENAL NEOPLASM

Except for the glomerulopathies associated with lymphomas and several solid tumors (Chap. 277), the renal manifestations of primary extrarenal neoplastic processes are confined mainly to the interstitium and tubules. Although metastatic renal involvement by solid tumors is unusual, the kidneys are often invaded by neoplastic cells in hematologic malignancies. In postmortem studies of patients with *lymphoma* and *leukemia*, renal involvement is found in approximately half. Diffuse infiltration of the renal parenchyma with malignant cells is seen most commonly. There may be flank pain, and x-rays may show enlargement of one or both kidneys. Renal insufficiency occurs in a minority, and treatment of the primary disease may improve renal function in these cases.

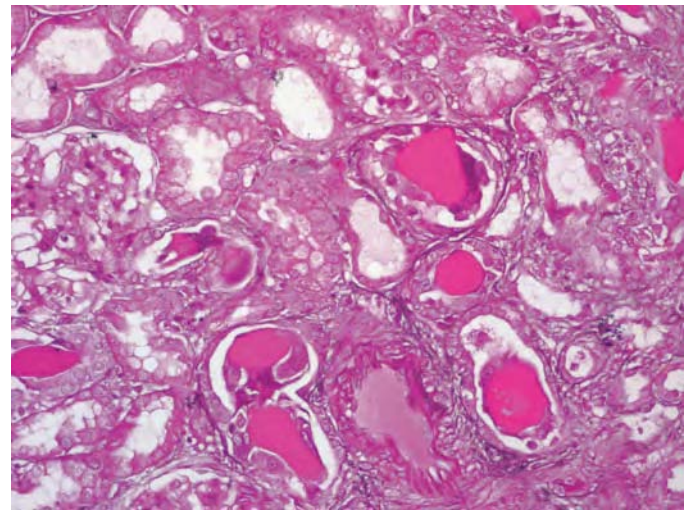

FIGURE 279-2 Histologic appearance of myeloma cast nephropathy. A hematoxylin-eosin-stained kidney biopsy shows many atrophic tubules filled with eosinophilic casts (consisting of Bence-Jones protein), which are surrounded by giant cell reactions. *(Courtesy of Dr. Michael N. Koss, University of Southern California Keck School of Medicine; with permission.)*

Plasma Cell Dyscrasias Several glomerular and tubulointerstitial disorders may occur in association with plasma cell dyscrasias (Chap. 106). Infiltration of the kidneys with myeloma cells is infrequent. When it occurs, the process is usually focal, so renal insufficiency from this cause is also uncommon. The more usual lesion is *myeloma kidney*, characterized histologically by atrophic tubules, many with eosinophilic intraluminal casts, and numerous multinucleated giant cells within tubule walls and in the interstitium (Fig. 279-2). Bence-Jones proteins are thought to cause myeloma kidney through direct toxicity to renal tubule cells. In addition, Bence-Jones proteins may precipitate within the distal nephron where the high concentrations of these proteins and the acid composition of the tubule fluid favor intraluminal cast formation and intrarenal obstruction. Further precipitation of Bence-Jones proteins can be induced by dehydration, which should, therefore, be avoided. Multiple myeloma may also affect the kidneys indirectly. Hypercalcemia or hyperuricemia may lead to the nephropathies described above. Proximal tubule disorders are also seen occasionally, including type II proximal RTA and the Fanconi syndrome.

Amyloidosis (See also Chaps. 277 and 324) Glomerular pathology usually predominates and leads to heavy proteinuria and azotemia. However, tubule function may also be deranged, giving rise to a nephrogenic diabetes insipidus and to distal (type I) RTA. In several cases these functional abnormalities correlated with peritubular deposition of amyloid, particularly in areas surrounding vasa rectae, loops of Henle, and collecting ducts. Bilateral enlargement of the kidneys, especially in a patient with massive proteinuria and tubule dysfunction, should raise the possibility of amyloid renal disease.

IMMUNE DISORDERS

Allergic Interstitial Nephritis An acute diffuse tubulointerstitial reaction may result from hypersensitivity to a number of drugs, including

β-lactams, sulfonamides, fluoroquinolone antibiotics, and the antituberculous drugs isoniazid and rifampin. Acute tubulointerstitial damage has also occurred after use of thiazide and loop diuretics, allopurinol, NSAIDs, and cyclooxygenase 2 (COX-2) inhibitors. Of note, the tubulointerstitial nephropathy that develops in some patients taking NSAIDs and COX-2 inhibitors may be associated with nephrotic-range proteinuria and histologic evidence of either minimal change or membranous glomerulopathy. Proton-pump inhibitors are an increasingly recognized culprit and have recently been implicated in up to half of cases of biopsy-proven acute tubulointerstitial nephritis. The use of mesalazine for the treatment of inflammatory bowel disease is associated with a more subacute disorder in which a severe indolent interstitial nephritis occurs several months after the initiation of the drug. Grossly, the kidneys are usually enlarged. Histologically, the interstitium of the kidney reveals pronounced edema and infiltration with polymorphonuclear leukocytes, lymphocytes, plasma cells, and, in some cases, large numbers of eosinophils. If the process is severe, tubule cell necrosis and regeneration may also be apparent. Immunofluorescence studies have either been unrevealing or demonstrated a linear pattern of immunoglobulin and complement deposition along tubule basement membranes.

Most patients require several weeks of drug exposure before developing evidence of renal injury. Rare cases have occurred after only a few doses or after a year or more of use. Renal failure is usually present; a triad of fever, skin rash, and peripheral blood eosinophilia is highly suggestive of acute tubulointerstitial nephritis but is present in only 10% of patients. Examination of the urine sediment reveals hematuria and often pyuria; occasionally, eosinophils may be present. Proteinuria is usually mild to moderate, except in cases of NSAID- or COX-2 inhibitor–associated glomerulopathy. The clinical picture may be confused with acute glomerulonephritis, but when acute renal failure and hematuria are accompanied by eosinophilia, skin rash, and a history of drug exposure, acute tubulointerstitial nephritis should be regarded as the leading diagnostic possibility. Discontinuation of the drug usually results in complete reversal of the renal injury; rarely, renal damage may be irreversible. Glucocorticoids may accelerate renal recovery, but their value has not been definitively established.

Sjögren's Syndrome (See also Chap. 317) When the kidneys are involved in this disorder, the predominant histologic findings are those of chronic tubulointerstitial disease. Interstitial infiltrates are composed primarily of lymphocytes, causing the histology of the renal parenchyma in these patients to resemble that of the salivary and lacrimal glands. Renal functional defects include diminished urinary concentrating ability and distal (type I) RTA. Urinalysis may show pyuria (predominantly lymphocyturia) and mild proteinuria.

Tubulointerstitial Abnormalities Associated with Glomerulonephritis Primary glomerulopathies are often associated with damage to tubules and the interstitium. Occasionally, the primary disorder may affect glomeruli and tubules directly. For example, in more than half of patients with the nephropathy of systemic lupus erythematosus, deposits of immune complexes can be identified in tubule basement membranes, usually accompanied by an interstitial mononuclear inflammatory reaction. Similarly, in many patients with glomerulonephritis associated with anti-glomerular basement membrane antibody, the same antibody is reactive against tubule basement membranes as well. More frequently, tubulointerstitial damage is a secondary consequence of glomerular dysfunction. The extent of tubulointerstitial fibrosis correlates closely with the degree of renal impairment. Potential mechanisms by which glomerular disease might cause tubulointerstitial injury include glomerular leak of plasma proteins toxic to epithelial cells, activation of tubule epithelial cells by glomerulus-derived cytokines, reduced peritubular blood flow leading to downstream tubulointerstitial ischemia, and hyperfunction of remnant tubules.

MISCELLANEOUS DISORDERS

Vesicoureteral Reflux (See also Chap. 283) When the function of the ureterovesical junction is impaired, urine may reflux into the ureters due to the high intravesical pressure that develops during voiding. Clinically, reflux is often detected on the voiding and postvoiding films obtained during intravenous pyelography, although voiding cystourethrography may be required for definitive diagnosis. Bladder infection may ascend the urinary tract to the kidneys through incompetent ureterovesical sphincters. Not surprisingly, therefore, reflux is often discovered in patients with acute and/or chronic urinary tract infections. With more severe degrees of reflux, characterized by dilatation of ureters and renal pelves, progressive renal damage often appears. Uncertainty exists as to the necessity of infection in producing the scarred kidney of reflux nephropathy. Substantial proteinuria is often present, and glomerular lesions similar to those of idiopathic focal glomerulosclerosis (Chap. 277) are often found in addition to the changes of chronic tubulointerstitial disease. Surgical correction of reflux is usually necessary only with the more severe degrees of reflux since renal damage correlates with the extent of reflux. Obviously, if extensive glomerulosclerosis already exists, urologic repair may no longer be warranted.

Radiation Nephritis Renal dysfunction can be expected to occur if ≥23 Gy (2300 rad) of x-ray irradiation is administered to both kidneys. Histologic examination of the kidneys reveals hyalinized glomeruli and arterioles, atrophic tubules, and extensive interstitial fibrosis. Radiation nephritis can present acutely or chronically with renal failure, moderate to malignant hypertension, anemia, and proteinuria that may reach the nephrotic range. Malignant hypertension without renal failure may follow unilateral renal irradiation and resolve with ipsilateral nephrectomy. Radiation nephritis has all but vanished because of heightened awareness of its pathogenesis by radiotherapists.

GLOBAL CONSIDERATIONS

The spectrum of causes of chronic tubulointerstitial nephritis shows marked geographical variation. Chinese herb nephropathy has mostly been reported in Belgium and in parts of Asia. Analgesic nephropathy has been found worldwide but is a particularly frequent cause of chronic renal failure in Scotland, Belgium, and Australia. Balkan endemic nephropathy is a chronic, slowly progressive tubulointerstitial disease of unknown etiology that is exclusively confined to Bulgaria, Serbia, Croatia, Bosnia, and Romania. These differences in incidence probably reflect geographical variation in exposure to particular nephrotoxins but could also be explained by genetic factors or differing diagnostic criteria.

280 Vascular Injury to the Kidney

Kamal F. Badr, Barry M. Brenner

Renal vasculature is commonly involved in atherosclerotic, hypertensive, embolic, inflammatory, and hematologic vascular disorders. Adequate delivery of blood to the glomerular capillary network is crucial for glomerular filtration and overall salt and water balance. Thus, in addition to threatening the viability of renal tissue, vascular injury to the kidney may compromise the maintenance of body fluid volume and composition. It is important to keep in mind the unique nature of the renal microvasculature, in particular the presence of a large network of (glomerular) capillaries which subserves the process of glomerular filtration.

ATHEROSCLEROSIS

Renal Vascular Injury in Systemic Atherosclerotic Vascular Disease (AVD)

• ***MACROVASCULAR ATHEROSCLEROTIC DISEASE*** As is the case in other vascular beds, the renal artery and its branches are potential sites for plaque formation, which may lead to ischemic renal disease and hypertension (see below).

MICROVASCULAR ATHEROSCLEROTIC DISEASE Numerous trials in cardiovascular medicine have focused attention on the clinical significance of the rate of urinary albumin excretion (UAE) as an early and powerful predictor of systemic AVD. As illustrated in Fig. 280-1, while both systemic and renal endothelial beds are subject to oxidant stress, inflammation, and hemodynamic injury, a measurable response (elevated UAE) is detectable in the renal microcirculation years before the emergence of systemic disease and/or adverse events in other vascular beds. The strong correlation between UAE and cardiovascular risk, and the parallel improvements noted in both with pharmacologic therapy, support the emerging concept of the renal circulation as an early detection site for atherosclerotic endothelial injury and an integrated marker of cardiovascular risk.

Atherosclerotic Renovascular Disease (ARVD) (Renal Artery Stenosis and Ischemic Nephropathy)

It is estimated that ~5% of cases of hypertension are caused by renal artery stenosis (RAS). In population-based studies, significant (>60%) stenosis is found in 9.1% of men and 5.5% of women over 65. The incidence, however, is considerably higher in those being studied for coronary (19%) or peripheral (35–50%) vascular disease. Autopsy studies in patients dying of stroke revealed that at least 1 renal artery is >75% stenosed in 10% of the patients studied. The common cause in the middle-aged and elderly is an atheromatous plaque at the origin of the renal artery. Bilateral involvement is present in half of the affected cases. Established plaques progress in >50% of cases over 5 years (15% to total occlusion). Renal hypotrophy is detectable in 20% of affected kidneys. In younger women (15–50 years), stenosis is due to intrinsic structural abnormalities of the arterial wall caused by *fibromuscular dysplasia*.

In addition to stimulation of renin release, renovascular disease is associated with increased sympathetic neural activity, resulting in frequently described flushing, loss of nocturnal blood pressure (BP) decrease, autonomic instability, and rapid BP swings. In most patients being evaluated for RAS, glomerular filtration rate (GFR) is <60 mL/min, with 85% having stage 3–5 chronic kidney disease. GFR in these ranges is a strong independent predictor of cardiovascular risk. Thus, patients with ARVD are more likely to suffer from stroke, heart failure, or myocardial infarction than to progress to end-stage renal disease.

DIAGNOSIS Diagnostic evaluation for significant RAS should begin with noninvasive approaches. An initial screening test is Doppler ultrasonography, which provides information on blood-flow velocity and pressure waveforms in the renal arteries and, when positive, is helpful (sensitivity is 70% at best). Its limitations, however, include significant operator dependence, technical difficulty in obese patients, and poor sensitivity in the presence of multiple renal arteries, distal stenoses, and total occlusion. Measurement of the intrarenal resistance index (RI) provides valuable information on the extent of parenchymal disease and, hence, on the prognosis for functional recovery following revascularization procedures. Absence of compensatory hypertrophy in the contralateral kidney should raise the suspicion of bilateral stenosis or superimposed parenchymal renal disease, most commonly hypertensive or diabetic nephropathy. Because angiotensin-converting enzyme (ACE) inhibitors magnify the impairment in renal blood flow and GFR caused by functionally significant renal artery stenosis, use of these drugs in association with ^{99m}Tc-labeled pentetic acid (DTPA) or ^{99m}Tc-labeled mertiatide (MAG_3) renography enhances diagnostic precision and is of additional predictive value. Gadolinium-enhanced three-dimensional magnetic resonance angiography (MRA) has replaced previous modalities as the most sensitive (>90%) and specific (95%) test for the diagnosis of RAS. The most definitive diagnostic procedure is contrast-enhanced arteriography. Intraarterial digital subtraction tech-

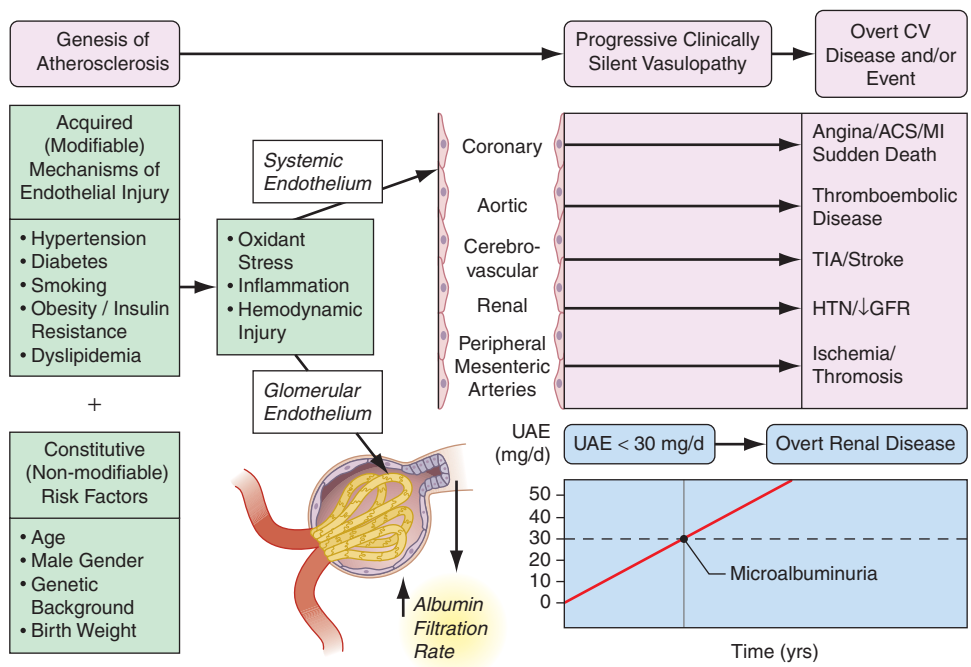

FIGURE 280-1 Comparative pathophysiology and clinical consequences of atherosclerosis-associated endothelial cell injury in systemic versus renal circulations. In contrast to the systemic endothelial bed in which early atherosclerotic injury is undetectable, the high volume of fluid filtered across the glomerular endothelium (140–180 L/day) markedly amplifies the functional consequence (increased albumin filtration) of early endothelial (and podocyte) injury in the glomerulus. The emergence of microalbuminuria thus unmasks systemic endothelial injury likely occurring simultaneously in other vascular beds, progressing silently to overt disease years later. CV, cardiovascular; ACS, acute coronary syndrome; MI, myocardial infarction; TIA, transient ischemic attack; HTN, hypertension; GFR, glomerular filtration rate; UAE, urinary albumin excretion.

niques minimize the requirements for contrast, reducing the risk of renal toxicity.

℞ RENAL ARTERY STENOSIS

When blood pressure is controlled and renal function is preserved, expectant therapy and careful follow-up form the best approach for managing RAS. This approach is justified by the devastating consequences of atheroembolic complications of percutaneous revascularization, including loss of renal function. Despite enthusiasm for revascularization procedures for tight RAS in the early to mid-nineties, the past decade has witnessed a significant change in management strategies, stressing more conservative approaches. Medical therapy is aimed at controlling BP and preserving GFR, and includes typically at least three drugs. Angiotensin antagonists (ACE inhibitors or angiotensin receptor blockers) and diuretics are required in most patients. When goal BPs are achieved, clinical outcomes and survival are comparable for medical and revascularization therapies. Revascularization therapy (angioplasty with stent placement) may improve the chances of attaining goal BP but should be considered only after optimal medical therapy has failed to achieve goal BP, or resulted in a >30% increase in serum creatinine. BP control and preservation of renal function following revascularization should not be expected when the RI of the targeted kidney is >80%. In experienced hands, the complications of angioplasty or stenting are acceptably low. Clinical studies suggest that percutaneous revascularization prevents additional deterioration or even improves renal function in selected patients. Despite technical advances in percutaneous renal revascularization, optimal technique is still evolving. Embolic protection devices may prove useful. **Table 280-1** lists current indications for revascularization in patients with RAS. Because of safety, cost, and long-term efficacy, surgical repair is now rarely indicated.

Success rates with conventional percutaneous transluminal angioplasty in young patients with fibromuscular dysplasia are 50% cure and improvement in BP control in another 30%.

Atheroembolic Renovascular Disease Atheroembolic renal disease is part of a systemic syndrome characterized by cholesterol crystal embolization. Renal damage results from embolization of cholesterol crystals from atherosclerotic plaques present in large arteries, such as the aorta, to small arteries in the renal vasculature. Atheroembolic renal disease is an increasingly common and often underdiagnosed cause of renal insufficiency in the elderly. Autopsy studies identify cholesterol emboli in 2.4–4% of renal tissue samples, but the incidence increases significantly in elderly individuals, especially in those who had undergone abdominal arteriography or surgery. Male gender, older age, hypertension, and diabetes mellitus are important predisposing factors, present in 85% of cases. Patients with cholesterol embolization syndrome also often have a history of ischemic cardiovascular disease, aortic aneurysm, cerebrovascular disease, congestive heart failure, or renal insufficiency. A significant association is present between RAS and atheroembolic renal disease. Inciting events, which include vascular surgery, arteriography, angioplasty, anticoagulation with heparin, and thrombolytic therapy, can be identified in ~50% of cases. Arteriographic procedures constitute the most common cause of cholesterol embolization.

TABLE 280-1 INDICATIONS AND PREREQUISITES FOR REVASCULARIZATION IN RENAL ARTERY STENOSIS

Indications
Uncontrolled BP despite maximal therapy
Progressive rise in creatinine (other causes excluded)
Intolerance to ACE-Is, ARBs (>30% increase in creatinine or severe hyperkalemia)
Recurrent pulmonary edema, CHF, or volume overload
Prerequisites
Experienced operator
Presence of two kidneys
RI < 0.80 in target kidney(s)

Note: BP, blood pressure; ACE-Is, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; CHF, congestive heart failure; RI, renal index.

Clinical manifestations usually appear 1–14 days after an inciting event, but their onset can be more insidious. Systemic manifestations occur in fewer than half of the patients and include fever, myalgias, headache, and weight loss. Cutaneous manifestations, such as livedo reticularis, "purple" toes, and toe gangrene, occur in 50–90% of patients and constitute the most common extrarenal findings. Other targets of cholesterol embolization include the retina, musculoskeletal system, nervous system, and gut. Accelerated or labile hypertension is present in one-half of patients; malignant hypertension has been described. Renal insufficiency is usually subacute and advances in a stepwise fashion over a period of several weeks. Renal failure, however, can be acute and oliguric. Uremic signs and symptoms requiring dialytic therapy develop in 40% of patients, only half of whom recover sufficient renal function to discontinue dialysis after 1 year. Renal infarction secondary to cholesterol embolization is rare. Cholesterol embolic disease in renal allografts has been reported and can be of donor or of recipient origin.

LABORATORY FINDINGS In addition to rising blood urea nitrogen (BUN) and creatinine, laboratory findings may include eosinophilia (60–80%), eosinophiluria, leukocytosis, elevated sedimentation rate, anemia, and hypocomplementemia.

Antemortem diagnosis of atherosclerotic renal emboli is difficult. The demonstration of cholesterol emboli in the retina is helpful, but a firm diagnosis is established only by renal biopsy. Histologic examination of the occluded vessels reveals biconvex needle-shaped clefts representing the sites of cholesterol crystal deposition. The cholesterol crystals themselves are removed by the usual solvents of tissue fixation but can be visualized in frozen sections of fresh tissue as birefringent crystals under polarized light. They may also be seen in asymptomatic skeletal muscle or skin. Atheroembolic renal disease is associated with a 64–81% mortality rate.

℞ ATHEROEMBOLIC RENAL DISEASE

No effective therapy for atheroembolic renal disease is available. Withdrawal of anticoagulation may be beneficial. In some patients, kidney function improved even after a prolonged period of renal insufficiency. Cholesterol-lowering agents may also improve outcome. An aggressive therapeutic approach with patient-tailored supportive measures may be associated with more favorable clinical outcome. Numerous reports suggest a beneficial effect for steroid therapy, but controlled studies are lacking.

Thromboembolic Renovascular Disease Thrombosis of the major renal arteries or their branches is an important cause of deterioration of renal function, especially in the elderly. It is often difficult to diagnose and, therefore, requires a high index of suspicion. Thrombosis may occur as a result of intrinsic pathology in the renal vessels (posttraumatic, atherosclerotic, or inflammatory) or as a result of emboli originating in distant vessels, most commonly fat emboli, emboli originating in the left heart (mural thrombi following myocardial infarction, bacterial endocarditis, or aseptic vegetations), or "paradoxical" emboli passing from the right side of the circulation via a patent foramen ovale or atrial septal defect. Renal emboli are bilateral in 15–30% of cases.

The clinical presentation is variable, depending on the time course and the extent of the occlusive event. Acute thrombosis and infarction, such as follows embolization, may result in sudden onset of flank pain and tenderness, fever, hematuria, leukocytosis, nausea, and vomiting. If infarction occurs, renal enzymes may be elevated, namely aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and alkaline phosphatase, which rise and fall in the order listed. Urinary LDH and alkaline phosphatase may also increase after infarction. Renal function deteriorates acutely, leading in bilateral thrombosis to acute oliguric renal failure. More gradual (i.e., atherosclerotic) occlusion of a single

renal artery may go undetected. A spectrum of clinical presentations lies between these two extremes. Hypertension usually follows renal infarction and results from renin release in the peri-infarction zone. Hypertension is usually transient but may be persistent. Diagnosis is established by renal arteriography.

℞ ACUTE RENAL ARTERIAL THROMBOSIS

Management options for *acute* renal arterial thrombosis include surgical intervention, anticoagulant therapy, intrarenal tissue plasminogen activator, percutaneous rheolytic thrombectomy, conservative and supportive therapy, and control of hypertension. The choice of treatment depends mainly on (1) the condition of the patient, in particular the patient's ability to withstand major surgery; and (2) the extent of renovascular occlusion and amount of renal mass at risk of infarction. In general, supportive care and anticoagulant therapy are indicated in unilateral disease. In *acute* bilateral thrombosis, medical and surgical therapies yield comparable results. About 25% of patients die during the acute episode, usually from extrarenal complications.

RENAL VASCULAR INJURY IN HYPERTENSION

Whether it is "essential" or of known etiology, hypertension results in development of intrinsic lesions of the renal arterioles (hyaline arteriolosclerosis) that eventually lead to loss of function (nephrosclerosis).

"Essential" Hypertension (Arteriolar Nephrosclerosis) Arteriolar nephrosclerosis is seen in patients who are hypertensive (BP > 150/90 mmHg) for an extended period of time but whose hypertension has not progressed to a malignant form (described below). Such patients, usually in the older age group, are often discovered to be hypertensive on routine physical examination or as a result of nonspecific symptomatology (e.g., headaches, weakness, palpitations).

The characteristic pathology is in the afferent arterioles, which have thickened walls due to deposition of homogeneous eosinophilic material (hyaline arteriolosclerosis). Narrowing of vascular lumina results, with consequent ischemic injury to glomeruli and tubules.

Physical examination may reveal changes in retinal vessels (arteriolar narrowing and/or flame-shaped hemorrhages), cardiac hypertrophy, and possibly signs of congestive heart failure. Renal disease may manifest as a mild to moderate elevation of serum creatinine concentration, microalbuminuria, or proteinuria.

"Malignant" Hypertension Patients with long-standing hypertension or patients not previously known to be hypertensive may develop malignant hypertension characterized by a sudden (accelerated) elevation of BP (diastolic BP often >130 mmHg) accompanied by papilledema, central nervous system manifestations, cardiac decompensation, and acute progressive deterioration of renal function. The absence of papilledema does not rule out the diagnosis in a patient with markedly elevated BP and rapidly declining renal function. The kidneys are characterized by a flea-bitten appearance resulting from hemorrhages in surface capillaries. Histologically, two distinct vascular lesions can be seen. The first, affecting arterioles, is fibrinoid necrosis, i.e., infiltration of arteriolar walls with eosinophilic material including fibrin, thickening of vessel walls, and, occasionally, an inflammatory infiltrate (necrotizing arteriolitis). The second lesion, involving the interlobular arteries, is a concentric hyperplastic proliferation of the cellular elements of the vascular wall with deposition of collagen to form a hyperplastic arteriolitis (onion-skin lesion). Fibrinoid necrosis occasionally extends into the glomeruli, which may also undergo proliferative changes or total necrosis. Most glomerular and tubular changes are secondary to ischemia and infarction. The sequence of events leading to the development of malignant hypertension is poorly defined. Two pathophysiologic alterations appear central in its initiation and/or perpetuation: (1) increased permeability of vessel walls to invasion by plasma components, particularly fibrin, which activates clotting mechanisms leading to a microangiopathic hemolytic anemia, thus perpetuating the vascular pathology; and (2) activation of the renin-angiotensin-aldosterone system at some point in the disease process, which contributes to the acceleration and maintenance of BP elevation and, in turn, to vascular injury.

Malignant hypertension is most likely to develop in a previously hypertensive individual, usually in the third or fourth decade of life. There is a higher incidence among black men. Presenting symptoms are usually neurologic (dizziness, headache, blurring of vision, altered states of consciousness, and focal or generalized seizures). Cardiac decompensation and renal failure appear thereafter. Renal abnormalities include a rapid rise in serum creatinine, hematuria (at times macroscopic), proteinuria, and red and white blood cell casts in the sediment. Nephrotic syndrome may be present. Elevated plasma aldosterone levels cause hypokalemic metabolic alkalosis in the early phase. Uremic acidosis and hyperkalemia eventually obscure these early findings. Hematologic indices of microangiopathic hemolytic anemia (i.e., schistocytes) are often seen.

℞ HYPERTENSION

Control of hypertension is the principal goal of therapy. The time of initiation of therapy, its effectiveness, and patient compliance are crucial factors in arresting the progression of benign nephrosclerosis. Untreated, most of these patients succumb to the extrarenal complications of hypertension. In contrast, malignant hypertension is a medical emergency; its natural course includes a death rate of 80–90% within 1 year of onset, almost always due to uremia. Supportive measures should be instituted to control the neurologic, cardiac, and other complications of acute renal failure, but the mainstay of therapy is prompt and aggressive reduction of BP, which, if successful, can reverse all complications in the majority of patients. Presently, 5-year survival is 50%, and some patients have evidence of partial reversal of the vascular lesions and a return of renal function to near-normal levels.

RENAL VASCULAR INJURY IN SYSTEMIC DISEASES

Hemolytic Uremic Syndrome (HUS) and Thrombotic Thrombocytopenic Purpura (TTP) (See also Chap. 109) HUS and TTP, consumptive coagulopathies characterized by microangiopathic hemolytic anemia and thrombocytopenia, have a particular predilection for the kidney and the central nervous system. Previously, the overlap in clinical manifestations had prompted investigators to regard the two syndromes as a continuum of a single disease entity. Recent evidence, however, points to clearly distinct molecular basis for their pathophysiology.

RENAL INVOLVEMENT Evidence of renal involvement is present in the majority of patients with HUS/TTP. Microscopic hematuria (78%) and subnephrotic proteinuria (75%) are the most consistent findings. Male sex, hypertension, prolonged anuria, and hemoglobin levels <10 g/L at onset are associated with a higher risk of renal sequelae in children. Gross hematuria is rare. More than 90% of patients with HUS have significant renal failure, one-third of whom are anuric. The mean duration of renal failure is 2 weeks. Severe acute renal failure or anuria occurs in <10% of cases of classic TTP. The degree of elevation of BUN on presentation may be a prognostic indicator in patients with HUS/TTP.

PATHOLOGY The characteristic lesion in HUS/TTP is thrombotic microangiopathy. Microthrombi are demonstrated in renal arterioles and capillaries. In TTP, microthrombi are composed predominantly of platelet aggregates and a thin layer of fibrin and stain strongly for von Willebrand factor (vWF), which has been implicated in its pathogenesis. In contrast, microthrombi in HUS contain predominantly fibrin. Subendothelial hyaline deposits and endothelial cell swelling also contribute to vascular occlusion. Glomerular lesions are ischemic. The glomerular capillary walls are wrinkled, the glomerular tuft may be atrophied, and the Bowman capsule is thickened. Acute cortical or tubular necrosis may occur. Immunofluorescence studies invariably demonstrate fibrinogen along the glomerular capillary walls and in arterial thrombi. Granular deposits of C3 and IgM may be observed in

vessel walls and glomeruli. Electron-microscopic studies demonstrate swelling of the glomerular endothelial cells and detachment from the glomerular basement membrane.

ETIOLOGY HUS Two forms of HUS have been described: (1) Diarrhea-associated HUS (D + HUS), the most common form in children, is associated with infection by Shiga toxin–producing *Escherichia coli* (most commonly O157;H7). This form has an excellent prognosis. Most cases occur in summer and autumn. (2) In contrast, non-Shiga toxin–associated HUS (D – HUS) typically affects adults but can occur at any age. It occurs in sporadic or familial forms, is noninfective, and is usually precipitated by drugs and pregnancy. Several studies have demonstrated genetic predisposition in atypical HUS, involving two regulatory proteins of the complement alternative pathway: factor H (FH) and membrane cofactor protein (MCP, or CD46).

TTP ADAMTS 13 is a member of the recently recognized ADAMTS (a disintegrin with thrombospondin type 1 motifs) zinc metalloproteinase family that cleaves vWF complexes and prevents vWF-platelet interaction. A *severe deficiency of ADAMTS 13* has been described in patients with TTP. Two forms have been identified: (1) In sporadic TTP, the deficiency appears to be *autoimmune suppression* of ADAMTS 13 by circulating IgG antibodies to the protein. (2) Schulman-Upshaw syndrome (a hereditary deficiency) is characterized by thrombocytopenia and microangiopathic hemolysis soon after birth, responding to plasma infusion. Most patients require plasma infusions every 2–4 weeks. Relapses are often triggered by fever, infection, pregnancy, or surgery.

Drug-induced HUS/TTP is well recognized in patients receiving chemotherapeutic agents, most commonly mitomycin C (cumulative dose of ≥20–30 mg/m^2). The onset of hemolytic anemia and renal failure is usually sudden, and mortality rate is high despite supportive therapy. Treatment with plasma exchange, glucocorticoids, immunosuppressive agents, and staphylococcal protein A immunoadsorption, however, are successful in some cases. Ticlopidine and clopidogrel use has also been associated with the disease. Cyclosporine-induced TTP was first reported following bone marrow transplantation but is more common in patients receiving renal transplants and other solid organs. In renal allograft recipients, cyclosporine-induced HUS occurs during the first week after transplantation as drug toxicity is dose-related. Renal failure reverses with the cessation of cyclosporine or reduction in its dose.

HUS/TTP may occur after bone marrow transplantation independent of prior radiation or cyclosporine therapy. TTP is commonly associated with pregnancy. Approximately 10–25% of patients with TTP are women who are either near-term pregnant or in the postpartum period; this is also the time for thrombotic events and the occurrence of preeclampsia, eclampsia, and HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count). These syndromes are difficult to distinguish from TTP-HUS. Decreased activity of ADAMTS 13 in late pregnancy may be an additional risk. Finally, thrombotic microangiopathy has been described in conjunction with vascular tumors, acute promyelocytic leukemia, and prostatic, gastric, and pancreatic carcinomas.

℞ HEMOLYTIC UREMIC SYNDROME

Supportive measures—including dialysis, antihypertensive medications, blood transfusions, and management of neurologic complications—have improved survival in patients with HUS/TTP. Adequate fluid balance and bowel rest are important in treating typical HUS associated with diarrhea. Antibiotics to treat infection caused by Shiga toxin–producing *E. coli* O157:H7 have been found to increase the risk of overt HUS by 17-fold, likely by favoring the acute release of large amounts of preformed toxin or by providing selective advantage to *E. coli* O157. Among the therapeutic modalities used to treat patients with HUS/TTP, plasma exchange (plasmapheresis combined with fresh-frozen plasma replacement) is currently the treatment of choice and is superior to plasma infusion alone. Plasmapheresis may remove the recently identified inhibitory autoantibodies against vWF protease from the circulation and supply larger amounts of the protease enzyme. Plasma exchange should be performed daily until remission is achieved, remission being normalization of platelet count, or resolution of neurologic symptoms, or both. Hemoglobin level, percent schistocytosis, reticulocyte count, and renal indices do not appear to be determinants of initial response to therapy, as they may be abnormal for an undefined period after remission. Continuation of plasma exchange for several sessions after remission has been advocated to prevent relapses. Severe renal insufficiency resulting from HUS/TTP often requires dialysis. Renal transplantation has also been performed. HUS/TTP may recur in up to 17% of transplanted patients, independent of cyclosporine use. Higher recurrence rates have been reported for familial HUS.

SCLERODERMA (PROGRESSIVE SYSTEMIC SCLEROSIS)

(See also Chap. 316) Renal involvement in scleroderma can present in one of two ways, depending on whether malignant hypertension is superimposed on the renal pathology: (1) *Persistent urinary abnormalities* and an indolent clinical course characterized by proteinuria (15–36%), hypertension (24%), and mild azotemia (15%). Anti-RNA POL3 antibodies are strongly associated with scleroderma renal disease. (2) *Scleroderma renal crisis* (SRC) is a rapid deterioration in renal function, usually accompanied by malignant hypertension, oliguria, proteinuria, fluid retention, microangiopathic hemolytic anemia, and central nervous system involvement. It occurs in 10% of patients, most commonly in the first 4 years following diagnosis, particularly in patients with diffuse cutaneous involvement, 25% of whom develop SRC. SRC may occur in patients with previously undemonstrable or slowly progressive renal disease. Untreated, it leads to chronic renal failure within days to months. A significant association exists between antecedent glucocorticoid therapy and the development of SRC.

℞ SCLERODERMA

In SRC, ACE inhibitors have improved 5-year survival from 10% to 65%. Some 60% of SRC patients who receive ACE inhibitors require no dialysis (or temporary dialysis) with a survival rate at 8 years of 80–85%, similar to scleroderma patients who do not develop renal crisis. More than half of patients with SRC who require dialysis and are treated aggressively with ACE inhibitors are able to discontinue dialysis 3–18 months later, suggesting that patients should continue ACE inhibitor therapy even after beginning dialysis. Angiotensin receptor antagonists have not proven to be a satisfactory substitute for ACE inhibitors in patients with SRC. SRC patients who progress to end-stage renal disease can undergo hemodialysis or peritoneal dialysis, the latter being occasionally limited by compromised peritoneal clearance. A decrease in graft and overall survival has been noted in scleroderma patients following renal transplantation, as well recurrence of progressive sclerosis in the transplanted kidney, particularly in patients with aggressive disease.

SICKLE CELL NEPHROPATHY

(See also Chap. 99) Sickle cell disease causes renal complications as a result of sickling of red blood cells in the microvasculature. The hypertonic and relatively hypoxic environment of the renal medulla, coupled with the slow blood flow in the vasa recta, favors sickling of red blood cells, with resultant local infarction (papillary necrosis). Functional tubule defects in patients with sickle cell disease are likely the result of partial ischemic injury to the renal tubules.

In addition to the intrarenal microvascular pathology described above, the sickle cell disease in young patients is characterized by renal hyperperfusion, glomerular hypertrophy, and hyperfiltration. Many of these individuals eventually develop a glomerulopathy leading to glomerular proteinuria (present in as many as 30%) and, in some, the nephrotic syndrome. Co-inheritance of microdeletions in the α-globin gene (α thalassemia) appear to protect against the development of nephropathy and are associated with lower mean arterial pressure and less proteinuria.

Mild azotemia and hyperuricemia can also develop. Advanced renal failure and uremia occur in 10% of cases. Pathologic examination re-

veals the typical lesion of "hyperfiltration nephropathy," namely, focal segmental glomerular sclerosis. This finding has led to the suggestion that anemia-induced hyperfiltration in childhood is the principal cause of the adult glomerulopathy. Nephron loss secondary to ischemic injury also contributes to the development of azotemia in these patients.

In addition to the glomerulopathy described above, renal complications of sickle cell disease include *cortical infarcts* leading to loss of function, persistent hematuria, and perinephric hematomas. *Papillary infarcts*, demonstrable radiographically in 50% of patients with sickle trait, lead to an increased risk of bacterial infection in the scarred renal tissues and functional tubule abnormalities. Painless gross hematuria occurs with a higher frequency in sickle trait than in sickle cell disease and likely results from infarctive episodes in the renal medulla. *Functional tubule abnormalities* such as nephrogenic diabetes insipidus result from marked reduction in vasa recta blood flow, combined with ischemic tubule injury. This concentrating defect places these patients at increased risk of dehydration and, hence, sickling crises. The concentrating defect also occurs in individuals with sickle trait. Other tubule defects involve potassium and hydrogen ion excretion, occasionally leading to hyperkalemic metabolic acidosis and a defect in uric acid excretion which, combined with increased purine synthesis in the bone marrow, results in hyperuricemia.

Management of sickle nephropathy is not separate from that of overall patient management (Chap. 99). In addition, however, the use of ACE inhibitors has been associated with improvement of the hyperfiltration glomerulopathy. Three-year graft and patient survival in renal transplant recipients with sickle nephropathy is diminished as compared to those with other causes of end-stage renal disease.

RENAL VEIN THROMBOSIS (RVT)

Thrombosis of one or both main renal veins occurs in a variety of settings (Table 280-2). Nephrotic syndrome accompanying membranous glomerulopathy and certain carcinomas seems to predispose to the development of RVT, which occurs in 10–50% of patients with these disorders. RVT may exacerbate preexisting proteinuria but is infrequently the cause of the nephrotic syndrome.

The clinical manifestations depend on the severity and abruptness of its occurrence. Acute cases occur typically in children and are characterized by sudden loss of renal function, often accompanied by fever, chills, lumbar tenderness (with kidney enlargement), leukocytosis, and hematuria. Hemorrhagic infarction and renal rupture may lead to hypovolemic shock. In young adults RVT is usually suspected from an unexpected and relatively acute or subacute deterioration of renal function and/or exacerbation of proteinuria and hematuria in the appropriate clinical setting. In cases of gradual thrombosis, usually occurring in the elderly, the only manifestation may be recurrent pulmonary emboli or development of hypertension. A Fanconi-like syndrome and proximal renal tubular acidosis have been described. RVT is a potential cause of early graft dysfunction following renal transplantation, and its incidence may be decreased with prophylactic

low-dose aspirin. The definitive diagnosis can only be established through selective renal venography with visualization of the occluding thrombus. Short of angiography, Doppler ultrasound, contrast-enhanced CT, and MRI often provide evidence of thrombus.

℞ RENAL VEIN THROMBOSIS

Treatment consists of anticoagulation, the main purpose of which is prevention of pulmonary embolization, although some authors have also claimed improvement in renal function and proteinuria. Encouraging reports have appeared concerning the use of streptokinase. Spontaneous recanalization with clinical improvement has also been observed. Anticoagulant therapy is more rewarding in the acute thrombosis seen in younger individuals. Nephrectomy is advocated in infants with life-threatening renal infarction. Percutaneous mechanical thrombectomy is effective in some cases.

TOXEMIAS OF PREGNANCY

See also Chap. 7.

BILATERAL CORTICAL NECROSIS

Acute bilateral cortical necrosis is associated with septic abortions, abruptio placentae, and preeclampsia. Coagulation in cortical vessels and arterioles leads to renal tissue necrosis. Anuria and renal failure ensue and may be irreversible. In other cases, renal function returns partially, but on long-term follow-up most patients slowly progress to uremia.

281 Nephrolithiasis

John R. Asplin, Fredric L. Coe, Murray J. Favus

Kidney stones are one of the most common urological problems. In the United States, ~13% of men and 7% of women will develop a kidney stone during their lifetime, and the prevalence is increasing throughout the industrialized world.

TYPES OF STONES

Calcium salts, uric acid, cystine, and struvite ($MgNH_4PO_4$) are the basic constituents of most kidney stones in the western hemisphere (Chap. e24). Calcium oxalate and calcium phosphate stones make up 75–85% of the total (Table 281-1) and may be admixed in the same stone. Calcium phosphate in stones is usually hydroxyapatite [$Ca_5(PO_4)_3OH$] or, less commonly, brushite ($CaHPO_4H_2O$).

Calcium stones are more common in men; the average age of onset is the third to fourth decade. Approximately 50% of people who form a single calcium stone eventually form another within the next 10 years. The average rate of new stone formation in recurrent stone formers is about one stone every 2 or 3 years. *Uric acid stones* account for 5–10% of kidney stones and are also more common in men. Half of patients with uric acid stones have gout; uric acid lithiasis is usually familial whether or not gout is present. *Cystine stones* are uncommon, comprising ~1% of cases in most series of nephrolithiasis. *Struvite stones* are common and potentially dangerous. These stones occur mainly in women or patients who require chronic bladder catheterization and result from uri-

TABLE 281-1 MAJOR CAUSES OF RENAL STONES

Stone Type and Causes	Percent of all Stones[a]	Percent Occurrence of Specific Causes[a]	Ratio of Males to Females	Etiology	Diagnosis	Treatment
Calcium stones	75–85		2:1 to 3:1			
Idiopathic hypercalciuria		50–55	2:1	Hereditary (?)	Normocalcemia, unexplained hypercalciuria[b]	Low-sodium, low-protein diet; thiazide diuretics
Hyperuricosuria		20	4:1	Diet	Urine uric acid >750 mg per 24 h (women), >800 mg per 24 h (men)	Allopurinol or diet
Primary hyperparathyroidism		3–5	3:10	Neoplasia	Unexplained hypercalcemia	Surgery
Distal renal tubular acidosis		Rare	1:1	Hereditary	Hyperchloremic acidosis, minimum urine pH >5.5	Alkali replacement
Dietary hyperoxaluria		10–30	1:1	High oxalate diet or low calcium diet	Urine oxalate >50 mg per 24 h	Low oxalate diet
Enteric hyperoxaluria		~1–2	1:1	Bowel surgery	Urine oxalate >75 mg per 24 h	Cholestyramine or oral calcium loading
Primary hyperoxaluria		Rare	1:1	Hereditary	Urine oxalate and glycolic or l-glyceric acid increased	Fluids and pyridoxine
Hypocitraturia		20–40	1:1 to 2:1	Hereditary (?), diet	Urine citrate <320 mg per 24 h	Alkali supplements
Idiopathic stone disease		20	2:1	Unknown	None of the above present	Oral phosphate, fluids
Uric acid stones	5–10					
Gout		~50	3:1 to 4:1	Hereditary	Clinical diagnosis	Alkali and allopurinol
Idiopathic		~50	1:1	Hereditary (?)	Uric acid stones, no gout	Alkali and allopurinol if daily urine uric acid above 1000 mg
Dehydration		?	1:1	Intestinal, habit	History, intestinal fluid loss	Alkali, fluids, reversal of cause
Lesch-Nyhan syndrome		Rare	Males only	Hereditary	Reduced hypoxanthine-guanine phosphoribosyltransferase level	Allopurinol
Malignant tumors		Rare	1:1	Neoplasia	Clinical diagnosis	Allopurinol
Cystine stones	1		1:1	Hereditary	Stone type; elevated cystine excretion	Massive fluids, alkali, D-penicillamine if needed
Struvite stones	5–10		1:3	Infection	Stone type	Antimicrobial agents and judicious surgery

[a]Values are percent of patients who form a particular type of stone and who display each specific cause of stones.
[b]Urine calcium above 300 mg/24 h (men), 250 mg/24 h (women), or 4 mg/kg per 24 h either sex. Hyperthyroidism, Cushing syndrome, sarcoidosis, malignant tumors, immobilization, vitamin D intoxication, rapidly progressive bone disease, and Paget's disease all cause hypercalciuria and must be excluded in diagnosis of idiopathic hypercalciuria.

nary tract infection with urease-producing bacteria, usually *Proteus* species. The stones can grow to a large size and fill the renal pelvis and calyces to produce a "staghorn" appearance.

MANIFESTATIONS OF STONES

As stones grow on the surfaces of the renal papillae or within the collecting system, they need not produce symptoms. Asymptomatic stones may be discovered during the course of radiographic studies undertaken for unrelated reasons. Stones rank, along with benign and malignant neoplasms and renal cysts, among the common causes of isolated hematuria. Stones become symptomatic when they enter the ureter or occlude the ureteropelvic junction, causing pain and obstruction.

Stone Passage A stone can traverse the ureter without symptoms, but passage usually produces pain and bleeding. The pain begins gradually, usually in the flank, but increases over the next 20–60 min to become so severe that narcotic drugs may be needed for its control. The pain may remain in the flank or spread downward and anteriorly toward the ipsilateral loin, testis, or vulva. A stone in the portion of the ureter within the bladder wall causes frequency, urgency, and dysuria that may be confused with urinary tract infection. The vast majority of ureteral stones <0.5 cm in diameter will pass spontaneously.

It has been standard practice to diagnose acute renal colic by intravenous pyelography; however, helical CT scan without radiocontrast enhancement is now the preferred procedure. The advantages of CT include detection of uric acid stones in addition to the traditional radiopaque stones, no exposure to the risk of radiocontrast agents, and possible diagnosis of other causes of abdominal pain in a patient suspected of having renal colic from stones. Ultrasound is not as sensitive as CT in detecting renal or ureteral stones. Standard abdominal x-rays may be used to monitor patients for formation and growth of kidney stones, as they are less expensive and provide less radiation exposure than CT scans. Calcium, cystine, and struvite stones are all radiopaque on standard x-rays, whereas uric acid stones are radiolucent.

Other Syndromes • ***STAGHORN CALCULI*** Struvite, cystine, and uric acid stones often grow too large to enter the ureter. They gradually fill the renal pelvis and may extend outward through the infundibula to the calyces themselves. Very large staghorn stones can have surprisingly few symptoms and may lead to the eventual loss of kidney function.

NEPHROCALCINOSIS Calcium stones grow on the papillae. Most break loose and cause colic, but they may remain in place so that multiple papillary calcifications are found by x-ray, a condition termed *nephrocalcinosis*. Papillary nephrocalcinosis is common in hereditary distal renal tubular acidosis (RTA) and in other types of severe hypercalciuria. In medullary sponge kidney disease (Chap. 278), calcification may occur in dilated distal collecting ducts.

Infection Although urinary tract infection is not a direct consequence of stone disease, it can occur after instrumentation and surgery of the urinary tract, which are frequent in the treatment of stone disease. Stone

disease and urinary tract infection can enhance their respective seriousness and interfere with treatment. Obstruction of an infected kidney by a stone may lead to sepsis and extensive damage of renal tissue, since it converts the urinary tract proximal to the obstruction into a closed, or partially closed, space that can become an abscess. Stones may harbor bacteria in the stone matrix, leading to recurrent urinary tract infection. On the other hand, infection due to bacteria that possess the enzyme urease can cause stones composed of struvite.

Activity of Stone Disease Active disease means that new stones are forming or that preformed stones are growing. Sequential radiographs are needed to document the growth or appearance of new stones and to ensure that passed stones are actually newly formed, not preexistent.

PATHOGENESIS OF STONES

Urinary stones usually arise because of the breakdown of a delicate balance between solubility and precipitation of salts. The kidneys must conserve water, but they must excrete materials that have a low solubility. These two opposing requirements must be balanced during adaptation to diet, climate, and activity. The problem is mitigated to some extent by the fact that urine contains substances that inhibit crystallization. These protective mechanisms are less than perfect. When the urine becomes supersaturated with insoluble materials, because excretion rates are excessive and/or because water conservation is extreme, crystals form and may grow and aggregate to form a stone.

Supersaturation A solution in equilibrium with crystals of calcium oxalate is said to be saturated with respect to calcium oxalate. If crystals are removed, and if either calcium or oxalate ions are added to the solution, the chemical activities increase, but no new crystals form. Such a solution is *metastably supersaturated*. If calcium oxalate crystals are now added, they will grow in size. Ultimately, as calcium or oxalate is added to the solution, supersaturation reaches a critical value at which a solid phase begins to develop spontaneously. This value is called the *upper limit of metastability*. Kidney stone growth requires a urine that, on average, is supersaturated. Excessive supersaturation is common in stone formation.

Calcium, oxalate, and phosphate form many soluble complexes among themselves and with other substances in urine, such as citrate. As a result, their free ion activities are below their chemical concentrations. Reduction in ligands such as citrate can increase ion activity and, therefore, supersaturation. Urine supersaturation can be increased by dehydration or by overexcretion of calcium, oxalate, phosphate, cystine, or uric acid. Urine pH is also important; phosphate and uric acid are acids that dissociate readily over the physiologic range of urine pH. Alkaline urine contains more dibasic phosphate, favoring deposits of brushite and apatite. Below a urine pH of 5.5, uric acid crystals (pK 5.47) predominate, whereas phosphate crystals are rare. The solubility of calcium oxalate is not influenced by changes in urine pH. Measurements of supersaturation in a 24-h urine sample probably underestimate the risk of precipitation. Transient dehydration, variation of urine pH, and postprandial bursts of overexcretion may cause values considerably above average.

Crystallization When urine supersaturation exceeds the upper limit of metastability, crystals begin to nucleate. Cell debris and other crystals present in the urinary tract can serve as templates for crystal formation, a process known as *heterogeneous nucleation*. Heterogeneous nucleation lowers the level of supersaturation required for crystal formation. Once formed, crystal nuclei will grow in size if urine is supersaturated with respect to that crystal phase. Multiple crystals can then aggregate to form a kidney stone.

In order for a kidney stone to form, crystals must be retained in the renal pelvis long enough to grow and aggregate to a clinically significant size. The mechanism of crystal retention has been a matter of much debate. Recent studies have shown that common calcium oxalate kidney stones form as overgrowths on apatite plaques in the renal papillae. These plaques, called Randall's plaques, provide an excellent surface for heterogeneous nucleation of calcium oxalate salts. The Randall's plaques begin in the deep medulla in the basement membrane of the thin limb of the loop of Henle and then spread through the interstitium to the basement membrane of the papillary urothelium. If the urothelium becomes damaged, the plaque is exposed to the urine, and calcium oxalate crystallization and stone formation begins.

Inhibitors of Crystal Formation Urine contains potent inhibitors of nucleation, growth, and aggregation for calcium salts. Inorganic pyrophosphate is a potent inhibitor that appears to affect formation of calcium phosphate more than calcium oxalate crystals. Citrate inhibits crystal growth and nucleation, although most of the stone inhibitory activity of citrate is due to lowering urine supersaturation via complexation of calcium. Other urine components such as glycoproteins inhibit calcium oxalate crystallization.

EVALUATION AND TREATMENT OF PATIENTS WITH NEPHROLITHIASIS

Most patients with nephrolithiasis have remediable metabolic disorders that cause stones and can be detected by chemical analyses of serum and urine. Adults with recurrent kidney stones and children with even a single kidney stone should be evaluated. A practical outpatient evaluation consists of two 24-h urine collections, with a corresponding blood sample; measurements of serum and urine calcium, uric acid, electrolytes, and creatinine, and urine pH, volume, oxalate, and citrate should be made. Since stone risks vary with diet, activity, and environment, at least one urine collection should be made on a weekend when the patient is at home and another on a work day. When possible, the composition of kidney stones should be determined because treatment depends on stone type (Table 281-1). No matter what disorders are found, every patient should be counseled to avoid dehydration and to drink copious amounts of water. The efficacy of high fluid intake was confirmed in a prospective study of first-time stone formers. Increasing urine volume to 2.5 L per day resulted in a 50% reduction of stone recurrence compared to the control group.

Rx NEPHROLITHIASIS

The management of stones already present in the kidneys or urinary tract requires a combined medical and surgical approach. The specific treatment depends on the location of the stone, the extent of obstruction, the nature of the stone, the function of the affected and unaffected kidney, the presence or absence of urinary tract infection, the progress of stone passage, and the risks of operation or anesthesia given the clinical state of the patient. Medical therapy can enhance passage of ureteral stones. Oral α_1-adrenergic blockers relax ureteral muscle and have been shown to reduce time to stone passage and the need for surgical removal of small stones. In general, severe obstruction, infection, intractable pain, and serious bleeding are indications for removal of a stone.

Advances in urologic technology have rendered open surgery for stones a rare event. There are now three alternatives for stone removal. *Extracorporeal lithotripsy* causes the in situ fragmentation of stones in the kidney, renal pelvis, or ureter by exposing them to shock waves. The kidney stone is centered at a focal point of high-intensity shock waves. The waves are transmitted to the patient using water as a conduction medium, either by placing the patient in a water tank or by placing water-filled cushions between the patient and the shock wave generators. After multiple shock waves, most stones are reduced to powder that moves through the ureter into the bladder. *Percutaneous nephrolithotomy* requires the passage of a cystoscope-like instrument into the renal pelvis through a small incision in the flank. Stones are then disrupted by a small ultrasound transducer or holmium laser. The last method is *ureteroscopy* with stone disruption using a holmium laser. Ureteroscopy is generally used for stones in the ureter but some surgeons are now using ureteroscopy for stones in the renal pelvis as well.

Calcium Stones • ***IDIOPATHIC HYPERCALCIURIA*** (See also Chap. 347) This condition is the most common metabolic abnormality found in patients with nephrolithiasis (Table 281-1). It is familial and is likely a polygenic trait, although there are some rare monogenic causes of hypercalciuria and kidney stones such as Dent's disease, which is an X-

linked disorder characterized by hypercalciuria, nephrocalcinosis, and progressive kidney failure. Idiopathic hypercalciuria is diagnosed by the presence of hypercalciuria without hypercalcemia and the absence of other systemic disorders known to affect mineral metabolism. In the past, the separation of "absorptive" and "renal" forms of hypercalciuria was used to guide treatment. However, these may not be distinct entities but the extremes of a continuum of behavior. Vitamin D overactivity, either through high calcitriol levels or excess vitamin D receptor, is a likely explanation for the hypercalciuria in many of these patients. Hypercalciuria contributes to stone formation by raising urine saturation with respect to calcium oxalate and calcium phosphate.

Rx HYPERCALCIURIA

For many years the standard therapy for hypercalciuria was dietary calcium restriction. However, recent studies have shown that low-calcium diets increase the risk of incident stone formation. Low-calcium diets may lead to stone formation by reducing the amount of calcium to bind oxalate in the intestine, thereby increasing urine oxalate levels. However, the mechanism by which a low-calcium diet increases stone risk has not been clearly defined. In addition, hypercalciuric stone formers have reduced bone mineral density and an increased risk of fracture compared to the non-stone-forming population. Low calcium intake likely contributes to the low bone mineral density. A 5-year prospective trial compared the efficacy of a low-calcium diet to a low-protein, low-sodium, normal-calcium diet in preventing stone recurrence in male calcium stone formers. The group on the low-calcium diet had a significantly greater rate of stone relapse. Low-calcium diets are of unknown efficacy in preventing stone formation and carry a long-term risk of bone disease in the stone-forming population. Low-sodium and low-protein diets are a superior option in stone formers. If diet therapy is not sufficient to prevent stones, then thiazide diuretics may be used. Thiazide diuretics lower urine calcium and are effective in preventing the formation of stones. Three 3-year randomized trials have shown a 50% decrease in stone formation in the thiazide-treated groups as compared to the placebo-treated controls. The drug effect requires slight contraction of the extracellular fluid volume, and high dietary NaCl intake reduces its therapeutic effect. Thiazide-induced hypokalemia should be aggressively treated since hypokalemia will reduce urine citrate, an important inhibitor of calcium crystallization.

HYPERURICOSURIA About 20% of calcium oxalate stone formers are hyperuricosuric, primarily because of an excessive intake of purine from meat, fish, and poultry. The mechanism of stone formation is probably due to salting out calcium oxalate by urate. A low-purine diet is desirable but difficult for many patients to achieve. The alternative is allopurinol, which has been shown to be effective in a randomized, controlled trial. A dose of 100 mg bid is usually sufficient.

PRIMARY HYPERPARATHYROIDISM (See also Chap. 347) The diagnosis of this condition is established by documenting that hypercalcemia that cannot be otherwise explained is accompanied by inappropriately elevated serum concentrations of parathyroid hormone. Hypercalciuria, usually present, raises the urine supersaturation of calcium phosphate and/or calcium oxalate (Table 281-1). Prompt diagnosis is important because parathyroidectomy should be carried out before renal damage or bone disease occurs.

DISTAL RENAL TUBULAR ACIDOSIS (See also Chap. 278) The defect in this condition seems to reside in the distal nephron, which cannot establish a normal pH gradient between urine and blood, leading to hyperchloremic acidosis. The diagnosis is suggested by a minimum urine pH >5.5 in the presence of systemic acidosis. If the diagnosis is in doubt because metabolic abnormalities are mild, an ammonium chloride loading test can be performed. Patients with distal RTA will not lower urine pH below 5.5. Hypercalciuria, an alkaline urine, and a low urine citrate level increase urine saturation with respect to calcium phosphate. Calcium phosphate stones form, nephrocalcinosis is common, and osteomalacia or rickets may occur. Renal damage is frequent, and glomerular filtration rate falls gradually.

Treatment with supplemental alkali reduces hypercalciuria and limits the production of new stones. The usual dose of sodium bicarbonate is 0.5–2.0 mmol/kg of body weight per day in four to six divided doses. An alternative is potassium citrate supplementation, given at the same dose per day but needing to be given only two to three times per day. In incomplete distal RTA, systemic acidosis is absent, but urine pH cannot be lowered below 5.5 after an exogenous acid load such as ammonium chloride. Incomplete RTA may develop in some patients who form calcium oxalate stones because of idiopathic hypercalciuria; the importance of RTA in producing stones in this situation is uncertain, and thiazide treatment is a reasonable alternative. Alkali can also be used in incomplete RTA. When treating patients with alkali, it is prudent to monitor changes in urine citrate and pH. If urine pH increases without an increase in citrate, then calcium phosphate supersaturation will increase and stone disease may worsen.

HYPEROXALURIA Oxalate is a metabolic end product in humans. Urine oxalate comes from diet and endogenous metabolic production, with ~40–50% originating from dietary sources. The upper limit of normal for oxalate excretion is generally considered to be 40–50 mg per day. Mild hyperoxaluria (50–80 mg/d) is usually caused by excessive intake of high-oxalate foods such as spinach, nuts, and chocolate. In addition, low-calcium diets may promote hyperoxaluria as there is less calcium available to bind oxalate in the intestine. Enteric hyperoxaluria is a consequence of small-bowel disease resulting in fat malabsorption. Oxalate excretion is often >100 mg per day. Enteric hyperoxaluria may be caused by jejunoileal bypass for obesity, pancreatic insufficiency, or extensive small-intestine involvement from Crohn's disease. With fat malabsorption, calcium in the bowel lumen is bound by fatty acids instead of oxalate, which is left free for absorption in the colon. Delivery of unabsorbed fatty acids and bile salts to the colon may injure the colonic mucosa and enhance oxalate absorption. Primary hyperoxaluria is a rare autosomal recessive disease that causes severe hyperoxaluria. Patients usually present with recurrent calcium oxalate stones during childhood. Primary hyperoxaluria type 1 is due to a deficiency in the peroxisomal enzyme alanine:glyoxylate aminotransferase. Type 2 is due to a deficiency of D-glyceric dehydrogenase. Severe hyperoxaluria from any cause can produce tubulointerstitial nephropathy (Chap. 279) and lead to stone formation.

Rx HYPEROXALURIA

Patients with mild to moderate hyperoxaluria should be treated with a diet low in oxalate and with a normal intake of calcium and magnesium to reduce oxalate absorption. Enteric hyperoxaluria can be treated with a low-fat, low-oxalate diet and calcium supplements, given with meals, to bind oxalate in the gut lumen. The oxalate-binding resin cholestyramine at a dose of 8–16 g/d, provides an additional form of therapy. Treatment for primary hyperoxaluria includes a high fluid intake, neutral phosphate, and pyridoxine (25–200 mg/d). Citrate supplementation may also have some benefit. Even with aggressive therapy, irreversible renal failure may occur. Liver transplantation, to correct the enzyme defect, combined with a kidney transplantation has been successfully utilized in patients with primary hyperoxaluria.

HYPOCITRATURIA Urine citrate prevents calcium stone formation by creating a soluble complex with calcium, effectively reducing free urine calcium. Hypocitraturia is found in 20–40% of stone formers, either as a single disorder or in combination with other metabolic abnormalities. It can be secondary to systemic disorders, such as RTA, chronic diarrheal illness, or hypokalemia, or it may be a primary disorder, in which case it is called *idiopathic hypocitraturia*.

Rx HYPOCITRATURIA

Treatment is with alkali, which increases urine citrate excretion; generally bicarbonate or citrate salts are used. Potassium salts are preferred as sodium loading increases urinary excretion of calcium, reducing the effective-
